**He is elderly,
he is on corticosteroids,
when he needs an antibiotic
he may be a candidate for**

DECLOSTATIN® 300

**Demethylchlortetracycline HCl 300 mg
and Nystatin 500,000 units
CAPSULE-SHAPED TABLETS Lederle**

b.i.d.

To guard susceptible patients against intestinal monilial overgrowth during broad-spectrum therapy—the protection of nystatin is combined with demethylchlortetracycline in DECLOSTATIN.

For your susceptible candidates, prescribe DECLOSTATIN—the broad-spectrum therapy that prevents monilial overgrowth.

Contraindication: History of hypersensitivity to demethylchlortetracycline or nystatin.

Warning: In renal impairment, usual doses may lead to excessive accumulation and liver toxicity. Under such conditions, lower than usual doses are indicated, and, if therapy is prolonged, serum level determinations may be advisable. A photodynamic reaction to natural or artificial sunlight has been observed. Small amounts of drug and short exposure may produce an exaggerated sunburn reaction which may range from erythema to severe skin manifestations. In a smaller proportion, photoallergic reactions have been reported. Patients should avoid direct exposure to sunlight and discontinue drug at the first evidence of skin discomfort. Necessary subsequent courses of treatment with tetracyclines should be carefully observed.

Precautions: Overgrowth of nonsusceptible organisms may occur. Constant observation is essential. If new infections appear, appropri
measures should be taken.

In infants, increased intracranial pressure with bulging fontanels h
been observed. All signs and symptoms have disappeared rapidly up
cessation of treatment.

Side Effects: Gastrointestinal system—anorexia, nausea, vomiting, di
rhea, stomatitis, glossitis, enterocolitis, pruritus ani. Skin—maculopa
ular and erythematous rashes; a rare case of exfoliative dermatitis h
been reported. Photosensitivity; onycholysis and discoloration of t
nails (rare). Kidney—rise in BUN, apparently dose related. Transie
increase in urinary output, sometimes accompanied by thirst (rare
Hypersensitivity reactions—urticaria, angioneurotic edema, anaphylax
Teeth—dental staining (yellow-brown) in children of mothers given t
drug during the latter half of pregnancy, and in children given the dr
during the neonatal period, infancy and early childhood. Enamel hy
plasia has been seen in a few children. If adverse reaction or idios
crasy occurs, discontinue medication and institute appropriate thera
Average Adult Daily Dosage: 150 mg q.i.d. or 300 mg b.i.d. Should
given 1 hour before or 2 hours after meals, since absorption is impair
by the concomitant administration of high calcium content drugs, foo
and some dairy products. Treatment of streptococcal infections shou
continue for 10 days, even though symptoms have subsided.

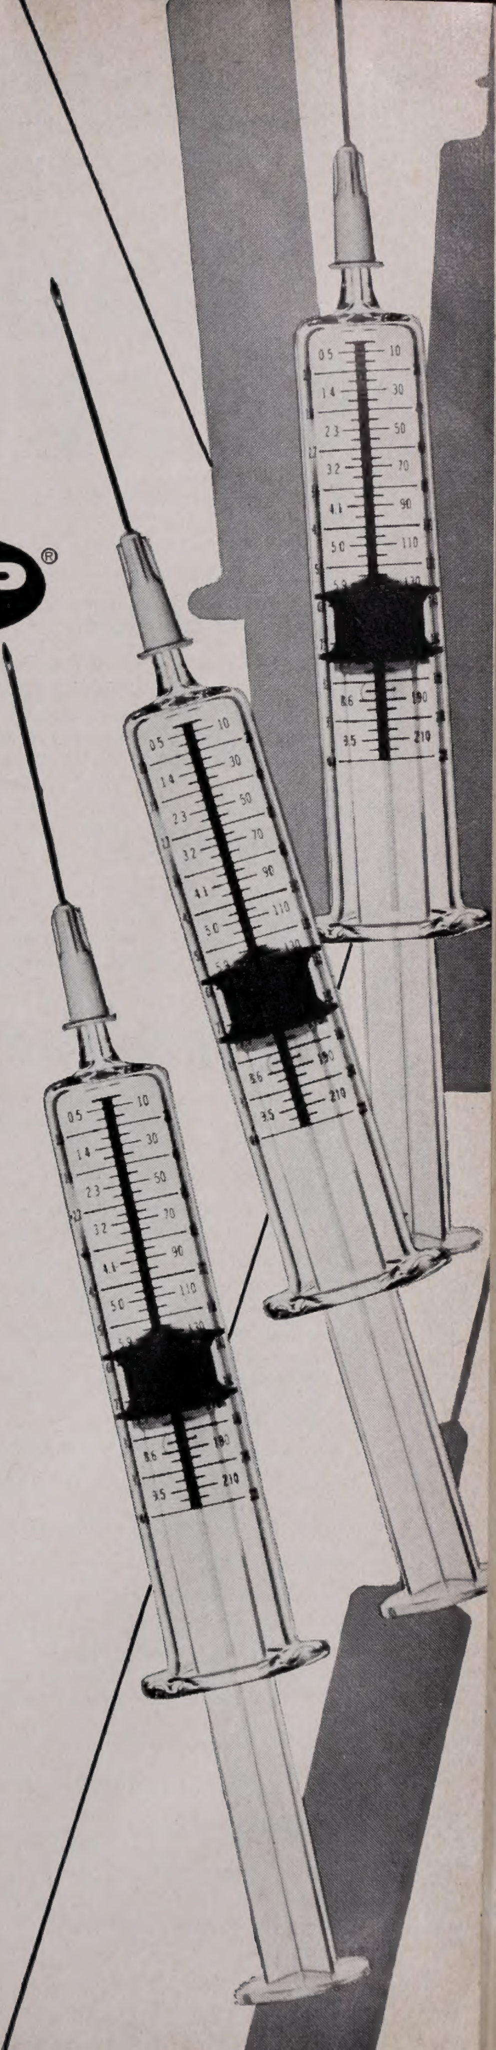
(50 mg. per ml.)

BSP®



BROMSULPHALEIN®
IN A COMPLETE,
STERILE,
DISPOSABLE,
& ECONOMICAL
PATIENT-UNIT.

BSP, one of the more valuable single laboratory procedures for determining hepatic function, is now packaged in a complete individual patient-unit.

The BSP Disposable Unit contains a sterile syringe with the dosage schedule imprinted on the barrel, a sterile needle, alcohol swab and a 7.5 ml. or 10 ml. size ampule of terminally sterilized BSP solution. Each unit contains complete directions for use, precautions and contraindications.

This all-inclusive disposable put-up lessens the chance of cross-infection and saves time and labor — the most costly commodities.

"All Interns are Alike"

It stands to reason. They all go through the same training; they all have to pass the same tests; they all have to measure up to the same standards; they all are underpaid, too. Therefore, all interns are alike.

That's utter nonsense, of course. But it's no more nonsensical than what some people say about aspirin. Namely: since all aspirin is at least supposed to come up to certain required standards, then all aspirin tablets must be alike.

Bayer's standards are far more demanding. In fact, there are at least *nine specific differences* involving purity, potency and speed of tablet disintegration. These Bayer® standards result in significant product benefits including gentleness to the stomach, and product stability that enables Bayer tablets to *stay* strong and gentle until they are taken.

So next time you hear someone say that all aspirin tablets are alike, you can say, with confidence, that it just isn't so.

You might also say that all interns aren't alike, either.

President's Letter

George E. Fahr, M.D. (1882-1968)

Emeritus Professor of Medicine, University of Minnesota

In early December of last year, our medical community lost one of its mighty men—Doctor George Fahr, a colorful teacher, a gifted researcher, and a respected clinician. To many he was "The Chief" at the old Minneapolis General Hospital. Doctor Owen H. Wangensteen used to liken Doctor Fahr's coming to Minnesota to "opening the window of a smoke-filled room." As we welcome our Swiss friends to these pages, it is only fitting that we dedicate this issue to Doctor Fahr, who loved Switzerland so dearly.

In his memoirs Doctor Fahr relates that he first visited Switzerland as a child in 1893. Later, as part of his extensive training on the continent, he went in 1914 to Berne. There he associated with Leon Ascher, in whose physiology laboratory Doctor Fahr demonstrated how to gild finely-drawn quartz strings with gold. He met the great Kocher but declined to become a surgical resident. He participated in the discussions in Herman Sahli's clinic, much delighting the students with his *schimpfen* (scolding). A lifelong friend was Ery Luescher with whom Doctor Fahr climbed mountains and went skiing. Other well-known names were recalled: R. Staehelin, Loeffler, Bing, and de Quervain.

One of the earliest of the many famous Swiss-born physicians was Paracelsus (Einsiedeln 1493), a controversial figure and for a few years Professor of Medicine at Basel (1527). His was a revolutionary influence on medicine and pharmacy and is best remembered as an advocate of the use of mercury (also sulfur, lead, antimony, iron and copper). He urged surgeons to practice asepsis—"do not touch wounds, because they cure themselves; it is the external agents which complicate processes of cicatrization." He severed bonds with the past, burning the works of Galen, Avicenna, and Averroes. He is quoted as having said, "I pleased no one but the sick whom I cured." More appropriate to this occasion, he also said, "If you really wish to learn, listen to what I say; attend to what I write."

In that spirit, we honor Doctor Fahr's memory and greet our Swiss friends today.

It's almost as if you were there to give an injection of penicillin

V-Cillin K®, Pediatric dependable oral penicillin therapy

Potassium Phenoxymethyl Penicillin

Description: V-Cillin K, the potassium salt of V-Cillin® (phenoxymethyl penicillin, Lilly), combines acid stability with immediate solubility and rapid absorption. Higher, more rapid serum levels are obtained than with equal oral doses of penicillin G.

Indications: Streptococcus, pneumococcus, and gonococcus infections; infections caused by sensitive strains of staphylococci; prophylaxis of streptococcus infections in patients with a history of rheumatic fever; and prevention of bacterial endocarditis after tonsillectomy and tooth extraction in patients with a history of rheumatic fever or congenital heart disease.

Contraindication: Penicillin hypersensitivity.

Warnings: In rare instances, penicillin may cause acute anaphylaxis which may prove fatal unless promptly controlled. This type of reaction appears more frequently in patients with a history of sensitivity reactions to penicillin or with bronchial asthma or other allergies. Resuscitative drugs should be readily available. These include epinephrine and pressor drugs (as well as oxygen for inhalation) for immediate allergic manifestations and antihistamines and corticosteroids for delayed effects.

Precautions: Use cautiously, if at all, in a patient with a strongly positive history of allergy.

In prolonged therapy with penicillin, and particularly with high parenteral dosage schedules, frequent evaluation of the renal and hematopoietic systems is recommended.

In suspected staphylococcus infections, proper laboratory studies (including sensitivity tests) should be performed.

The use of penicillin may be associated with the overgrowth of penicillin-insensitive organisms. In such cases, discontinue administration and take appropriate measures.

Adverse Reactions: Although serious allergic reactions are much less common with oral penicillin than with intramuscular forms, manifestations of penicillin allergy may occur.

Penicillin is a substance of low toxicity, but it possesses a significant index of sensitization. The following hypersensitivity reactions have been reported: skin rashes ranging from maculopapular eruptions to exfoliative dermatitis; urticaria; and reactions resembling serum sickness, including chills, fever, edema, arthralgia, and prostration. Severe and often fatal anaphylaxis has occurred (*see* Warnings). Hemolytic anemia, leukopenia, thrombocytopenia, and nephropathy are rarely observed side-effects and are usually associated with high parenteral dosage.

Administration and Dosage: Usual dosage range, 125 mg. (200,000 units) three times a day to 500 mg. (800,000 units) every four hours. For infants, 50 mg. per Kg. per day divided into three doses.

See package literature for detailed dosage instructions for prophylaxis of streptococcus infections, surgery, gonorrhea, and severe infections.

How Supplied: Tablets V-Cillin K® (Potassium Phenoxymethyl Penicillin Tablets, U.S.P.), 125 mg. (200,000 units), 250 mg. (400,000 units), and 500 mg. (800,000 units).

V-Cillin K® (potassium phenoxymethyl penicillin, Lilly), Pediatric, for Oral Solution, 125 mg. (200,000 units) and 250 mg. (400,000 units) per 5 cc. of solution (approximately one teaspoonful). [042567A]

The Genesis and Therapy of the Trigger Finger*

K. LENGGENHAGER, M.D.†
Berne, Switzerland

THE TRIGGER FINGER which snaps or jerks at active or passive movements constitutes a typical example of those "minor" ailments which are of considerable practical importance. If the optimum treatment is not applied, the trigger finger can cause the patient much discomfort, and a good many working hours may be lost.[1] The genesis of the trigger finger will therefore be discussed and a simple operative procedure described which has been consistently satisfactory in our hands.

Etiology

Disregarding those rare cases which are caused by osseous changes, three different mechanisms have been proposed as a cause of the trigger finger observed in adults:

Stenosis of the Flexor Tendon Sheath

Stenosis of the flexor tendon sheath with localized pressure on the tendon[2,3,7] seems an unsatisfactory explanation for the etiology as continuous pressure on the tough tendinous tissue would certainly lead to necrosis followed by relaxation. To circumvent this theoretical contradiction, Hauck[2] assumed that the indurated tendon sheath would be indented during flexion and thus produce a stenosis in this situation only (Figure 1). Personal observations suggest, however, that neither of these theories is correct. As a rule, snapping of the finger persists if the finger is kept extended in the metacarpophalangeal joint while being simultaneously and maximally extended and flexed in the interphalangeal joints.

Stenosis and Thickening

The combination of localized stenosis of the tendon sheath and thickening of the tendon itself, which was proposed by Lapidus and Fenton[5] as well as by other authors, for the

---

†Professor of Surgery and Chief of the Department of Surgery, University of Berne School of Medicine, Berne, Switzerland.

*See editorial page 81.

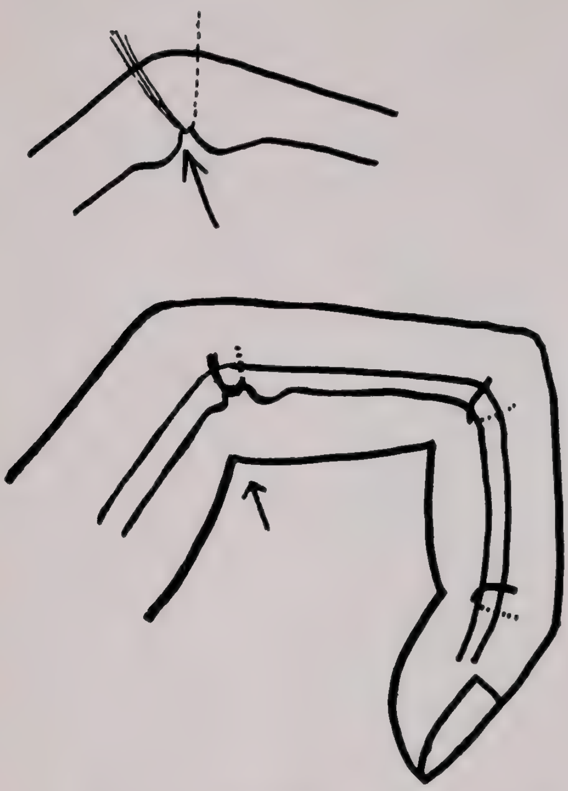

Fig. 1—In this presentation the snapping would occur only in flexion of the metacarpophalangeal joint which does not correspond to reality.

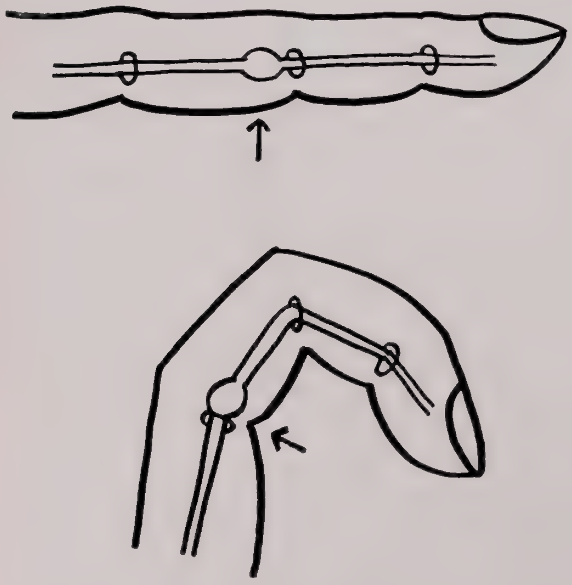

Fig. 2—At extension the club-shaped thickening of the tendon is not at the site of operation. It appears only at active flexion. This position corresponds to the closing of a hand around an object.

reasons outlined above also appears to be a questionable etiologic factor.

Thickening of Tendon

The circumscribed, club-shaped thickening of the flexor tendon[4,9] as a causative factor agrees with our experience accumulated during the past decades.[6,8]

Divergent Opinions

The divergent opinions encountered in the literature and suggesting alterations of the tendon sheath as a cause of the trigger finger may be explained by the following personal observations:

Tendon Thickening Not Visualized

Trigger fingers are usually operated upon from the volar side with the fingers extended. Under these conditions the thickenings of the flexor tendons are not visible after slitting the sheaths and, for this reason, the tendons are presumed to be normal. If, however, the operation is done under local anesthesia and the patient is requested to bend his finger actively, the club-shaped thickening of the tendon will appear with maximal flexion only. This is exactly the position in which the tendon is pressed against the hard, protruding metacarpophalangeal joint while passing through its sheath when the fingers are closed around some hard object (Figure 2). When operation is performed under general anesthesia, the thickening of the tendon cannot be visualized by passive movements of the finger, just as the snapping cannot be demonstrated by passive flexion and extension.

There is yet another reason which argues against the snapping caused principally by the sheath. If a series of model experiments with encircling wires is done on the claws of a dead chicken, it will be observed that a tremendous pressure on the flexor tendon is required to produce snapping when the proximal stump is pulled. In fact, the encircling pressure must be so great as to lead invariably to rapid necrosis of the tendon in the living animal. One person alone will not succeed in tying a single knot of the wire around the tendon tightly enough to produce snapping. The loosening of the first knot despite a continuous pull on the wire ends while the second knot is being tied suffices to defeat the purpose. A jerk will be obtained only if an assistant pulls the tendon stump while the sheath is kept under maximum compression by a continuous pull on the first knot. If the experiment is repeated with a wire sling which is progressively twirled, a jerk may again be obtained with maximum compression of the sheath. Once elicited, however, a double and even triple jerk will be registered when the tendon stump is pulled and the claw subsequently extended to the full. By contrast, in our clinical experience the finger snaps only once when bent or extended and almost regularly with the same degree of flexion. For these reasons, the theory implicating the tendon sheath as the primary factor seems to be of more theoretical than practical interest.

Mechanism of Sensitive Tendon Sheath

Why then is the area around the metacarpophalangeal joint of the trigger finger sensitive to pressure during the clinical examination, regardless of the position of the finger rather than the tendon thickenings themselves? By extending a finger passively, the latter are pulled distally. They are much less sensitive to pain than the better innervated tendon sheaths which are irritated each time the thickening tendon squeezes through. Hence they attain a state of hypersensitivity with or without secondary swelling. The tendon and its sheath are pressed more firmly against the protruding metacarpophalangeal joint when a hard object is grasped than against the more distally located finger joints. For that reason, too, blisters develop over the proximal finger joints after unaccustomed work and not more distally. The thickening of the irritated tendons may thus be compared to that of a clavus.*

Effect of Blunt Trauma

The absent irritation of the skin is hardly astonishing if we consider the frequent occurence of internal damage to muscles, blood vessels and nerves without superficial injury. It is common experience that a blunt trauma preferentially affects the innermost soft tissue areas bordering the underlying hard bone. Well-known examples are the division of the radial nerve following a blow against the lateral side of the arm, intimal rupture of the femoral artery caused by blunt trauma to the inguinal region, the contusion of muscles following a blow against an extremity, and the intestinal and mesenteric lacerations often occuring after blunt abdominal trauma.

Frequently, the snapping of the trigger finger is more pronounced and also more painful in the morning than later in the day. We may deduce that a reparative, sterile inflammatory edema is present at first, which is massaged away as the fingers are moved; hence the space available for the thickened tendon to pass through progressively increases. This interpretation is supported by an observation made on a colleague of mine: A trigger finger of recent origin may disappear completely and spontaneously if an intelligent and cooperative patient will scrupulously avoid active movements and thus keep the finger from snapping for about three weeks.

Diagnosis

The following features are useful for the diagnosis of a trigger finger: If fingers two to

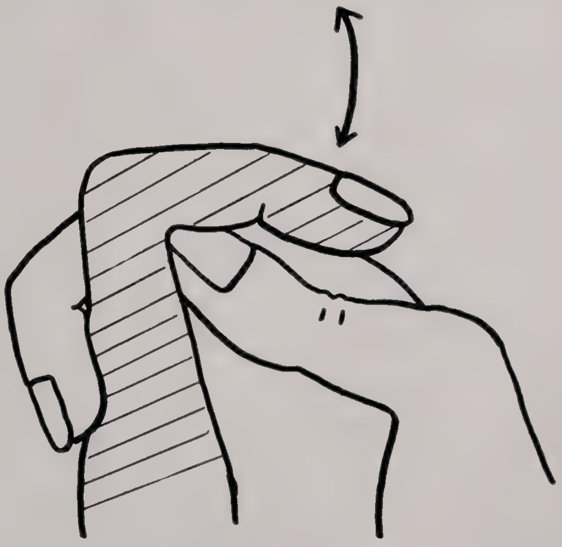

Fig. 3—A test for the existence of a localized thickening of the tendon is the snapping of the finger which is extended in the metacarpophalangeal joint, whereas in the distal joint it is actively bent and straightened.

---

*See Test Your Word Score Page 89.

five are bent and straightened actively while the metacarpophalangeal joint is kept extended, a single jerk occurring repeatedly with the same degree of flexion shows a club-shaped thickening of the tendon to be present (Figure 3). Slight volar pain over the metacarpophalangeal joint belongs to the clinical picture. In the case of the thumb, the isolated flexion of the interphalangeal joint will not suffice to induce snapping, because the thickened tendon will not reach the middle joint. Both joints must therefore be moved to elicit the trigger phenomenon.

Therapy

In our experience, a trigger finger of recent origin may disappear completely within three to four weeks if active movements are scrupulously avoided. This phenomenon might be compared to the rapid disappearance of a clavus not maintained by external stimuli.

A simple, "semi-operative" treatment for established cases of trigger finger is the transcutaneous stab incision under local anesthesia proposed by us in 1964.[6] Once introduced through the skin, the slender tenotome moves under the skin only and slits the tendon sheath at the location of pain. All subcutaneous movements should be done strictly lengthwise in the direction of the tendon so as to avoid oblique or even transverse injuries. The sheath is slit further in both directions until the active snapping disappears.

In the case of fingers two to five, the procedure is simple. We do not recommend treating a snapping thumb that way until some experience has been gained with the flexor sheaths of the other fingers, which are more easily found.

No suture is necessary; a small protective dressing suffices. After 10 to 18 days, the patient can close the fist without pain. Up to now we have treated 15 patients with uniformly good results. The first case was operated upon 12 years ago.

Summary

The observations and experiments recorded clarify the divergent opinions about the genesis of the trigger finger and favour the circumscribed thickening of the flexor tendon itself. Conflicting views may be explained by the fact that the club-shaped thickenings of the tendon move into the region where the sheath is slit at operation only when the fingers are actively flexed. Thus they remain unnoticed when the operation is performed under general anesthesia. Their localization corresponds to the region which is chronically irritated when the fingers are closed around some hard object. Experimentally, a single or even multiple snapping can be elicited by placing a wire sling around the flexor tendon sheath of a chicken's claw, but the pressure required would be intolerable in vivo and produce rapid necrosis of the tendon. A simple method of operative treatment is suggested: the tendon sheath is slit subcutaneously under conduction anesthesia with a slender stab scalpel. No suture is necessary.

If you aspire to the highest place it is no disgrace to stop at the second, or even the third.—Cicero

Treatment of Tetanus

A 50-Year Review*

HANS STIRNEMANN, M.D.†
Berne, Switzerland

During the past fifty years (1918-1967) 217 recorded cases of tetanus were treated at the University of Berne Surgical Clinic. This number does not represent the total incidence of tetanus for these years as some records of the first years were lost. This report presents a comprehensive review of the incidence and treatment of tetanus over the past half century at the University of Berne Surgical Clinic.

Incidence

Table 1 shows the age distribution and mortality of our patients for three age groups: It can be seen that the incidence of tetanus in our adult classification has diminished in recent years. This decrease is probably the result of a massive active immunization program carried out by the army since 1940. Relative to the decrease was an increase in the older adults, who never became part of the immunization program.

The sex distribution of the incidence of tetanus from 1918-1967 is shown in Table 2. The ratio of males to females has diminished from 3.3 to 1 (1918-1955) to 1.4 to 1 (1956-1967). This decrease in males could reflect the immunization programs described above.

Treatment

The 100 cases of tetanus recorded during the period (1918-1955) were treated with either $MgSO_4$, chloroform, morphin, avertin or barbiturates.

Since 1956 the severe cases were treated with curare-Succinylcholine 28 cases; d-tubocurare 30 cases; Alloferin® and artificial respiration 19 cases, while the moderate cases (40) were treated with sedatives or valium® (Diazepam).

---

*Treatment at the Surgical Clinic, University of Berne, Switzerland.

See editorial page 87.

†Privat-Dozent and Assistant Chief of Surgical Services, Surgical Clinic, University of Berne, Switzerland.

Skeletal Muscle Relaxants

In the early cases the muscle relaxants were administered in much higher doses and the patients maintained in complete relaxation. Succinylcholine and curare were given as a continuous infusion in 0.9% NaCl or 5% glucose solutions. Succinylcholine was replaced later by curare and Alloferin® because of tachyphylaxis and excessive bronchial secretion.

Alloferin® is now given intravenously in much smaller, repeated doses (five - 20 mg every 15 to 30 minutes). Complete relaxation is avoided and the drug is administered only when the patient begins to move his face and fingers. Such movements do not interfere with artificial respiration.

The treatment with muscle relaxants (77 cases) was continued for five to 26 days (mean = 13 days). Normal breathing occurred spontaneously one to three days after the last dose of curare. The use of an antagonist such as prostigmin was not necessary.

Treatment of Hypokalemia

Some of our first curarized patients had to be ventilated because paralysis lasted up to 22 days after termination of curare or Succinylcholine. Muscle activity returned very slowly, beginning in face, hands and feet and moving proximally toward the trunk. These patients did not have normal muscular control. Later analysis showed, however, that most had developed severe hypokalemia. These long periods of irregular muscular control after curarization disappeared when potassium was controlled and replaced regularly.

Artificial Respiration

Artificial respiration was given manually in early cases, and later by machine respirators (type Engstrom, Lundia). The respiration is monitored by the rebreathing method (Capnograph Godart[1] and occasionally by blood gas analysis. Before these controls were instituted, many of our patients, particularly children, became chronically hyperventilated. This was the cause of the hyperventilation syndrome and of severe lesions of the central nervous system in some patients.

Hyperventilation Syndrome

In 10 children (two to 16 years) we observed the following syndrome sixteen times: dilatation of the pupils (without reaction to light), edema of tongue and face, salivation, tachycardia (140-180) and marked hypertension. The pressure of the cerebral-spinal fluid increased to 30-40 mm Hg, and a carotid angiogram in one case showed edema of the brain. In this patient with partial curarization, an epileptic state was observed.

The causes for the damage to the central nervous system by hyperventilation are:

1. Constriction of arterioles in the brain

with hypocapnea.

2. Impaired dissociation of oxy-hemoglobin with alkalosis of the blood.
3. Edema of the brain by alkalosis of brain tissue and positive pressure respiration (increased venous pressure).

The only effective treatment of this syndrome was hypoventilation with pure oyygen for several minutes. The symptoms disappeared in 30-60 minutes. Two children died a short time after this complication, and the autopsy showed malacia of the brain. Two other children later developed epilepsy. We did not analyze for blood gas or pH in these cases, but since our artificial respiration was later controlled by capnograph and gas analysis, this complication never occurred again.

Homologous Serum

Since 1965 we have used homologous serum (Tetuman^{R} Berna) rather than heterologous serum. The patient is given 250-500 I.U., half by continuous I.V. infusion, half by intramuscular injection. Using this procedure, we had no fatalities in nine severe and 16 moderate cases. Although this data appears highly significant, it still does not prove the superiority of homologous to heterologous serum; in rabbits the homologous antitoxin therapy was not superior to heterologous antitoxin.[2] Many other factors relating to improved management and care of these patients influenced the improved results obtained over the past two years.

Passive-Active Immunization

We have combined serum therapy with active immunization (immunisation simultanée). In a different site from the serum injection, 1 ml of anatoxin (Toxoid) or ½ ml of Anatoxal (adsorbed Toxoid) was given intramuscularly or subcutaneously. After heterologous antitoxin injection, the simultaneous immunization was followed by an interval of about 15 to 25 days without detectable antibodies. This phase occurred between the passive and active immunization. Because of the long half-life of homologous antibodies, no antibody-free interval was detected.

The advantages of the use of homologous

serum in the treatment of tetanus are the absence of anaphylactic or other allergic reactions, a continued presence of antibodies and perhaps a lower mortality.

Antitoxin

The figure shows the titers of antitoxin in the blood of eight patients after simultaneous immunization with 250 or 500 I.U. Tetuman® and anatoxin. The titer was higher in children and the level appears proportional to the amount of injected antitoxin. The figure shows that the ideal dosage to yield a continuous titer higher than 0.01 I.U./ml blood, would be 500 I.U. for children and 1000 I.U. for adults. It is of interest that in some of these patients, the titer did not rise after the second or even after the third injection of anatoxin. After six months some patients had a titer of less than 0.005 I.U./ml blood; however, all patients showed a normal and prompt booster effect after 1 ml of anatoxin. In therapy involving simultaneous use of homologous serum and anatoxin, three injections of anatoxin followed by a booster dose after six months are strongly advised.

Miscellaneous Treatment

We did not use *hyperbaric oxygen,* because we could not demonstrate its effectiveness in rabbits.[3]

Antibiotics were used therapeutically to combat pneumonia or other septic complications. Prophylactic use did not diminish septic com-

plications.

Tracheotomy was performed in all 77 patients given curare therapy and in 13 of the 40 moderate cases. There were 20 complications from the tracheotomy: 19 in patients with artificial respiration and one in a patient without artificial respiration. The complications found were:

Bleeding	6
(2 fatal from truncus brachiocephalicus)	
Stenosis in trachea	5
Ulcus in trachea	4
Retracted skin scar	4
Abscess	1

Nutrition

The feeding of a tetanus patient by a thin gastric tube is extremely important. Intestinal peristalsis is reduced in a curarized patient by direct action of curare on the muscles of the gut and by lowered intraabdominal pressure. This curare effect results in delayed emptying of the stomach and in vomiting. In nine patients, oral feeding was prohibited; these patients needed more blood- and- plasma transfusions during treatment. Six of the nine patients developed acute peptic ulceration of the stomach and duodenum. Four of the ulcers perforated and two had repeated bleedings. These complications were avoided when a light diet and antacids every two hours were given.

Results

Mortality

Table 1 shows the overall mortality (1918-1955) to be 57%. The more recent patients (1956-1967) showed a decreased mortality of 36.7%. In severe cases, treated with curare and artificial respiration, mortality diminished from 76.8% to 44.1%. In mild cases the mortality has increased from 12.9% to 22.5%. This increase can be ascribed to the increased number of older patients. For older patients, even mild tetanus, without convulsions, is often fatal. Many died of cardiac arrest and autopsy revealed atheromatosis of the coronaries.

The cause of death is shown in Table 6. The high incidence of pneumonia (1918-1955) was related to the inability of the tetanus patient to expectorate. Cardiac arrest or asphyxia occurred during the dreadful convulsions.

Septic and Cardiac Complications

In the more recent group (1956-1967), septic and cardiac complications still remain important causes of death. Pneumonia is no longer a factor of impaired expectoration, but occurs from hospital infection during treat-

TABLE 7

Mortality in Relationship to Incubation Time and Period of Onset

		1918-1955			1956-1967		
			Died			Died	
Incubation time	3-10 days	50	38	= 76 %	41	10	= 24.3%
	11-20 days	29	12	= 41.4%	22	6	= 27.2%
	> 20 days	7	1	= 14.2%	10	3	= 30.0%
Length of period of onset	2 days	63	50	= 79.3%	47	16	= 34.0%
	3-4 days	15	5	= 33.3%	27	8	= 29.6%
	> 4 days	15	1	= 6.6%	42	19	= 45.2%

ment. Prophylactic use of antibiotics did not diminish the frequency of pneumonia; however, most important in the prevention of pneumonia is the technique of respiration: regular aspiration of mucus by means of a sterile catheter and change of the position of the patient to avoid atelectasis.

Cardiac Arrest

Cardiac arrest occurred in 14 patients. Ten were older than 50 years (six of them were mild cases). Autopsy, in every case, revealed sclerosis of coronary arteries. Four of the patients with cardiac arrest were younger than 11 years; they had severe tetanus and acute myocarditis.

Prognosis

Incubation time and length of period of onset were good criteria for prognosis before the use of curare (Table 7). A short incubation time and period of onset was usually followed by severe tetanus. Because the early patients before 1956 died of anoxia during the convulsions, these cases had a high mortality; with curare treatment the convulsions are no longer a direct cause of death. Other complications, septic as well as some relating to the new techniques of treatment (bleeding from stoma, hyperventilation, perforation of peptic ulcer), may be fatal. Therefore the criteria of period of onset and incubation time have lost their prognostic value.

The age of the patient, however, is significant for the prognosis (Table 1). The middle-aged patient has the best prognosis; the child has a little less favorable prognosis, and the older age group (50 years and over) has the highest mortality.

Convalescence and Invalidism

Follow-up studies of the 38 living patients from 1956-1964 (24 curarized, 14 non-curarized) demonstrated that some had a long convalescence and that *restitutio ad integrum** was not always present.

LENGTH OF CONVALESCENCE	CURARIZED	NON CURARIZED
0-1 month	8	7
1-3 months	3	4
3-6 months	3	2
6-12 months	3	1
Invalidity (25-100%)	7	0
	24	14

The invalidism was caused by: fatigue, muscle pain, weakness in five adult patients, and epileptic fits in two boys (after hyperventilation syndrome).

Enzymatic Changes in Tetanus

During 1964 and 1965 the serum activities of several enzymes were studied in 20 patients. The serum activity of creatine-phosphokinase was elevated upon admission to hospital but, during the next two weeks, progressively de-

clined.

Lactate dehydrogenase activity was increased at the time of admission and remained so during the entire stay in hospital.

Activity of alphahydroxybutyrate dehydrogenase was increased from the ninth to the twelfth day in the hospital.[4,5]

Prophylaxis

There are different methods of prophylaxis against tetanus in an injured non-immunized person: excision of the wound, antibiotic therapy, serum therapy, and eventually rapid immunization with anatoxin. These four methods may be used singly or in combination. None is ideal and can guarantee against the outbreak of tetanus.

Thirty-five of our 217 tetanus patients had prophylaxis (see Table 8).

Tetanus after complete active immunization is extremely rare. We have, however, observed the following case: In 1962, a fifty-one-year-old man, previously vaccinated against typhoid, paratyphoid, and tetanus, presented with a contaminated forehead wound. After five days, a mild tetanus, limited to the facial nerve, developed but healed after injection of 1 ml anatoxin.

Discussion

Methods of treatment have changed several times in the last five decades: from morphine to chloroform to $MgSO_4$ and later to barbiturates. Experience with machine respirators, gained in polio patients, was later applied to the treatment of severe cases of tetanus. Finally, total curarization and artificial respiration[6,7] evolved as a therapeutic measure. In moderate cases, Valium® was used with success.

Every new method brought new hope for doctor and patient in the fight against this dreadful disease. Garland[8] wrote in 1959: "With modern methods of treatment nobody dies of tetanus." Unfortunately, with increasing experience this initial optimism was followed by pessimism, expressed in 1935 by Miller:[9] "Treatment in general is hardly more satisfactory than when Hippocrates handled the cases at the battle of Salamis." However, curare therapy represented real progress in treatment of severe cases; patients no longer suffer from painful cramps and the lethality has been reduced.

But this new method of treatment was not without specific complications.

Tracheotomized and ventilated patients were very prone to infections of airways and lungs and apt to succumb to bleeding from the stoma.

Oral feeding of a curarized patient is difficult because of lack of peristalsis; nevertheless, it is very important. The curarized patient does not swallow saliva. If he is not fed by means of a gastric tube, gastric acid is not neutralized for days, and gastric or duodenal ulceration with bleeding or perforation may result. Pelloja[10] suggested central nervous origin of peptic ulceration in tetanus; but we consider it more the consequence of absent neutralization of stomach acid. With antacids and nutrition peptic ulcers were no longer seen in our patients.

Artificial respiration must be controlled by a rebreathing method[11] or by blood gas analysis. The dangers of hypoventilation are well known and can be avoided. Hyperventilation may be equally dangerous, especially in children, who may develop the hyperventilation syndrome.[12,13]

Small series of patients with good results do not prove the superiority of any special therapy. Kloetzel,[14] who treated 52 patients with a total mortality of 42%, found a consecutive series of 19 patients without mortality. We too had no mortality in our last 25 cases. We feel that this improvement is due not only to the homologous serum used in this series, but to other factors such as improved techniques of nutrition, artificial respiration and patient care.

Fatality will never be reduced to zero in tetanus patients, as long as there is only a symptomatic therapy, because specific complications like tetanus-myocarditis cannot be prevented.

Since Ramon,[15] there has been great progress in immunological understanding and treatment of tetanus. However, today little is known of the pathogenesis of the disease.[16] Hopefully new enzymological methods may further knowledge.

Summary

From 1918 to 1967, 217 cases of tetanus

were treated in the Surgical Clinic of the University of Berne.

The use of curare lowered the mortality rate from 57% to 37%. In recent years an idiopathic type of tetanus, without detectable wound, has become prevalent.

During the last 12 years, 77 severe cases were curarized and given artificial respiration. Monitoring of ventilation to prevent complications such as the hyperventilation syndrome is important. Potassium replacement is also indicated. Regular tube feeding is advocated to prevent peptic complications. Moderate cases can be successfully treated with Valium® (Diazepam).

Heterologous serum in high doses did not affect mortality. In 25 cases treated with homologous serum there was no mortality.

Pneumonia, other septic complications, and cardiac arrest are still the prevailing causes of death. Prophylactic use of antibiotics did not diminish septic complications.

Tetanus is often followed by long convalescence and invalidism.

Creatine phosphokinase, lactate dehydrogenase and alphahydroxybutyrate dehydrogenase are elevated in tetanus. Thirty-five of the 217 cases had prophylaxis after injury. The safest means of preventing tetanus in a injured patient is through active prophylactic immunization.

Etymologically Speaking*

Lank from Anglo-Saxon *hlank*—flexible.

In Arkansas there still remains some Old English, retained since Elizabethan days. After a strenuous morning of gastrointestinal X-rays and no food the patient remarked that he was "lank."

The term had been used by Milton: "Her lank head" and by Swift: "Meager and lank with fasting grown."

Webster gives the synonyms: slender, shrunken, languid, etc. In colloquial Arkansas use, however, it means all pooped out and awfully hungry.

Raymond C. Read, M.D.
Little Rock, Arkansas

Derivatively Speaking*

Cretin—from French *cretin,* a dialectal term for Christian, from Latin *christianus.*

---

*Derivatively speaking refers just to word origins; Etymologically speaking also includes word development and historical changes in meaning.

Cardiac Metabolism in Experimental Hemorrhagic Shock*

P. LUNDSGAARD-HANSEN, M.D.†
C. MEYER, M.D.†
H. RIEDWYL, M.D.†
G. ZIEROTT, M.D.
Berne, Switzerland

HEMODYNAMIC ALTERATIONS recorded by several authors show that cardiac deterioration occurs in prolonged experimental hemorrhagic shock. Whether or not myocardial function constitutes the crucial parameter for the progression of shock towards irreversibility remains a matter of dispute. Electrocardiographic and histological changes indicating subendocardial damage have been repeatedly observed. Besides unspecific necrotic foci, a presumably characteristic kind of "zonal lesions" involving fragmentation of myocardial cells was recently described by Hackel's group.[11]

The metabolic basis of cardiac deterioration in hemorrhagic shock remains to be elucidated. An insufficient oxygen supply was suggested by earlier findings pertaining to the oxygen tension in coronary sinus blood and to alterations of lactate/pyruvate metabolism. Another possible cause of myocardial depression might be alterations of enzyme activities, whether due to hypoxia, to excessive catecholamine activity producing structural derangements within the heart muscle,[3] or to some toxic substance(s) of extracardiac origin,[6] which might be produced in peripheral tissues damaged by shock-induced hypoxia. Combinations of such mechanisms might, of course, well be operative.

Our laboratory has been interested in cardiac metabolism during hemorrhagic shock for some time, and the results obtained so far will now be presented briefly. For the details and fuller bibliographies, we may refer to more extensive reports published in specialized journals.[7-10]

Oxygen Supply of the Heart in Hemorrhagic Shock

Direct measurements of tissue oxygen tension in the beating heart are technically ex-

†Department of Surgical Research, University Department of Surgery, and Institute of Mathematical Statistics, Berne, Switzerland.

acting, not easy to interpret, and demand equipment and experience available in a limited number of specialized laboratories. A relatively simple and sufficiently accurate technique consists in sampling coronary sinus blood and determining its oxygen saturation. The oxygen tension can be monitored directly or calculated from the percent saturation and pH. The percent oxygen saturation and oxygen tension of venous blood from the heart reflects the situation of cells deriving their oxygen supply from the venous end of capillaries, which are most likely to suffer an oxygen deficit. A number of studies reveal that the "critical" oxygen saturation or oxygen tension of coronary sinus blood below which lactate output indicates myocardial anaerobiosis is very low, less than 10% or 10 mm of mercury, respectively. Thus the essential question is whether that level is attained during hemorrhagic shock.

In shock studies on previously healthy, open-chest dogs maintained on constant artificial ventilation, the coronary sinus oxygen level under control conditions depends to a considerable extent upon the ventilation employed. With high control levels, oxygen saturation declines significantly during shock, whereas with low control levels, there is hardly any change. This is illustrated by Figure 1 which shows the behavior of the coronary sinus oxygen saturation in two series of experiments performed in our laboratory.

In neither study was the critical level of coronary sinus oxygen saturation (or oxygen tension) attained. If we assume that the changing balance between coronary perfusion pressure and cardiac workload basically tended to restrict myocardial oxygen supply under the hemodynamic conditions of shock, coronary vasodilation compensated sufficiently for this to prevent an oxygen deficit of the heart.

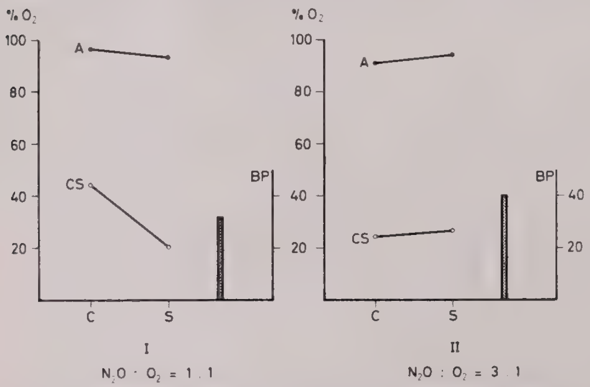

Fig. 1—Arterial and coronary sinus percent oxygen saturations in two series of experiments with shock blood pressures of 32 mm (I) and 40 mm of mercury (II). Gas mixture in series I $N_2O : O_2 = 1 : 1$; in series II, $N_2O : O_2 = 3 : 1$. A= arterial, CS = coronary sinus, C = pre-shock control, S = shock.

What are the clinical implications of these findings? With arterial oxygen saturations above 90%, coronary vessels capable of responding adequately to incipient tissue hypoxia and a normal oxygen transport capacity of the blood, an oxygen deficit of the heart during hemorrhagic shock does not appear to be relevant. Conversely, a substantial degree of arterial hypoxemia—due, for instance, to obstructed airways or thoracic trauma—and preexisting coronary disease may well produce a critical degree of coronary sinus desaturation. This may also result from excessive hemodilution with erythrocyte-free artificial colloids; circulatory improvement equals an increase in cardiac workload and thus of myocardial oxygen consumption, which must be covered by a reduced oxygen transport capacity of the blood. Cardiac oxygen extraction, which is already high under normal conditions may thus become excessive and produce a critically low saturation or oxygen tension on the venous side of myocardial capillaries. Altogether, then, adequate ventilation is mandatory, excessive hemodilution must be avoided, and the coronary patient is particularly susceptible to myocardial damage during shock.

The evaluation of myocardial oxygen supply by the analysis of coronary sinus blood is complicated by the fact that gradients of oxygen tension exist within the normal heart.[5] The oxygen tension in the subendocardial layers is only about half that recorded in the outer layers of the left ventricle. If such gradients persist during shock with oxygen saturation and oxygen tension in the "average" coronary sinus blood approaching the critical threshold, they might cause a subendocardial oxygen deficit escaping detection by the analysis of blood draining hypoxic as well as non-hypoxic areas of the left ventricle wall. This problem will be dealt with later.

Lactate/Pyruvate Metabolism

From present knowledge, alterations of

myocardial lactate and pyruvate metabolism may be considered the most sensitive indicator of a cardiac oxygen deficit. The normal heart muscle extracts lactate and pyruvate from the blood in proportion to their arterial concentrations. Under the conditions of pure arterial hypoxemia, the critical threshold of coronary sinus oxygen saturation and tension is revealed by the change of the myocardial lactate balance from uptake to output. As stated before, it equals saturations of 10 – 5% or an oxygen tension of 10 – 5 mm of mercury.

Another approach is the analysis of the lactate/pyruvate ratio in arterial and coronary sinus blood. This ratio is in fact a redox quotient, and it is usually slightly lower on the venous side of the heart, indicating oxygen supply of the myocardium to be adequate. Under conditions probably inducing excessive catecholamine activity, it may be slightly higher in coronary sinus blood in the face of oxygen saturations not suggesting a deficient supply. With pure arterial hypoxemia, the lactate/pyruvate ratio in the coronary sinus rises above that of arterial blood entering the heart in proportion to lactate output, and an evaluation of the critical threshold of the coronary sinus oxygen saturation produces the same results with both parameters. During shock, alterations of the lactate/pyruvate ratio may become equivocal because prolonged shock tends to induce a myocardial output of pyruvate which is probably not related to oxygen supply per se.

The myocardial extractions of lactate and pyruvate were studied in our laboratory simultaneously with the parameters of oxygen supply illustrated in Figure 1. In the first series of experiments with a mean blood pressure of 32 mm of mercury during shock lasting for a maximum 1½ hours, myocardial output of lactate was registered in about one third of the samples. In nearly every instance, however, there was a concomitant output of pyruvate. For this reason, the average change of the lactate/pyruvate ratio across the heart did not suggest the presence of a myocardial oxygen deficit.

In the second series, shock was maintained at 40 mm of mercury until the animals had taken up one third of the maximum blood volume lost into the reservoir, or an average 5¾ hours. During the final stages of this shock period and with the coronary sinus oxygen saturations depicted in Figure 1, there was a consistent uptake of lactate and nearly always output of pyruvate. The decrease of the lactate/pyruvate ratio across the heart was therefore accentuated in the shock state. Thus the alterations of lactate/pyruvate metabolism during prolonged hemorrhagic shock at 40 mm of mercury confirmed the impression obtained from the behavior of coronary sinus oxygen parameters that an oxygen deficit does not contribute to the cardiac deterioration regularly observed following retransfusion in studies of this type. As judged from the results of the first series, however, a blood pressure approaching 30 mm of mercury may create borderline conditions with respect to myocardial oxygen supply.

It is suggested that studies designed to evaluate cardiac performance in shock should include an analysis of oxygen saturations and lactate/pyruvate metabolism in arterial and coronary sinus blood. This would facilitate comparison of results obtained with different blood pressure levels and respiratory conditions selected by various authors for such investigations.

For the analysis of lactate and pyruvate in coronary sinus blood, the problem of a non-uniform metabolism of heart muscle cannot be neglected. Besides the gradient of oxygen tension between the superficial and the deep layers of the left ventricle, Honig found the lactate/pyruvate ratio to be 28 in the outer and 34 in the inner layers. The oxygen and lactate/pyruvate gradients thus run in opposite directions and fit the concept of a higher glycolytic activity in the subendocardial layers of the left ventricle wall under normal conditions. It is entirely conceivable that such gradients may be important in shock.

Enzyme Activities in Left Ventricular Myocardium

Recent studies on frog sartorius muscle suggest that enzymatic activities may adapt themselves to alterations of contractile activity within a matter of hours. Furthermore, characteristic activity changes of certain glycolytic enzymes were established in the guinea pig heart when heart-lung preparations were subjected to increasing workloads or hypoxemia to the point of cardiac failure.[12] Both kinds of stress produced the same alterations; myocardial hypoxia was therefore regarded as their common cause. These findings suggested an approach to the problem of metabolic gradients within the heart in the normal state and during shock, which has recently been explored in our laboratory.[9,10] Briefly stated, the procedure is as follows.

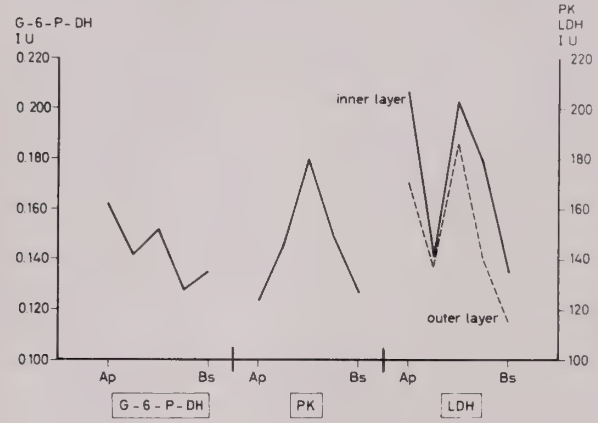

Fig. 2—Enzyme activity gradients in the direction from apex to base of left ventricle following shock. Maximum-minimum differences for each enzyme significant with $p < 0{,}05$.

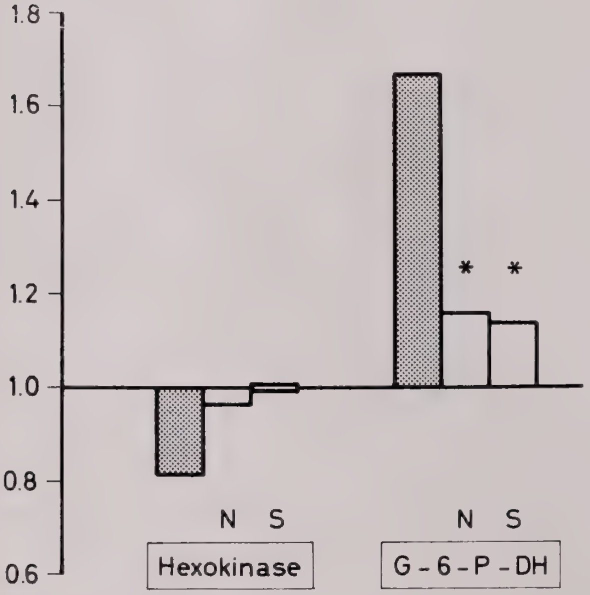

Fig. 3—Activity ratios "cardiac failure (hypoxia) / control" (hatched columns) from Hochrein's data[12] and activity ratios "inner layer/outer layer" of left ventricle wall (open columns) in present study. N = normal state, S = post-shock state, * = significantly different from unity with $p < 0{,}05$. Hexokinase and Glucose-6-Phosphate Dehydrogenase.

The metabolic status of the heart was monitored in one series of 12 dog experiments during a 2½-hour period of presumably normal working conditions as judged by conventional oxygen, lactate/pyruvate and acid-base parameters in the blood. In a second series of 12 experiments with identical ventilation, the same blood parameters were studied during the final stages of a 5¾-hour shock period at 40 mm of mercury and following retransfusion. At the end of these experimental periods, the heart was excised in toto.

Myocardial samples were taken from five sampling sites in the direction from apex to base of the left ventricle. From each sampling site, the tissue was divided into one portion each from the inner and the outer third of the left ventricle wall. In addition, three samples from papillary muscle were secured from each animal. The following enzymatic activities were assayed in each tissue sample: hexokinase, glucose-6-phosphate dehydrogenase, fructose-1,6-diphosphate aldolase, glyceraldehyde phosphate dehydrogenase, pyruvate kinase, lactate dehydrogenase, alpha-hydroxybutyrate dehydrogenase, isocitrate dehydrogenase and malate dehydrogenase. The results were subjected to statistical analysis by means of a two-way analysis of variance and significance tests (F-test and t-test). In this way, the activity differences between animals, sampling sites, and inner and outer layers of the left ventricle wall could be assessed.

Significant activity differences were found among animals for all enzymes in the normal state and following shock; but they will not be further considered here.

In the normal state there were no significant activity differences or gradients between sampling sites, i.e., in the direction from apex to base of the left ventricle. Following shock, however, such gradients appeared in the inner layer of the left ventricle wall for G-6-P-DH, pyruvate kinase and lactic dehydrogenase. For the latter enzyme, the activity differences between sampling sites were also significant in the outer or subepicardial layer. As seen from Figure 2, the general trend was for the enzyme activities to rise in the direction from base towards apex of the left ventricle.

The picture was irregular, however, and suggested a functional disorganization afflicting the subendocardial layers preferentially.

Figures 3 to 5 illustrate two groups of activity ratios. The activity ratios "cardiac failure/control" calculated from Hochrein's data[12] are shown as hatched columns. A ratio in excess of one denotes that the activity of the enzyme in question rises with cardiac failure due to workload or hypoxia, the latter supposedly being the common denominator for both conditions. Similarly, a ratio less than one denotes a falling activity of the enzyme in question under such conditions of "stress."

The columns designed as "N" and "S" show the activity ratios "inner layer/outer layer" found by us in the normal state and following shock.[9,10] A ratio in excess of one denotes a higher activity in the inner layer, and vice versa. GAP-DH and alpha-HB-DH were omitted in these Figures, because no data were available from Hochrein's study[12] with which they might have been compared.

Let us first compare the ratios "cardiac failure (hypoxia)/control" to the normal ratios "inner/outer layer." It is seen that with the exception of IDH, their deviations from unity are concordant. Without exception, the activity ratios "papillary muscle/outer layer" (not shown in Figures 3-5) were also concordant with the ratios "inner/outer layer", reflecting the essentially comparable situation of the subendocardium and papillary muscle and showing the same agreement with Hochrein's data.[12] These findings suggested that a permanent metabolic adaption to a restricted oxygen supply might exist in the subendocardial layers of the normal left ventricle,[9] in accordance with the differences of oxygen tension and the lactate/pyruvate ratio reported by Honig.[5]

Second, let us compare the activity ratios "inner layer/outer layer" found in the post-shock state with the other two. With the exception of lactic dehydrogenase and MDH, they change in a direction opposite to that presumed to reflect a restricted oxygen supply. The strict concordance between the ratios "inner/outer layer" and "papillary muscle/outer layer" observed in the normal state was disrupted for several enzymes following shock, among them for lactic dehydrogenase (I/O > 1,0; P/O < 1,0).

On the whole, therefore, the behavior of the enzymes studied does not support the assumption of an overall oxygen deficit of the myocardium during shock, nor does it suggest the presence of a hidden subendocardial oxygen deficit which might escape detection by an analysis of coronary sinus blood. When considered together with the activity differences between sampling sites affecting mainly the subendocardial layers, the alterations of the transmural activity gradients in the post-shock state suggest a functional disorganization of the myocardium at the cellular or subcellular level.

With the lack of evidence for an oxygen deficit, which factors may be invoked to ex-

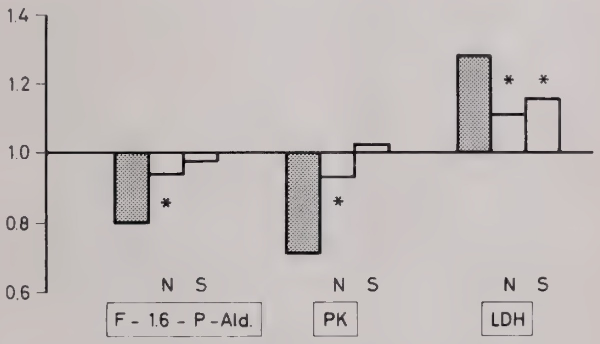

Fig. 4—Activity ratios as in Figure 3, for fructose-1,6-diphosphate aldolase, pyruvate kinase and lactate dehydrogenase.

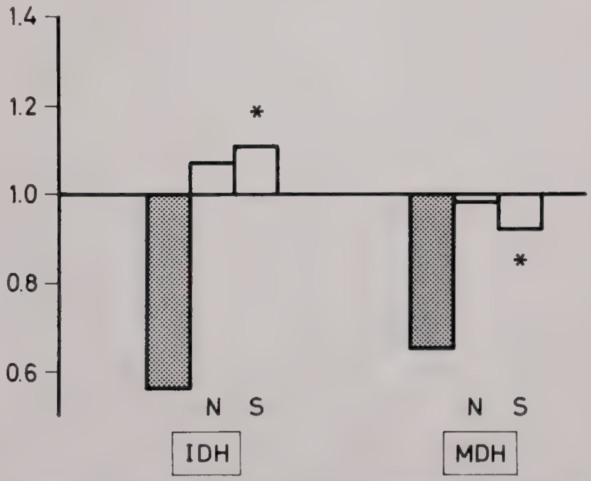

Fig. 5—Activity ratios as in Figures 3 and 4, for isocitrate dehydrogenase and malate dehydrogenase.

plain a functional disorganization of the myocardium following prolonged hemorrhagic shock? A reasonable assumption would be that it is related to the structural derangements predominating in the subendocardium in the postshock state. From experiments with beta receptor blockade in shock, it has recently been inferred that such structural derangements might be related to excessive catecholamine effects.[3] Experiments designed to shed further light on this mechanism are currently in progress in our laboratory. In the meantime, we have found that β-receptor blockade by propranolol does in fact abolish the activity gradients between sampling sites found in "untreated" shock (Figure 2). Excessive catecholamine effects thus appear to be involved.

Another possible mechanism would be myocardial depression by some toxic substance(s) arising in hypoxic peripheral tissues during shock.[6] They might interfere directly with cardiac metabolism or indirectly by way of structural alterations probably occurring at the subcellular level. Disturbances of cellular ultrastructures have recently been described in vascular smooth muscle, striated muscle, liver and kidney following shock[1,4] and it has been suggested that such changes might induce alterations of enzymatic processes.[2] As a working hypothesis, the findings reported here may be interpreted as an example of such relationships between cellular or subcellular disturbances of myocardial structure and function due to prolonged hemorrhagic shock.

Summary

The metabolic basis of cardiac deterioration following prolonged hemorrhagic shock remains to be elucidated. Under experimental conditions as usually employed for the study of such relationships, neither the parameters of myocardial oxygen supply nor those of cardiac lactate/pyruvate metabolism suggest that impaired performance of the otherwise intact heart following shock might be due to an oxygen deficit. The study of activity distribution patterns of several glycolytic enzymes within the left ventricle wall of the dog heart furnishes no evidence of a hidden subendocardial oxygen deficit during hemorrhagic shock when arterial oxygen saturations remain above 90%, coronary vessels are healthy, and the oxygen transport capacity of the blood is normal. Definite alterations as compared to the normal state are, however, recorded. They are interpreted to suggest a functional disorganization of the myocardium at the cellular or subcellular level, which might be connected with structural derangements due to excessive catecholamine activity or with the effects of toxic substances produced by peripheral tissues during shock.

Hypoxia and Renal Function

A Review of Experimental and Clinical Findings

H. G. PAULI, M.D.[*]
Berne, Switzerland

Early in this century the mechanisms of acclimatization to high altitude in man were studied by several groups of physiologists.[6,8] This for the first time drew attention to changes in renal function after transition into a hypoxic environment. Investigations were mostly concerned with homeostasis of acid-base components. Some of our present knowledge on acid-base metabolism is, in fact, founded on these observations. After arrival at altitude, diminution of plasma bicarbonate content was observed which had to be explained by renal bicarbonate loss. More recently Relman et al.[16] demonstrated the dependence of renal tubular bicarbonate reabsorption on plasma carbon dioxide tension which is low during hypoxic hyperventilation at high altitude. Increased renal bicarbonate elimination under such circumstances appears to involve a tubular $Na^+ - H^+$ exchange mechanism and is therefore accompanied by sodium diuresis.[19]

Since methods are available to estimate renal glomerular filtration rate and effective renal plasma flow acute hypoxia has been shown to elevate these two parameters.[3]

Effect of High Altitude

In permanent high-altitude residents, on the other hand, glomerular filtration rate and, more so, the effective renal plasma flow were found to be significantly below the range of sea-level values.[12] This finding is even more marked in patients with chronic mountain sickness.[10] The tendency for sodium and fluid retention in these patients stands in contrast to the above mentioned sodium diuresis in the beginning of exposure to hypoxia. Direct comparison of sea-level residents with permanent high-altitude dwellers, however, makes interpretation difficult, as many regulatory and metabolic factors have to be taken into account which might develop over months, even years of high-altitude residency or be active before or at birth in such an environment. Observations of changes in renal function during the first days of exposure of sea-level residents to high altitude had to fill this gap.*

Sea-Level Dwellers

Eight healthy sea-level dwellers have recently been observed before and during a 10-day sojourn at 3454 meters above sea level.[1] Among many physiological and biochemical measurements glomerular filtration rate and effective renal plasma flow were estimated by radioisotope-disappearance techniques as well as renal handling of sodium, chloride and potassium by the classical clearance methods.[15] During this high altitude period changes in renal handling of electrolytes (Figure 1 a and b) were more pronounced, although with a wider scatter than in glomerular filtration rate and effective renal plasma flow (Figure 2). Increased sodium and chloride elimination during prolonged hypoxia appears to involve a tubular mechanism, as is the case for diminished potassium elimination. Changes in glomerular filtration rate and effective renal plasma flow are comparatively slight during this observation period. The mean of all values for effective renal plasma flow, however, calculated for the days seven to 10 is significantly decreased in comparison to control values at the 5% confidence level (Wilcoxon-test). No correlation of these changes with simultaneously determined circulatory parameters in these subjects could be found.[9]

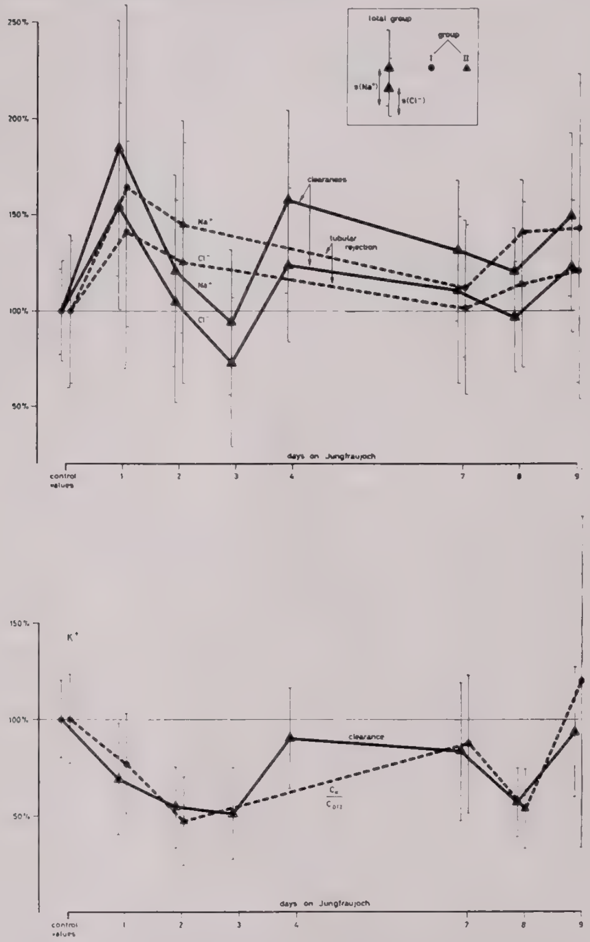

Fig. 1—Renal clearance for sodium, chloride (a-top) and potassium (b-bottom) in eight healthy sea-level residents (Copenhagen) before and during a 10-day sojourn at Jungfraujoch (Switzerland). Renal "tubular rejection" is the ratio between electrolyte clearance and clearance of diatrizoate (representing glomerular filtration rate, see Figure 2). All values are related to control data (Copenhagen) which are made to equal 100%. Single standard deviations are indicated (for Na^+ at the left, for Cl^- at the right side of the vertical lines). The mean values for clearances cannot be directly compared with the ones for "tubular rejection" as they include the total group (eight subjects) or the sub-groups I and II (four subjects) on each day respectively.[15]

Chronic Hypoxia

In patients with chronic hypoxia due to pulmonary insufficiency and ensuing cor pulmonale effective renal plasma flow and glomerular filtration rate are diminished.[5,17] Fishman et al.[5] found these values to increase during acute additional hypoxia, while they were further lowered under acute reoxygenation by O_2 inhalation. In the same patients acute additional hypoxia increases and reoxygenation decreases sodium elimination. The observed changes were not found to correlate with changes in cardiac output measured simultaneously.[5] These experiments seemed to indicate that derangements in renal function in patients with cor pulmonale were due to an unknown factor, not identical with hypoxia. On the contrary, hypoxia was assumed to increase effective renal plasma flow from an even lower value (i.e., the level attained during reoxygenation).

At the time of these reports serious objections against O_2 inhalation in patients with cor pulmonale had been raised for other reasons.[4] These reports and the above mentioned findings of Fishman et al.,[5] on the other hand,

---

*In the following this type of exposure will be called *prolonged* in contrast to *acute* (exposure up to several hours) and *chronic* (permanent residence at altitude).

seemed to contradict the long known clinical fact that under long-term O_2 inhalation some patients with chronic cor pulmonale exhibit a marked increase in diuresis, followed by disappearance of edema.[2] The results of oxygen administration in such patients seem to depend on the careful observation of acid base components in the arterial or capillary blood of the patients, and to the dosage of oxygen in the inspired air by suitable devices.[2,7,14,17] Under such conditions renal function values tend to change in the *opposite* direction, as under short-term application of high oxygen concentrations in the inspired air.[14] In Figure 3 an example of observations during such a treatment is given.

Comments

The combined experimental and clinical evidence of the influence of hypoxia on glomerular filtration rate, effective renal plasma flow, and renal handling of sodium therefore indicates that one has to distinguish between acute and chronic effects which seem to operate by different mechanisms. *Acute* hypoxia is followed by an increase mainly of effective renal plasma flow, less so of the glomerular filtration rate, of only a few hours' duration, most probably connected with general and renal autoregulatory hemodynamic changes. At the same time tubular sodium reabsorption seems to decrease concomitantly with an elevated renal elimination of bicarbonate, which has been shown to depend on the decrease of plasma pCO_2 during the development of hypoxic hyperventilation. This alteration in renal tubular handling of sodium is therefore not dependent on hypoxia *per se*[18] but on acid base derangements triggered by the hypoxic ventilatory drive and can be observed during *prolonged* hypoxia (Figure 1 a).

Evidence of increased activity of the adrenal cortical and the renin-aldosterone systems[11,13] under such conditions cannot be interpreted as primary but possibly as compensatory to such a derangement in tubular function.

It is doubtful whether renal hemodynamic changes as evidenced by decreased values in effective renal plasma flow and less so in glomerular filtration rate in high-altitude dwellers and patients with chronic cor pulmonale can be explained by general circulatory mechanisms. Sodium and fluid retention in the latter as well as in patients with chronic mountain sickness must depend on other mechanisms than renal sodium handling during acute and prolonged hypoxia. As long-term relief from hypoxia can correct these derangements, a direct metabolic disturbance of renal tubular transport of sodium during chronic hypoxia must be considered.

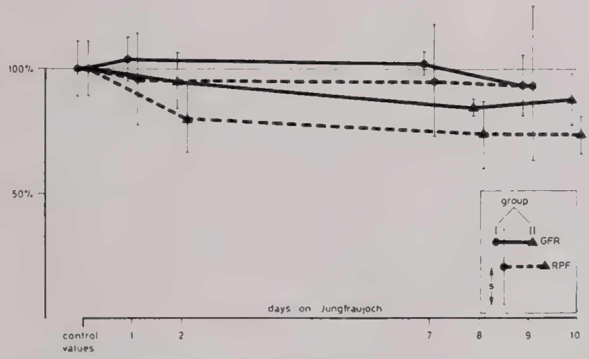

Fig. 2—Mean renal clearances for diatrizoate (glomerular filtration rate = GFR) and orthoiodohippuric acid (effective renal plasmal flow = RPF) before and after ascent to high altitude (same subjects as in Figure 1). The lines connect the mean values of 2 subgroups (I and II; 4 subjects each).[15]

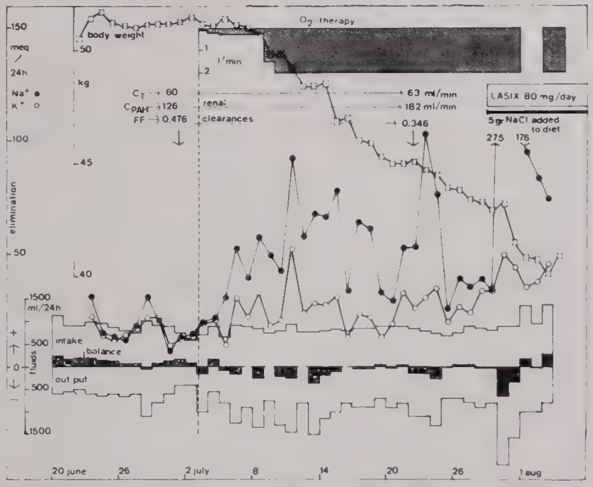

Fig. 3—Fluid balance, renal sodium and potassium elimination, weight change and renal clearances of thiosulfate (C_T = GFR) and paraaminohippurate (C_{PAH} = RPF) in a 63-year-old female with obstructive pulmonary emphysema and congestive heart failure due to cor pulmonale. Diet and all medication were kept constant during the control period and continuous O_2 inhalation through a nasal catheter, except where indicated. Furosemid (Lasix) was given after clinically manifest edema had disappeared.

The Algebra of Quackery

"Ailment plus medicine equals cure" is an equation widely cherished as true. But the algebra is not so simple. Countless times, of course, the true equation is "Ailment plus Nature equals cure," and if any drug is added its value is zero. Why, a physician once asked, was quackery more prevalent in medicine than in other areas of science? "Because," he answered himself, "the medical quack attributes to himself what is due to Nature. Nature can not build a railway, but she can very often cure disease." Quacks have harvested countless testimonials from customers whose gratitude was thus misplaced.

Another version is this: "Symptoms equal disease," hence, add medicine to produce cure. A vastly confusing aspect of medical science, to physician as well as to layman, is the way so many ailments, major and minor, are heralded by the same symptoms. An Atlanta chest specialist, checking medical textbooks, found 56 different causes for spitting blood, 76 different causes for pain in the chest, 137 different causes for coughing. The quack has taken advantage of such confusion, claiming that his bottled remedy has cured a dread disease at the serious end of the cough spectrum—say, tuberculosis—when in fact a change in the weather has dried up postnasal drip. To the quack and his most susceptible victims, all coughs are consumption, all lumps cancer, all backaches kidney disease.

Since "symptoms equal disease" in the mathematics of credulity, the quack can go a step further in tampering with the equation. He can, through his promotion, substitute false symptoms for real symptoms. He can convert normal physiological conditions, like low spirits, tiredness, mild insomnia, spots before the eyes, into dire harbingers of syphilis and insanity. Therefore, in the patent medicine algebra, "non-symptoms equal disease," ergo, add Helmbold's Extract of Buchu to produce cure.*

Antidiuretic Action

of Chlorpropamide and Tolbutamide

A. LUETHI, M.D.*
H. STUDER, M.D.*
Berne, Switzerland

In the course of studies aimed at assessing the antidiuretic activity of several newly synthesized polypeptides chemically related to the natural antidiuretic hormone of man, we became aware of two reports pointing at antidiuretic hormone-like activity of Chloropropamide,† a drug widely used for treatment of maturity-onset diabetes mellitus.[1-4] Since the antidiuretic effect of Chlorpropamide is of considerable theoretical and practical interest, this drug along with Tolbutamide‡ was further investigated in overhydrated healthy volunteers. Meinders et al. failed to produce antidiuresis in two overhydrated normal subjects given Chlorpropamide p.o. The question of whether or not Chlorpropamide decreases free water clearance only in patients with lack of endogenous antidiuretic hormone and fails to do so in subjects with functionally suppressed antidiuretic hormone release, is of paramount importance for further studies on the mode of action of this drug.

Methods

Eleven healthy male volunteers (aged 20-26), three of them trained in previous experiments, were hydrated by the ingestion of 20 ml water/kg body weight. A steady state of hyperhydration was maintained by the ingestion of an amount of water equal to the volume of urine voided during the preceding 15 minutes. The experimental procedure was started when reasonably comparable urine volumes were voided at subsequent 15-minute intervals. No catheter was used, but the subjects were instructed to empty their bladder completely at exactly 15-minute intervals. All subjects remained in a recumbent position during the whole procedure except for the time necessary to void. A blood sample for measurement of osmolality was obtained through an indwelling venous catheter at approximately the midpoint of the experiment. Drugs were injected through this same catheter. A Fiske osmometer was used for measurements of osmolality in blood and urine samples. All samples had been previously frozen.

†1—propyl-3-p-chlorobenzenesulfonylurea.

‡1—butyl-3-tolylsulfonylurea.

Since this work was submitted a further important contribution to the problems discussed here has been published: Reforzo-Membrives, J. Moledo, L. I., Lanaro, A. E. and Megías, A.: J Clin Endocr 28:332, 1968.

Osmolal clearance was calculated as $C_{osm} = \frac{V \times U_{osm}}{P_{osm}}$ and Free Water Clearance as $C_{H_2O} = V - C_{osm}$ (V = urine flow in ml/min U_{osm} and P_{osm} = The solute concentration of urine and plasma in milliosmols/kg water).

Experiments A, B, C, F, G, J, K, L, M were started at 8 a.m. in fasting subjects; D, E, H were started at 2 p.m. in subjects having taken a light meal.

Experimental procedures aimed at assessing antidiuretic compounds in human subjects are prone to produce many kinds of artefacts, since the suppression of endogeneous antidiuretic hormone production induced by heavy hydration may be overridden by other stimuli to antidiuretic hormone secretion such as emotional stress (e.g., insertion of needles) or even slight changes of position. Care was taken to avoid such artefacts (see Exp. C and G, where the indwelling needle had to be reinserted). The experimental set-up is illustrated in Figure 1 representing a study on dose-response relationship of Lysine^8-Vasopressine*, Tyrosine^2-Ornithine^8-Vasopressine* and Phenylalanine^2-Isoleucine^3-Ornithine^8-Vasopressine*.

Five hundred mg Chlorpropamide (Diabinese Pfizer), dissolved in 5 ml 0.9% NaCl solution, and 1000 mg Tolbutamide (Artosin Boehringer), dissolved in slightly alkaline solution, were given intravenously. Blood sugar levels were assessed enzymatically at least twice, before and 30 to 40 minutes after injection of the drug. No symptoms of hypoglycemia were noted except possibly in subject H who complained of dizziness 30 minutes after injection of Chlorpropamide.

In one single experiment (A, not illustrated) 500 mg Chlorpropamide were injected in a patient hypophysectomized for diabetic retinopathy three days before. The patient suffered from moderately severe diabetes insipidus. No clearcut acute effect of Chlorpropamide on urine flow was found (osmolality was not measured).

Results

Individual results of six studies with Chlorpropamide are presented in Figure 2.

Chlorpropamide Effect

In three subjects (E, F, G) definite antidiuresis occurred immediately after injection of 500 mg Chlorpropamide. One subject (D) responded only moderately, whereas no antidiuresis occurred in two cases (B and C). Whenever antidiuresis did occur, it was accounted for by a decrease in free water clearance, C_{osm} remaining practically constant.

Lysine-Vasopressine Before and After Chlorpropamide

In Subject B a dose of 0.009 I.U. Lysine-Vasopressine injected before and after Chlorpropamide had almost identical antidiuretic activity. In Case G 0.008 I.U. Lysine-Vasopressine given two hours after Chlorpropamide produced slightly more marked antidiuresis than the drug, although Chlorpropamide antidiuresis lasted longer.

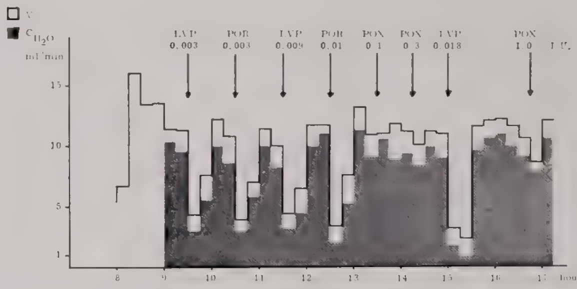

Fig. 1—Experimental protocol used to study the antidiuretic potency of unknown drugs (here designated as Tyrosine-Ornithine-Vasopressine (POR) and Phenylalanine-Isoleucine-Ornithine-Vasopressine (POX); details see section "Methods") in comparison to Lysine-Vasopressine. Effect on urine flow (V, white area) and free water clearance (free water clearance, hatched area). This experiment is illustrated in order to provide data on fluctuations of "steady-state" diuresis, reproducibility and drug specificity of antidiuresis, duration of antidiuresis produced by antidiuretic-hormone-like polypeptides. The drug effects may be compared with those of Chlorpropamide and Tolbutamide (Figure 2 and 3). These latter substances are not suitable for repeat injection.

---

*These compounds were synthesized by Sandoz S. A.

Antidiuretic Hormone Effect

The peak antidiuretic effect of Chlorpropamide occurred in four cases (D, E, F, G) within 15 to 30 minutes, just as it does after injection of Lysine-Vasopressine. However, with polypeptides akin to antidiuretic hormone, preinjection steady states were usually reattained within approximately 45 minutes after the injection (see Figure 1; Figure 2, exp. B and G; Figure 3, exp. L), whereas the Chlorpropamide antidiuresis lasted somewhat longer.

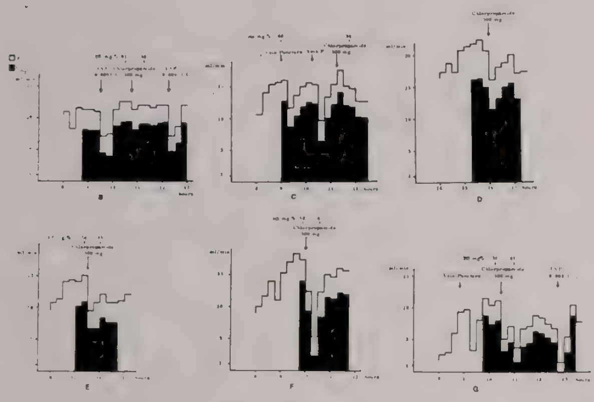

Fig. 2—Effect of 500 mg Chlorpropamide I.V. on urine flow (V, white area) and free water clearance (free water clearance, hatched area) in six subjects. In subjects B and C there was no response. D showed a possible response, whereas definite antidiuresis occurred in subjects E, F and G. Blood sugar levels are indicated when measured. In experiments B and G the effect of Lysine-Vasopressine was also investigated (see text).

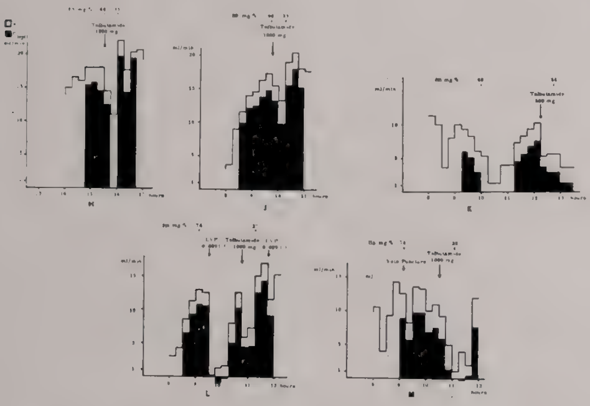

Fig. 3—Effect of 1000 mg Tolbutamide I.V. on urine flow (V, white area) and free water clearance (hatched area) in five subjects. (Note that in experiment H no free water clearance could be measured in the 16-hr. sample. The same is true for the five samples voided between 10 and 11:15 a.m. in experiment K). Definite antidiuresis occurred in subjects J, L and M. H and K gave equivocal results. In K an unexplained spontaneous and transient antidiuresis makes one hesitate to accept the second antidiuresis following the drug's injection as a Tolbutamide-dependent phenomenon. Subject H was disturbed during voiding the 16-hour sample. Blood sugar concentration decreased in all but subject K by more than 10 mg/100 ml.

Tolbutamide

In a further study, Tolbutamide, another antidiabetic drug, was investigated for possible antidiuretic activity (Figure 3). Out of five experiments, Tolbutamide had a definite antidiuretic effect in three, and a possible effect in the other two. Subject H was disturbed by a third person at the very moment of micturation 30 min. after Tolbutamide. We are therefore not sure if the antidiuresis is apparent or really drug-dependent. In subject K spontaneous antidiuresis occurred for no apparent reason after a urine flow of 10 ml/min had been obtained. Again there is some doubt about the specificity of the antidiuresis after this Tolbutamide injection, although the prompt decline in free water clearance speaks in favour of such a relationship.

In subject L a dose of 0.009 I.U. Lysine-Vasopressine was injected before and after Tolbutamide. The effect of the second dose was definitely smaller.

Discussion

Arduino et al. and Meinders et al. have recently reported that Chlorpropamide has antidiuretic properties in patients suffering from diabetes insipidus due to lack of antidiuretic hormone. The drug was ineffective in diabetes insipidus of renal origin and, in the study of Meinders, in two overhydrated normal subjects.

Our studies, carried out in normal human male volunteers previously hydrated to suppress endogeneous antidiuretic hormone secretion, show that Chlorpropamide does induce moderate antidiuresis in some, but not in all overhydrated normal subjects. Previous studies, undertaken in our laboratory in order to establish a dose-response relationship for Lysine-Vasopressine and some newly synthesized related polypeptides, had clearly shown that the minimal effective dose of antidiuretic hormone and its congeners may considerably vary from one subject to another and may not even be constant for a given individual. The inconstant antidiuretic effect of 500 mg Chlorpropamide is thus compatible with the concept that this dose is nearly as effective as a small, borderline antidiuretic dose of antidiuretic hormone (for Lysine-Vasopressine this would be around 0.001 I.U.). Higher doses of Chlorpropamide and Tolbutamide were not used for fear of causing side effects. We do not believe that a dose-response relationship can be obtained in man.

As stated for Chlorpropamide, Tolbutamide also causes slight but definite antidiuresis in hyperhydrated humans.

In diabetes insipidus there is often no need for a potent antidiuretic agent, since even a slight increase of the maximum concentrating power of the kidney may decrease the urine flow to an acceptable level. The clinical usefulness of Chlorpropamide has indeed already been established. However, an antidiuretic activity in overhydrated normal subjects had not previously been observed (Meinders).

No definite answer as to the probable mode of action of the two drugs emerges from these studies. There was no definite correlation between the fall of blood sugar and an antidiuretic effect. Blood sugar concentration dropped in seven out of 10 subjects tested by more than 10 mg/100 ml. Moreover, the two compounds did not potentiate the action of Lysine-Vasopressine (see experiments B and L). It cannot be decided from our studies whether or not the drugs directly stimulate endogenous antidiuretic hormone release or whether they themselves have antidiuretic hormone-like properties.

If the relatively long half-lives of the two drugs (five hrs. for Tolbutamide and 36 hrs. for Chlorpropamide) and their rather short antidiuretic action are taken into consideration, one is tempted to speculate on the antidiuretic action being the consequence of the acute release of endogeneous antidiuretic hormone stores. However, the rather strong antidiuretic effect of Chlorpropamide in diabetes insipidus of central origin is an argument (although not a definite one) against this hypothesis.

Still another possibility should be considered: It is well known that diuretics such as thiazides or ethacrinic acid are of some value in treatment of diabetes insipidus, even in the renal variety of the disease (Brown et al. and Crawford et al.). Thiazides are chemically related to Chlorpropamide and Tolbutamide since most of these drugs belong to the sulfonamide group. Therefore the possibility of a common mode of action should be further explored even if the two cases of diabetes insipidus renalis reported by Arduino et al. did not seem to respond to Chlorpropamide.

Summary

Chlorpropamide, given per os, was recently reported to lower urine flow and to decrease free water clearance in subjects with diabetes insipidus due to a deficiency of antidiuretic hormone, but not in overhydrated normal subjects.

Our studies show, however, that 500 mg Chlorpropamide injected I.V. into overhydrated volunteers induce definite antidiuresis in about half the subjects. The antidiuretic activity of this dose is thus equal, both quantitatively and qualitatively, to a very small dose of Lysine-Vasopressine, which may also fail to induce antidiuresis in some subjects. The qualitative similarity of the antidiuretic effect of Lysine-Vasopressine and Chlorpropamide is all the more surprising as the two drugs have very different biological half-lives. No definite answer as to the mode of action of Chlorpropamide can be given.

It was furthermore shown that Tolbutamide, another antidiabetic drug, has similar antidiuretic properties in overhydrated human volunteers.

Renal Clearances

Comparative Studies of Sodium Thiosulfate and Na_2Cr (Cr^{51}) Ethylenediaminetetracetate (Cr^{51}-EDTA) in Man*

C. VORBURGER, M.D.†
F. REUBI, M.D.†
Berne, Switzerland

In the past few years a variety of glomerular markers, tagged with a gamma-ray emitting isotope, have been proposed as substitutes for inulin. Radio-labelled compounds such as C^{14}-carboxylinulin,[1] I^{125}-allyl inulin,[2] CO^{57}-cyanocobolamine[3,4] have been discarded because of expense or other major disadvantages. Good correlation with conventional inulin clearances were reported in rather small series with newer glomerular markers such as I^{131}-sodiumdiatrizoate (Hypaque),[5] I^{131}-meglumindiatrizoate (Renografin),[6] I^{131}-sodiumiothalamate (Conray),[7] I^{125}-iothalamate (Glofil)[8] and Cr^{51} labelled Na_2Cr-ethylenediaminetetracetate (Cr^{51}-EDTA).[9-11]

The enthusiasm for substitutes for inulin will be shared by everybody who struggled along with chemical determination of inulin. One should not, however, sacrifice accuracy for simplicity. We felt that the appropriateness of a glomerular marker could be established only on the basis of extensive correlative studies between the substitute and the two standard glomerular markers, inulin and Na-thiosulfate. Among the new glomerular markers Cr^{51}-EDTA seems to qualify best since this complex is stable in vivo, since Cr^{51} has a very convenient half-life and physical properties, and since it is low-priced.

We have therefore compared simultaneously-determined renal clearances of either Na-thiosulfate or inulin and Cr^{51}-EDTA in a large number of patients. Our results indicate that the clearance of Cr^{51}-EDTA is slightly but definitely below the clearance of Na-thiosulfate and inulin. Still the line of regression defining the correlation of the two clearances may be used as a calibration curve to derive glomerular filtration from the Cr^{51}-EDTA clearance. In this short paper we shall comment only on the results of the Na-thiosulfate series.

†Medical Outpatient Department, University of Berne, Switzerland.

Material and Methods

Under standard clearance conditions,[12] we determined in 47 patients with normal renal function or various degrees of renal impairment the clearances of Na-thiosulfate and Cr^{51}-EDTA in 103 clearance periods. Na-thiosulfate determination was performed according to the usual technic in our laboratory.[12] Cr^{51}-EDTA was obtained from the Farbwerke Hoechst, Frankfurt, Western Germany, with a specific activity of 40 μCi/mg Cr. The stock solution contained 1 mCi/ml (corresponding to 180 μg Cr-EDTA per ml), and it was diluted with sterile saline to contain about 50 μCi/ml. 15-20 μCi Cr^{51}-EDTA were added to the priming infusion; the sustaining infusion was made up of 200 ml sterile saline (9%) and of 12-15 μCi Cr^{51}-EDTA. It was infused at a rate of 3 ml/min. After an equilibration period of at least 20 minutes, the urinary bladder was emptied and the first clearance period started. Two to three clearance periods were obtained from each patient.

Great care was taken to maintain plasma levels of Na-thiosulfate above 25 mg%, since it is known that if plasma concentration falls below 25 mg%, the Na-thiosulfate clearance tends to be higher than the inulin clearance.[12] Blood was withdrawn from an antecubital vein with no or only minimal hemostasis and centrifuged at 2000 rounds per minute for 15 minutes to avoid hemolysis. Two ml of plasma and 2 ml of urine were pipetted into plastic counting test tubes (Packard International) and counted in a well-type NaI scintillation crystal. At least 10,000 counts per minute were obtained from each sample. The lower level of the discriminator was set at 280 keV, the upper at 350 keV.

Results

Our results are plotted in the Figure. Each point corresponds to one clearance period. It can be seen that the correlation between the two parameters is very good. The equation of regression runs as follows: $y = 1.066 \cdot x$ ($s_b = \pm 0.0068629$). The 95% confidence limits are indicated by dashed lines. The mathematical model which applies best to the distribution of our data has been taken from M. G. Nutrella.[13] The clearance of Cr^{51}-EDTA was deliberately taken as independent parameter and plotted on the abscissa, since we believe that it can be determined with a smaller technical error than the Na-thiosulfate clearance. The line of regression which follows the equation $y = 1.066 \cdot x$ is significantly different from $y = x$, and it may therefore be used as a calibration curve.

Discussion

Cr^{51}-EDTA can very easily be measured by means of its gamma-ray emission. The low price and the convenient physical properties of Cr^{51} make it a desirable substitute for Na-thiosulfate. Radiation dosage to the patient is trivial since it is of the order of 5 mrad to the kidney in normal individuals with the tracer dose used in this study. No side effects have ever been observed from EDTA. To derive glomerular filtration rate, one has to multiply the clearance of Cr^{51}-EDTA by 1.066. At present we cannot explain the fact that the Cr^{51}-EDTA clearance is slightly lower than the clearance of Na-thiosulfate. Plasma protein binding is of the order of 0.5-2.0%[9,11] and will therefore not fully account for the difference. Recovery for Cr^{51}-EDTA in normal individuals is 95% after 24 hours.[11] We could not find measurable amounts of Cr^{51} in washed erythrocytes 16 hours after the clearance test,

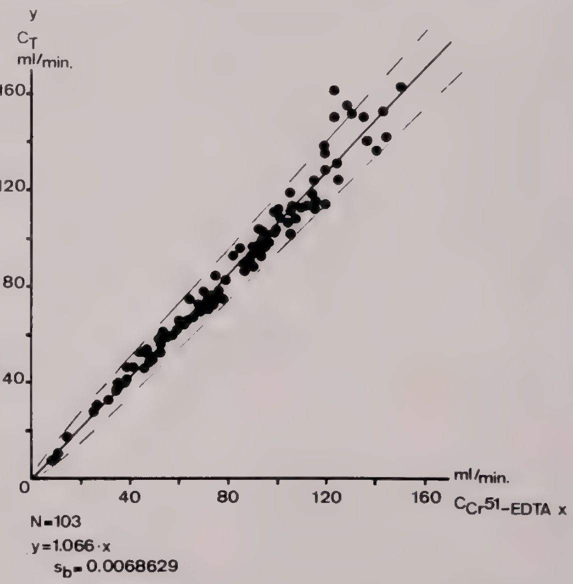

Figure 1—The Na-thiosulfate clearance (y) is plotted against the Cr^{51}-EDTA clearance (x). The line of regression is marked with an unbroken, thick line; the 95% confidence limits for a future value are indicated with dashed thin lines.

so that a split-off of Cr^{51} is very unlikely. Increasing the plasma concentration of Cr^{51}-EDTA 15 times or increasing the urinary volume up to 28.0 ml/min had no effect on the correlation with inulin clearance.[14,15]

Comparison of the renal clearances of Cr^{51}-EDTA and inulin in 181 clearance periods leads to the same conclusion.[14,15] The pattern of correlation is practically the same as in Figure 1, the coefficient of regression being slightly higher, 1.077. On the basis of this study, it seems justified to recommend Cr^{51}-EDTA as a valid substitute for Na-thiosulfate or inulin as a glomerular marker using a mean correction factor of 1.073. Thus the true glomerular filtration rate may be easily and accurately determined by any laboratory which uses a well-type NaI scintillation counter. This technique permits one to overcome the difficulties arising from the time-consuming inulin determination, and should be preferred to the inaccurate single injection method.

Summary

Under standard clearance conditions we have performed in 47 patients with normal renal function and various degrees of renal impairment (103 clearance periods) simultaneous clearances of Na-thiosulfate and Cr^{51}-EDTA. The priming infusion contained 15-20 Ci, the sustaining infusion 12-15 μCi of Cr^{51}-EDTA in 200 ml 0.9% sterile saline, infused at the rate of 3 ml/min. Cr^{51}-EDTA was determined from 2 ml plasma and 2 ml urinary samples, counted in a well-type NaI scintillation counter up to at least 10,000 counts. A high degree of correlation between the two clearances was found, the equation of correlation running as follows: $y = 1.066 \cdot x$ ($s_b = \pm 0.0068629$). On the basis of our results we feel that Cr^{51}-EDTA makes a valid substitute for Na-thiosulfate and inulin as well. The clearance of Cr^{51}-EDTA, however, has to be multiplied by 1.073 to obtain the true glomerular filtration rate.

Prerequisites for a Physician

The physician should be of tender disposition, of wise and gentle nature, and more especially an acute observer, capable of benefiting everyone by accurate diagnosis, that is to say, by rapid deduction of the unknown from the known. And no physician can be of tender disposition if he fails to recognize the nobility of man; nor of philosophical nature unless he be acquainted with Logic; nor an acute observer unless he be strengthened by God's guidance; and he who is not an accurate observer will not arrive at a correct understanding of the cause of any ailment.*

Marriage is neither heaven nor hell; it is simply purgatory.—Abraham Lincoln

It's the Law

Primer of Parliamentary Procedure*
The Tactics of Delay

At some point in an organized meeting it may become necessary for proponents and/or opponents of a particular action to consider some means of deferring or halting action on a motion, whether for the good of the assembly or for a strategic purpose.

If it is the intent of the assembly to defer action on a motion for a specific period of time, say until the next regular or annual meeting, the proper phrase is: "Mr. Chairman, I move that we *postpone consideration* of this motion till the next meeting." After being seconded and debated, a simple majority of the society may thus defer action for a stated period. This motion, *to postpone to a certain time,* is usually confused with the motion to *lay on the table.* Very frequently, a member will move "to lay this matter on the table until next month," thereby confusing the assembly and often the chair. A prudent chairman, hearing this erroneous phrase, will immediately ask the mover which of the two motions he is proposing, explaining if need be, as a point of order, the difference between the two.

The motion, *to lay on the table,* is another distinct means of deferring action on a particular proposal in order to allow the assembly to attend to more urgent business. The effect of this motion is to place the pending question in charge of the Secretary temporarily, usually until more urgent matters have been disposed of and the assembly is ready to consider new or unfinished business. Properly employed, the motion *to table* defers temporarily, and does not enable a majority to kill a measure instantly (which is the effect of this motion in the U.S. Congress) but preserves the right of a majority vote to *take from the table* those matters deferred at the proper moment during the same or a succeeding meeting.

The motion *to table* has a high priority of entry, must be seconded, but is undebatable. It cannot be qualified by adding a phrase such as "until Friday" or "until the next meeting." A simple majority is necessary for approval of this motion.

Perhaps this lesson should include some brief mention of a motion directed toward avoiding delay, of forcing the assembly to vote promptly on a pending matter. Suffice it to say, then, that the motion "*to close debate* and vote immediately on the pending question" must be seconded and requires a *two-thirds* affirmative vote. Like the motion *to table, to close debate* (move the Previous Question) is undebatable.

Every shut eye ain't asleep.—American Negro proverb

Central European Encephalitis ("Tick-borne Encephalitis") in Switzerland

Discussion of Nine Known Cases

H. SPIESS, M.D.*
M. MUMENTHALER, M.D.*
Berne, Switzerland

ARTHROPOD-BORNE VIRAL infection (ARBOR-Virus Group B) has been repeatedly described in Europe during the last few years.[1,2,3,6,7,8,9,10,11,13,15,18,20,23,24,26,29,30,31,32,] In general a spreading of the infection from east to west has been established. The occurence in southern Germany has been proven.[25,26] In Switzerland, however, until now no cases have been described although, theoretically, they are to be expected because of similar climatic conditions.

Synonymous Terminology

In the literature there has been a great variety of names used synonymously, e.g., Biundulant meningoencephalitis, Biundulant milk fever, Far Eastern forestencephalitis, Kumlinge-disease, Central European encephalitis (CEE), Russian spring-summer encephalitis, Tajga-encephalitis, Tick-borne encephalitis and Louping-ill. Certain differences exist clinically as well as in regard to the biological vector and antigen type.[17] It is of practical importance to distinguish between an eastern (Russian spring-summer encephalitis) and a western (Central European encephalitis) type.[4] The eastern type with Ixodes persulcatus as biological vector manifests itself clinically usually in one phase, and has a higher mortality than the Ixodes ricinus-transmitted diphasic western form.

Also on other continents tick-borne viral infections in man have become known, e.g., in India by Kayasanur forest disease, in Malaya the Langat (T.P. 21), in Japan the Japanese encephalitis, in North America the Powassan and Colorado tick fever, in Australia the Murray-valley encephalitis, and in Africa the Nairobi sheep disease[7,14,17,27,28]. These diseases certainly are more widespread than now suspected on the basis of serological examinations.

The Virus Host

The virus of Central European encephalitis can survive in several generations of the tick Ixodes ricinus. It is transmitted by tick bite to wild animals who develop a viremia but only rarely an encephalitis. Further spread occurs when the infected animal is bitten by susceptible ticks. Tick larvae feed on mice, the nymphs partly on small mammals, and the mature ticks almost always on large animals and sometimes man. The mouse-larva-nymph-mouse cycle represents a kind of virus reservoir. As the virus passes during viremia into the milk of infected animals, during the phase of viremia, infection is possible by drinking unboiled milk. Rarely do laboratory infections result from inhalation.[4,11,17,29]

---

*From the Neurological Clinic of the University of Berne, Switzerland.

See editorial page 85.

Central European encephalitis shows a clear incidence with a peak in June and July.

The Carrier

Vector* herds exist in wooded areas.[5,19,21,24,29] Therefore farmers, woodsmen and hunters are especially exposed to infection. The variability of annual incidence through the years depends upon changes in vector concentration and the contamination rate. The combination of short winters and moist summers is said to cause an increase in tick population, resulting in an increase in infections.[22]

The Inoculation

At the site of the *tick bite* there is a localized inflammatory reaction and infiltration resulting from the local reaction to toxins.

The Incubation Period

In the *incubation period* (three to 21 days, usually 10 to 12) the already reproducing virus spreads from the lymph channels into the blood. In milk infection the virus is taken up by the epithelial cells lining the upper part of the alimentary tract, and the multiplying virus penetrates via the lymph vessels into the blood.

Inhalation Infection

In the rare case of inhalation infection, the virus would be transmitted from the olfactory epithelium and nerve fibers directly to the ganglions and central nervous system; in this case the so-called first phase of the illness would not exist. The vast majority of infections are abortive and inapparent.

The Stage of Viremia

After the incubation period, in the *stage of viremia (first phase,* average length four to six days) the clinically well-known general symptoms of viral infection appear: fever, mild upper respiratory manifestations and headache. Sometimes the illness ends in this first phase.

Organ Manifestations

Autonomic Nervous System

In other cases, a few days after viremia, the second phase with the *organ manifestations* of this pantropic virus follows. The quite variable symptomatology depends, among other things, upon the site of entry, the amount and virulence of the virus, and the general condition of the macroorganism. Gastrointestinal symptoms, disturbance of sweating, salivation and sphincter control are signs of involvement of the autonomic nervous system.

Central Nervous System

Infection of the central nervous system results in different manifestations, especially in meningitis, encephalitis, polioencephalitis and rarely radicular syndromes, as well as combinations of the above. In the spinal fluid protein content is slightly raised; occasionally pathological colloidal curves and a pleocytosis of several 100/3 cells p.cc are seen. These changes usually disappear after three to four weeks. The blood findings are characteristic of viral infection. The mortality varies considerably and may amount to several percent. There are no characteristic pathological anatomical findings. The differential diagnosis includes other viral infections, e.g., ECHO; Coxsackie-, parotitis-, herpes- and poliomyelitis virus.[4,16,17,24,30,31]

Diagnosis

Isolation of Virus

A definite diagnosis is only possible by means of isolation of the virus or serological examination. Except in some rare cases the isolation of the virus from blood is successful only in the first phase of infection and later from parenchymal cells of the central nervous system. However, isolation of the virus in the early, uncharacteristic stage of the illness is seldom attempted. Virus isolation from spinal fluid has been reported in isolated cases. In clinical medicine the serological methods are practically the only promising ones.[4,11,12,16,17,25,26,28] Three blood samples are recommended. The first is to be taken at the earliest sign of neurological involvement, the second after two weeks, the third four weeks after the first sample.

---

*See Test Your Word Score Page 89.

Serological Studies

Unfortunately serological studies of Central European encephalitis are made in only a few centers of Western Europe. A combination of three serological methods has proven to be most useful: the hemagglutination inhibition test (HIT), the complement fixation test (CFT), and the neutralization test (NT). The goal of all three reactions is to detect specific antibodies. With the hemagglutination test common antibodies against other strains of ARBOR-B-virus are detected; however, with the homologous antigen higher antibody titers are found. Therefore the hemugglutination test is not type-specific; this also applies to the complement fixation test. The complement fixation test is suitable only in detecting fresh cases, because complement-fixing antibodies appear about three weeks after the beginning of neurological involvement; six months later they are no longer detectable by a dilution of 1:4. According to the literature the complement fixation test is positive in only two thirds of the cases with a positive neutralization test.

The neutralization test is the most specific. Since it is type-specific it is not unimportant which strain is used in the neutralization test in a given case. Often there is no isolation strain from the geographical area of infection available for serological purposes. For this reason generally the Czechoslovakian strain "Hypr" is used. But this may lead to false-negative results. Neutralizing antibodies in man are always present at the beginning of the second phase of illness. Practically, therefore, a negative neutralization test (less than 1:5) at the beginning of the second phase eliminates Central European encephalitis as the cause of infection. However, a positive neutralization test (1:40) does not tell us how old the infection and antibodies are.

The titer change is decisive (comparison with earlier or later antibody titers). A rise in titer is frequently found if the first examination was made early in the infection; the titer maximum is reached at the end of the first month of central nervous system involvement. Neutralizing antibodies probably are found in man years after infection. A positive titer in dilution of 1:5 at the beginning of neurological involvement indicates an old infection with Central European encephalitis virus, whereas a titer of 1:40 makes an acute infection probable. A rise in titer in the neutralization test and in the hemagglutination test, as well as a positive complement fixation test, is proof of recent infection.[4,5,11,12,16,17,19,20,27,29]

Treatment

The problem of *active immunization* through vaccination against Central European encephalitis-virus is not yet satisfactorily solved. Preventive methods such as suitable clothing for woodsmen, boiling of milk (especially goats' milk), reducing tick population, vaccination of farm animals, and perhaps reconvalescent serum are of value. There is no specific *therapy*. Gamma globulin has only a prophylactic value because at the earliest possible moment of diagnosis of Central European encephalitis, antibodies are already present in serum and a further application of antibodies cannot improve the prognosis.

Personal Observations

The frequency of viral disease of the central nervous system of unknown origin in the summer months and stimulation of interest resulting from investigations in West Germany[1,19,24,25,26,29] have led us to search more carefully for cases of Central European encephalitis in Switzerland. As systematic serological examination of large groups of patients was technically impossible, we depended primarily upon a history of certain or questionable tick bite. Serological examinations were not made in all cases and in some only after many months. A local virus strain is not available for serological purposes; hence a type-specific neutralization test could not be made.

TABLE I

Case Nr., Age, Profession	Case and History of tick bite	Clinical features and Seasonal incidence	Cerebrospinal fluid	Serological tests	Late findings

We have observed *nine suspected cases*. They are summarized in Table 1. An instructive case follows in detail (Case 3 in Table 1).

Case Report

A. Werner*, male, aged 41, salesman and voluntary gamewarden of forest direction in Berne. In the months before illness several tick bites, the last on August 22, 1965, on which evening he found a pea-sized tick in the right inguinal region. In the following days redness, swelling and slight infection developed at the site of the bite. On August 29 malaise and the feeling of fever; on the following day a fever of 38.5°C, headache, and increasing pain in the right inguinal region; on August 31 neck stiffness, slight paralysis of the arms; on September 1 difficulty in swallowing and diplopia. A spinal tap showed elevated protein (103 mg %) and 1500/3 cells per cubic millimeter. An increase in flaccid paralysis followed. On September 6 somnolent, lethargic, flaccid paralysis of all extremities, especially proximal on the arms which could no longer be raised actively. Dyspnea and weakness of cough. Babinski positive on both sides. Serological findings on September 9, hemagglutination test for Central European encephalitis greater than 1:20 positive, complement fixation test more than 1:128 positive. Slight simultaneous agglutination of adenovirus, mumps and Coxsackie B2.

During the next weeks recovery was slow, with some residual paralysis. Intensive physical treatment followed. A control examination in May 1967 showed generalized, moderate, flaccid paralysis of the right arm, especially proximal, with obvious muscle atrophy. Slight weakness and atrophy of the left deltoid muscle. Stretch reflexes lively and symmetrical, no sensory disturbances. Light to moderate paresis, especially distal, of the right leg. Babinski inconstantly positive on the left side. Dysesthesia on the lateral side of the right thigh. Serological findings on May 9, 1967: complement fixation test 1:4 positive, neutralization test 1:256 positive (tested with 1000 ID50). Neutralization index 4.00†

Epicrisis: serologically proven Central European encephalitis occurring after tick bite with the clinical picture of serious meningo-encephaloradiculitis. Recovery with residual asymmetrical motor damage.

Discussion

As shown in Table 1 we were successful in just one case in obtaining serological proof of tick-transmitted infection of the virus of Central European encephalitis. It proves, however, that the virus of Central European encephalitis is present in Switzerland and that increasing numbers of infections are to be expected. The other cases were suspect, partly because of clinical evidence and partly because of the serological finding of a previous contact with the virus of Central European encephalitis, although it could be proved that this contact was responsible for the present illness. In two cases no serological examinations were done; in four others the first examination took place four to 28 months later, so that no significant changes in titer could be expected. We cannot judge the value of a negative neutralization test for the strain "Hypr" or fränkisches virus" in eliminating Central European encephalitis after such a length of time. It would be important to conduct examinations with a virus strain isolated from our own immediate geographical area.

In suspected cases, early and repeated serological examinations (three times at intervals of two weeks) should be made. This was not possible in all of our cases, as many were referred late in the course of infection. A history of tick bite was proven in three cases by detection of the insect. Twice typical local inflammatory changes were also found. In five other cases local changes suspicious of possible tick bites were found in addition, when exposure in a wooded area had taken place. In only one case, that of a soldier in military service, was there no history in this respect, although as a soldier he was potentially exposed to tick bites.

The age of the patients at the time of infection varied between 20 and 69 years. Seven males and two females were affected. The seasonal incidence with eight cases in the months of July to September (one case in November) correlates with the distribution reported in cases of Central European encephalitis. The clinical manifestations appeared four times as meningoencephaloradiculitis, twice as meningitis, once as meningoradiculitis, once as a peripheral facial paralysis, and once as a brachialgia. The blood picture corresponded to the findings in viral infection; and in cerebrospinal fluid a pleocytosis between 40/3 and 1500/3 cells per cubic millimeter, a protein concentration ranging from normal to 144 mg% (Kafka method), and sometimes a pathological colloidal curve were found. Pathological spinal fluid findings were present for months to more than two years after illness. As a result the course of illness was sometimes very much prolonged. Follow-up studies revealed complete recovery in three cases and residual neurological damage of varying degrees in five others. One case could not be followed.

---

*The patient was first seen in the Clinic of Internal Medicine of the Tiefenau Hospital. We wish to thank Prof. G. Riva for permission to publish this case.

†Professor Ackermann of the Neurological Clinic of Köln (Western Germany) was kind enough to do the serological tests.

Summary

One serologically-confirmed, and eight clinically suspected cases of Central European encephalitis transmitted by tick bite and occurring in Switzerland are reported. This ARBOR-virus infection is steadily spreading toward Western Europe and is clinically manifest at the outset as a mild upper respiratory infection, later showing organ manifestations, and may culminate in more serious symptoms of meningitis, encephalitis, polioencephalitis radiculitis or a combination of these. The modes of infection, the seasonal and geographical incidence, as well as the clinical and serological diagnosis are discussed.

Ferrokinetics in Polycythemia and Iron Deficiency Anemia*

H. KUMMER, M.D.†
U. BUCHER, M.D.†
Berne, Switzerland

THE CLOSE RELATION between plasma iron turnover and erythropoietic activity has been clearly demonstrated in the normal and in many pathological conditions with increased or decreased red cell production.[1,5,6] Therefore it may be assumed that the maintenance of an elevated total red cell volume in polycythemia is associated with an increase of plasma iron turnover. While in most cases of secondary polycythemia one can observe a close parallelism between total red cell mass and ferrokinetic, polycythemia vera is most often characterized by a disproportionate elevation of plasma iron turnover.[5,7,9,15] Ellis and coworkers[2] observed recently that untreated polycythemia vera is regularly associated with depleted marrow iron stores in contrast to the normal or increased amount of iron seen in cases of secondary polycythemia, and they demonstrated that plasma iron disappearance time is highly affected by depletion or repletion of iron stores in both primary and secondary polycythemia.[3] They concluded that differences in iron kinetics‡ between the two diseases are more related to the size of available iron stores than to the type of polycythemia.

In a simultaneous study we reached the same conclusions based upon the observation that iron deficiency anemia is characterized by a ferrokinetic pattern similar to that of primary polycythemia.[14]

It is the purpose of this paper to re-examine the clinical value of ferrokinetic studies in polycythemia.

Material and Methods

Thirty-six patients were investigated: seventeen with polycythemia vera (sixteen untreated, one treated), nine with polycythemia secondary to decreased oxygen saturation in connection with chronic respiratory insufficiency or cardiac malformation, six with rela-

†From the Department of Hematology, Inselspital, Berne, Switzerland.

‡See Test Your Word Score Page 89.

tive polycythemia, and five with anemia secondary to iron deficiency. The exact diagnosis was made in each case on the basis of clinical, laboratory and cytological data.

Hematological routine examinations were done by standard techniques of the Inselspital Berne. Erythrocytes and leucocytes were counted in an electronic counter (Coulter Counter, model A). Platelet counts were made, using phase microscopy. Alkaline phosphatase activity in granulocytes was determined by the method of Merker and Heilmeyer.[10] Serum iron was determined by the method of Lauber.[8] Bone marrow smears were stained for iron, using the Prussian Blue reaction. Measurement of total red cell volume was done with chromium-51 labeled red cells by the method of Hughes Jones et al.[11] Plasma volume was calculated from the total red cell volume with the whole body hematocrit (venous hematocrit x 0.87). Plasma iron disappearance was measured after in-vitro labeling of patient plasma with 4-8 microC ^{59}Fe; plasma iron disappearance time, serum iron concentrations and plasma volume by the formula of Huff and coworkers[5] P.I.T. =

$$\frac{0.693 \cdot \text{Plasma volume (ml)} \cdot \text{Pl.Fe.(mg/1)} \cdot 24}{T\frac{1}{2}\ \text{(minutes)}}$$

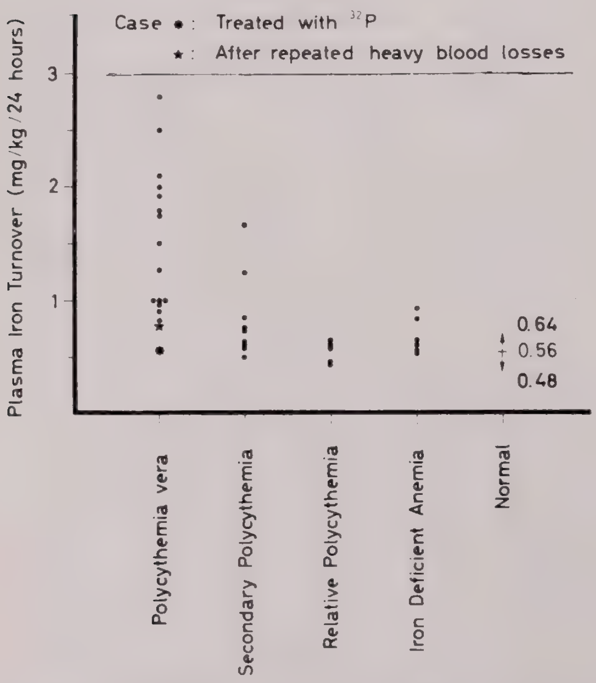

Fig. 1—Plasma iron turnover in different types of polycythemia and in iron deficient anemia.

The results of total red cell volume were expressed in ml/kg body weight, those of plasma iron turnover in mg/kg body weight. In obese patients the actual weight was replaced by the theoretical weight, calculated from the height by the formula:
theoretical weight (kg) = height (cm) − 100.

Results

Results of blood volume determinations, serum iron concentration and studies of iron metabolism are presented in the Table and Figure 1. The mean total red cell mass and plasma volume are slightly higher in polycythemia vera than in secondary polycythemia, but the wide scattering of the individual figures in both groups makes any diagnostic evaluation elusive in the individual case.

Discussion

Plasma iron kinetics are normal in all patients with relative polycythemia. This was to be expected since relative polycythemia is due to faulty regulation of plasma volume and not to a disorder of erythropoiesis. In secondary polycythemia, plasma iron turnover was found to be moderately increased, whereas it was greatly elevated in the majority of the patients with untreated polycythemia vera. This represents a further confirmation of the findings of Huff and other investigators.[5,7,9,15] However, several observations in our material warrant more detailed comment.

Iron Turnover

Plasma iron turnover values between 0.8 and 1.0 mg/kg/day are frequently encountered in secondary as well as in primary untreated polycythemia. This overlap restricts the diagnostic value of the method.

In a few instances secondary polycythemia may be associated with a very high increase in plasma iron turnover.

Case B.F., 35-year-old male, height 182 cm, weight 135 kg. This obese patient was suffering from severe chronic bronchitis complicated by a Pickwick syndrome with a resulting arterial oxygen saturation of less than 70%. The total red cell volume reached 6000 ml within a few years. There was no clinical suspicion of concomitant polycythemia vera.

The clinical situation of this patient was therefore characterized by the extraordinary degree of polycythemia and the relatively rapid development of the disease.

Normalization of Blood

Effective cytostatic treatment of polycythemia vera with 32 P or chemotherapeutic agents is followed by a rapid *normalization of plasma iron turnover*, the latter thus providing a useful tool for early judgment of the effectiveness of the therapeutic procedure. This normalization of plasma iron kinetics occurs within a few days after injection of 32 P, whereas an appreciable lowering of the total red cell mass—consequent on the long erythrocyte life span—will not occur before four to six weeks.

Heavy blood loss with consecutive *normalization of blood volume and hematocrit* does not lower plasma iron turnover to the same extent. This may be of great diagnostic importance when a history of important blood loss is opposed to a normal hematocrit as in the following case.

Case K.G., 57-year-old female. This patient entered the hospital with a history of intestinal blood loss which was not in accordance with a hematocrit of 42%. Plasma iron turnover at that time was still elevated to 0.8 mg/kg/day and pointed to the diagnosis of polycythemia vera in a patient with heavy blood loss.

Erythropoietic Activity

The ultimate proof of a disproportion between plasma iron turnover and erythropoietic activity in polycythemia vera presumes the direct measurement of erythropoiesis. This is not possible at the present time; however, one can evaluate erythropoietic activity by measuring total red cell mass and the rate of both intra- and extramedullar hemolysis.

In our patients we have done no erythrocyte survival studies and no measurements of bile pigment excretion. Several investigators have demonstrated normal red cell survival in polycythemia vera at least in the early stages of the disease when the splenomegaly is not yet pronounced and no extramedullary erythropoiesis is present.[4] Likewise in that stage of the disease morphological criteria which might presume an enhanced intramedullary hemolysis do not exist. Our patients were examined soon after diagnosis had been established, and they presented no signs of increased peripheral or medullary hemolysis as judged by reticulocyte counts and bone marrow morphology. It seems therefore reasonable to consider total red cell mass in our patients with polycythemia as an acceptable parameter for erythropoietic activity.

TABLE
Blood Volumina, Serum Iron and Ferrokinetic Datas
(mean and range)

	Number of cases	PCV	Total red cell volume (ml/kg)	Plasma volume (ml/kg)	Serum iron (γ/100 ml)	Plasma iron disappearance time (T_{50} in min.)	Plasma in turnover (mg/kg/da)
Polycythemia vera							
— untreated	15	60.1 (45-71)	57 (43.2-73)	47.4 (35-60)	56.5 (20-91)	16.9 (6-43.5)	1.62 (0.82-2.8)
— treated (^{92}P + phlebotomy)	1	41	25	46	20	20	0.57
— after heavy gastro-intestinal bleeding	1	44	23.4	35	23	10	0.8
Secondary polycythemia	9	60.9 (55-67)	49 (34.3-81)	42.7 (35.5-53.5)	102.8 (20-179)	60 (8-107.5)	0.83 (0.5-1.67)
Relative polycythemia (Polycythemia of stress)	6	54.3 (50-59)	32 (26-36.9)	33 (28-36)	116.5 (72-186)	77.17 (54-105)	0.55 (0.44-0.64)
Iron deficiency anemia	5	33.6 (20-42)	19.8 (13.5-25 5)	54 (4.45-63)	27.4 (12-47)	22 (11-38)	0.63 (0.53-0.83)
Normal mean ± one standard deviation	20	45±4	29±3	43±4	110±25	78±18	0.56±0.08

The disproportionate rise of plasma iron turnover indicates that a lesser part of iron leaving the plasmatic pool is used for erythropoiesis than in the normal individual: a situation well known in idiopathic hemochromatosis where an increased exchange takes place between plasma iron and storage iron. A similar situation of relatively increased plasma iron turnover is observed in iron deficiency anemia as demonstrated in Figure 2. An explanation for this peculiar fact has been offered by Pollycove[13] and Najean and coworkers,[12] who presented evidence that iron on its way from plasma into the erythrocyte precursor passes through a labile iron pool. Its size and exchange rates have been evaluated by mathematical analysis of the plasma iron disappearance curve. In the presence of iron deficiency this pool was found to be small, but its rate of exchange with the plasma iron pool very high. Iron is then shifting rapidly from plasma in this labile pool and in part back to plasma, resulting in an increased plasma iron turnover as compared to circulating red cell mass. It has been postulated that this labile iron pool might be located on the cell surface of the erythrocyte precursors[13] and possibly even in part attached to circulating reticulocytes; others believe that this exchangeable compartment is diffuse in the whole organism (marrow, liver, spleen, intestine).[12]

Iron Turnover vs. Red Cell Mass

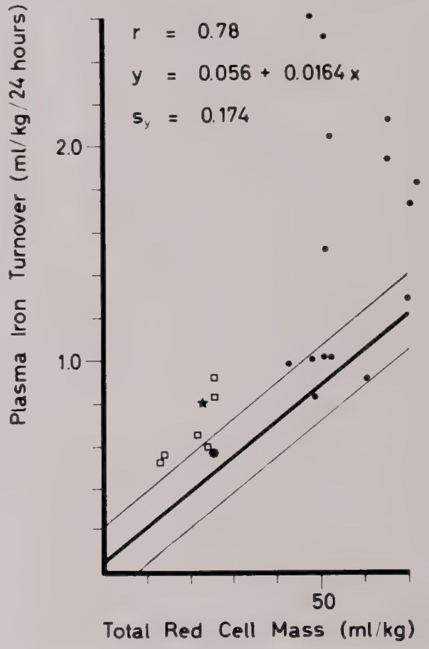
Figure 2 demonstrates the linear relationship between plasma iron turnover and total red cell mass for normal individuals and for patients with relative and secondary polycythemia, whereas many cases with polycythemia vera present a disproportionate increase of plasma iron turnover similar to patients with iron deficiency. It seems tempting to speculate that the observed abnormality of plasma iron turnover in polycythemia vera is in fact a mere consequence of a state of iron deficiency and not inherent in the nature of the disease.

Few investigators have drawn attention to the frequency of the obvious iron deficiency in patients with untreated polycythemia vera. As shown in Figure 1 serum iron levels were low in all of our patients. Moreover, in agreement with Ellis and coworkers[2] we could detect no stainable iron in the bone marrow of five patients examined. The frequency of iron deficiency in polycythemia vera is not surprising; in the normal individual approximately two thirds of the total body iron are located in the circulating erythrocytes. An increase of this red cell mass by only fifty percent would therefore shift all the storage iron of the body into the red cells.

Actually it is more surprising that patients with secondary polycythemia, who do have a similar increase in total red cell mass, present no signs of iron deficiency. One may speculate that the duration of the disease is important.

Conclusion

Development of secondary polycythemia in patients with chronic respiratory or cardiac disease is usually very slow and often starts in early childhood. This gives the organism a fair chance to compensate the increased iron "sequestration" in the circulating red cell mass by increased absorption from the gut. Although



Note: Polycythemia vera • ● ★
Iron Deficiency □

Case ● : Treated with ^{32}P
★ : After repeated heavy blood losses

Fig. 2—Relation between plasma iron turnover and total red cell mass in patients with polycythemia vera and iron deficient anemia.

no pertinent data are available it seems very likely that the time interval between onset and full clinical manifestation of polycythemia vera is usually not more than a few months, much too short a period to allow effective compensation of the "iron loss" by increased absorption.

New Look to Medicine

The years passed and the frontier was changing. Even Dr. Weideman's San Antonio was becoming educated not only to scientific ways but to scientific jargon. In 1882 a ranch-country scribe summed up what he felt about the new look to medicine in the city of the Alamo. In his home town people still died of simple frontier diseases such as lead poisoning, but in San Antonio, well now! Science was running rampant.

"Over in San Antonio," he observed, "the people die of icterus senilis, of seven kinds of tuberculoses, of icterus amenorrhoea, intestinal pulmonalis, and five other kinds of icterus. They can also die, if they want to, of anenisina, colica flatulenta biliosa—particularly when complicated with atropia medullae spinalis or morasmus infantium caused by too much vox populi, nux vomica, e pluribus unum, particularly etc."*

It's spring when you turn on the heat that yesterday you thought you'd turned off for the year.—Changing Times

Nobel Prize Winners In Medicine and Physiology

Emil Theodor Kocher 1909

For his work on the physiology, pathology, and surgery of the thyroid gland

"In the spring of 1883, at the Congress of the German Surgical Society (Gesellschaft fur Chirurgie), we announced that some thirty of our first one hundred thyroidectomies, which we could follow up and investigate, presented a quite definite, characteristic disease-picture, which we designated simply with the name cachexia strumipriva. This appeared in its completely distinct form only in those patients from whom we had removed the whole thyroid gland; with no more than transitory signs, on the other hand, where all goiter tissue had supposedly been removed, but where in point of fact a piece had remained behind, which grew larger.

"Isolated observations on the connection of cretinoid disturbances with changes in the thyroid gland had already been made by early investigators.

"At the time (April 1883) when, in Berlin, I described cachexia strumipriva as the *constant* result of total excision, on the ground of numerous observations, and warned against such excision because it always leads to consequences displaying a well-marked cretinoid character, a brilliant discourse was delivered at the same congress by a first-rate surgeon on the advantages and technique of total excision.

"Further corroborative information on the nature and conduct of the new disease soon followed my contribution . . . At a famous meeting of the Clinical Society in London (November 23, 1883) Felix Semon referred to my work and mentioned a confirmatory case, following total excision by Lister; and Ord read a letter I had written to him on the etiology of the disease and the connection of myxedema with cachexia thyreopriva.

"The impulse was thereby given for the splendid investigations of the Clinical Society Committee, which came to the conclusion that myxedema and sporadic cretinism are identical, and probably cachexia strumipriva also, and that close connections exist with endemic cretinism."*

---

*Emil Kocher as quoted in Theodore Sourkes: Nobel Prize Winners in Medicine and Physiology, 1966.

Emil Theodor Kocher, M.D.

Emil Theodor Kocher, eminent Swiss surgeon, was born in Berne in 1841. He studied there and at Berlin, London, Paris, and Vienna, where he was one of Albert Billroth's pupils. Later he returned to his native Berne to become Professor of Surgery there and subsequently Director of the Surgical Clinic, a post he held for 45 years.

Most notable of his achievements was his application of experimental and physiological principles to surgery of the thyroid gland; for that contribution he received the Nobel Prize in Medicine and Physiology in 1909.

By 1912 Kocher had to his credit 5,000 operations for goiter. While thyroid gland surgery was his specialty, recognition was also accorded him for meritorious and pioneer work in other fields: reduction of shoulder dislocations, in particular, and modifications of older methods of surgery on the stomach, lungs, gallbladder, tongue, and cranial nerves, and also for hernia.

When Kocher died in 1917 the British Medical Journal said: "The world loses its greatest surgeon."

Fatal Posttransfusional Hepatitis in Switzerland

K. STAMPFLI, M.D.*
Berne, Switzerland

In June 1965 the Committee on Plasma and Plasma Substitutes of the National Academy of Sciences and the National Research Council published a study on the incidence, mortality and prophylaxis of posttransfusion hepatitis in the United States.[1] This board of experts concluded that in the United States, an average of five cases of manifest posttransfusion hepatitis occurs for every 1,000 transfusions administered. Referring to the papers of Allen[2] and Grady[3] they estimated that 10 to 12% of such cases terminate fatally. Supposing that some six million whole blood transfusions are administered each year to about 1.8 million patients, they calculated that 30,000 cases of posttransfusion hepatitis must be expected annually in the United States, of which some 3,600 would be lethal. These figures were impressive and called for an assessment of the problem in our country, too.

Results of Survey

We studied the autopsy records of the University Departments of Pathology from Basel, Berne and Zürich for the years 1960 to 1964 inclusive. Deaths due to hepatic failure were screened out and subjected to retrospective evaluation. All cases in which the pathologists found evidence of "hepatitis," "jaundice" or "liver dystrophy" were included.

In the departments mentioned, a total of 25,730 autopsies were performed during the five-year period 1960 through 1964; 532 cases, or 2.1%, were considered to have died from hepatic failure. From the clinical history and the complete pathological findings it was possible to divide these 532 cases into the subgroups summarized in Table 1.

Discussion

The statistical analysis of these results and the study of the individual case histories published in detail elsewhere[28] yield the following picture:

---

* Department of Pathology, Universities of Basel, Berne and Zürich, and Central Laboratory of the Swiss Red Cross Blood Transfusion Service, Berne, Switzerland.

Statistical Significance

The average incidence of fatal posttransfusion hepatitis in the autopsy material of the three departments participating in the study was 0.12%. Assuming a Poisson distribution* to be valid, we obtain a 95% confidence interval of 0.08-0.16%. In this calculation, all cases in which a connection with the transfusions administered remained a possibility only are included. The regional differences—0.14% in Basel, 0.12% in Berne and 0.10% in Zürich — are irrelevant. The statistical evaluation of these figures by means of the Chi-square test reveals no differences of the 5% level.

It is hardly justified to accept these results as being generally valid for Switzerland without further scrutiny. It may reasonably be supposed that hepatic failure is more frequent among deaths coming to autopsy than among deaths not subjected to post-mortem examination. Also, the proportion of autopsies relative to fatal deaths shows considerable regional differences. Whereas only 7.6% of all registered deaths in the Berne area came to autopsy in the period under study, the percentages in Zürich and Basel were 27 and 52, respectively. During 1960-1964, a total of 58,434 autopsies were performed in the department of pathology and forensic medicine throughout Switzerland, equalling 22% of the 268,821 deaths registered in the country during the same period. If we apply the mean mortality rate of 0.12% calculated as previously stated to the total number of autopsies performed in Switzerland during 1960-64, we may estimate it to have included some 70 cases of posttransfusion hepatitis, or an average of 14 cases a year. If, furthermore, we base our assessment on an upper limit to the mortality figures on the assumption that the incidence of posttransfusion hepatitis was equally high among autopsied and non-autopsied deaths, we arrive at an estimated 320 deaths from posttransfusion hepatitis in Switzerland during the five-year period 1960-64. During the same period the Swiss Red Cross Blood Transfusion Service delivered 702,436 units of whole blood to hospitals and physicians throughout Switzerland. Simultaneously, 91,734 donations of fresh whole blood were arranged for. The Central Laboratory provided 94,053 units of single-donor dried plasma and 15,293 units of two-donor fraction I preparation (fibrinogen, antihemophilic globulin). As judged from the total of these figures, the risk of contracting a fatal posttransfusion hepatitis amounts to between 1:2800 and 1:12.900 per unit administered. Supposing — as did the American Committee — that the average patient receives three units of whole blood or blood products, the mortality risk per treatment lies between 1:900 and 1:4300.

TABLE I

Among 532 cases of fatal hepatic failure, we find 74 cases of viral hepatitis without any history of blood transfusion, 21 cases of probable posttransfusion hepatitis and a further 10 cases in which that complication was considered possible.

Hepatic failure with cirrhosis or dystrophy, due to:		
—chronic alcoholism	208	(39.1%)
—further toxic agents	22	(4.1%)
Hepatic failure with occlusive jaundice, due to:		
—biliary tract inflammation	52	(9.8%)
—malignancy	101	(19.0%)
—echinococcus alveolaris	4	(0.7%)
Hepatic failure with inflammation, due to:		
—Weil's disease	2	(0.4%)
—epidemic viral hepatitis	74	(13.9%)
—posttransfusion hepatitis	31	(5.8%)
Hepatic failure with cirrhosis or dystrophy of unknown origin	38	(7.2%)
	532	(100.0%)

Incidence of Fatal Posttransfusion Hepatitis

As a check on the validity of these calculations, we may base our estimate of the incidence of fatal posttransfusion hepatitis on the findings pertaining to the town of Basel, in which 6,232 of 11,953 deaths, or 52% were autopsied. An estimate of the minimum incidence is obtained as follows: Assuming no deaths from posttransfusion hepatitis to have occurred in the group not examined post mortem and including only "probable" cases, we have 10 cases out of 11,953 deaths, or a mortality of 0.08%. The maximum incidence may be estimated by assuming the incidence of posttransfusion hepatitis to have been equally high in the autopsied and non-autopsied groups and including the "possible" cases too. This yields 25 cases out of 11,953 deaths, or a mortality rate of 0.21%. Now a total of 88,367 units (83,093 of whole blood, 3,501 of dried plasma and 1,773 of fraction I preparations) were provided by the regional blood banks during the period under study. In other words, the risk of contracting a fatal posttransfusion hepatitis was between 1:3500 and 1:8500 per unit of blood and blood products. If we assume again that the average patient received three units, the mortality risk per treatment lies between 1:1200 and 1:2800. As will be recalled, the corresponding estimate obtained by extrapolation of the results from all three cities to the whole Country were 1:900 and 1:4300.

For the reasons specified, the data from the town of Basel are probably more precise. If they are extrapolated to yield a nation-wide estimate, the following results are obtained: In Switzerland 268,821 deaths were recorded from 1960-1964. A mortality rate from posttransfusion hepatitis of 0.08-0.21% thus equals between 43 and 113 deaths annually. Let us compare this estimate to that arrived at by the American Committee: During 1960-1964, a total of 8,786,000 deaths were recorded in the United States, or 32 times the figure for Switzerland. If the data obtained for Basel are extrapolated to the United States, we arrive at between 1,400 and 3,600 annual deaths from posttransfusion hepatitis. The United States estimate was 3,600 deaths a year, which agrees remarkably well with the upper mortality limit calculated for Switzerland.

As previously mentioned, we estimated the mortality risk per unit of whole blood or the blood products specified to lie between 1:3500 and 1:8500, as judged from the data obtained for the town of Basel. According to Gsell[4] a lethality rate of 10 to 12% would be too high; so we may postulate the lethality to equal 5% for the calculation to follow. With a mean mortality risk of 1:5000, we may estimate that one case of clinically manifest posttransfusion hepatitis will occur for each 250 units administered. This figure agrees with the American rate estimated to be 1:200 and also with the morbidity figure of 0.2 to 0.5% per transfusion previously arrived at for Switzerland by Hässig[5] and Dubs.[6]

Relation to Preexisting Disease

From the study of the individual case histories published in detail elsewhere,[28] the impression emerges that fatal posttransfusion hepatitis frequently occurs as a complication

TABLE 2

Autopsies—Deaths—Transfusions—Hepatitis

probable	2 } 4	11 } 15	8 } 12
possible	2	4	4

of severe preexisting disease. Elderly patients are especially prone to contract it. Among our 21 cases with "probable" posttransfusion hepatitis, only one was less than 45 years old; among the 10 cases of "possible" posttransfusion hepatitis, a single patient was younger than 57. Thirteen patients with "probable" posttransfusion hepatitis died from acute or subacute liver dystrophy; in another four, the pathological diagnosis was subacute or acute hepatitis. Two patients suffered from postnecrotic cirrhosis of the liver. For the 10 cases of "possible" posttransfusion hepatitis, liver dystrophy and hepatic cirrhosis were recorded in five patients each. Among the patients with "probable" posttransfusion hepatitis, six out of 21 suffered from malignant disease, four from complicating diabetes mellitus and two from toxic liver damage due to alcohol or carbon tetrachloride. Among the 10 patients with "possible" posttransfusion hepatitis, we encountered one case each of carcinoma and chronic lymphatic leukemia, two cases of hepatic damage due to chronic alcoholism and two cases possibly complicated by drug-induced liver damage. In five patients with "probable" posttransfusion hepatitis, dried plasma or fibrinogen must be considered as a source of infection besides whole blood; two out of 10 cases of "possible" posttransfusion hepatitis also belong to this category.

Our case records[28] are too few to permit final conclusions to be drawn as to the kind of preexisting disease especially susceptible to fatal posttransfusion hepatitis. However, they appear to confirm the impression recorded by other authors[2,7-11] that increasing age, preexisting liver damage or malignant disease increases the risk of a fatal course of posttransfusion hepatitis.

Additional information on the relationship between preexisting disease and the course of posttransfusion hepatitis may be obtained from a number of reports analyzing the case histories of patients with this complication.[5,6,7,12-27] The 19 papers studied by us contain 209 cases of posttransfusion hepatitis, 45 of which—or 21.5%—terminated fatally. Of the total number of patients, only 35 were less than 30 years old when afflicted with the sequelae of transfusion, the remaining 174 patients belonging to the higher age group. Among all patients, 54 suffered from preexisting gastrointestinal disease, 28 of these from an ulcer of the stomach or duodenum. Malignancy was present in 29 patients and 11 suffered from biliary or pancreatic disease. In nine patients, preexisting liver damage was recorded, due either to chronic alcoholism (two cases), previous epidemic viral hepatitits (two cases), or to morphine addiction, carbon tetrachloride poisoning, sequelae of hepatic coma or preeclampsia. Seventeeen female patients were pregnant or had suffered an abortion. Five cases were complicated by diabetes mellitus. We consider it remarkable that in patients with hematological disease such as leukemia or pancytopenia, requiring multiple transfusions, the risk of contracting posttransfusion hepatitis appears to be small. Among the 209 case histories found in the literature, there were only two instances of chronic leukemia.

Conclusions

From the study presented, we must conclude that the administration of a single unit of whole blood or dried plasma carries a mortality risk from posttransfusion hepatitis alone about equalling that of childbirth, or that of everyday surgical interventions such as herniotomy, tonsillectomy, or the removal of a non-perforated appendix. Despite the immense amount of labour devoted to the prevention of posttransfusion hepatitis, prophylactic methods of proven value are not yet available. For this reason, every transfusion of whole blood, dried plasma or fraction-I-preparations obliges the physician responsible for their administration to weigh the expected benefit carefully against the damage which such therapeutic measures may cause.

Among a total of 25,730 autopsies performed at the Departments of Pathology in Basel, Berne and Zürich in the five-year period 1960-1964, hepatic failure was the cause of death in 532 cases (2.1%). Within this group we found 74 cases of viral hepatitis without a history of blood transfusions, 21 cases of "probable" and 10 cases of "possible" posttransfusion hepatitis. From these figures a mean mortality rate of 0.12% for posttransfusion hepatitis may be deduced. On the basis of additional statistical data, collected mainly in Basel where more than 50% of all deaths came to autopsy, the mortality risk per treatment with an average of three units of blood was calculated to range from 1:1000 to 1:4000. From the evaluation of individual case histories it is concluded that in the majority of patients who succumbed to posttransfusion hepatitis, there was evidence of severe underlying disease, notably preexisting liver damage, gastrointestinal disease, or malignancy. This conclusion agrees with other reports in the literature.

Cervical Syndrome

"Cervical syndrome" is a nonspecific term coined to include most of the other syndromes concerned with the head, neck, shoulders, and arms. It is caused by irritation of the cervical nerve roots, the fifth and sixth being most frequently involved, and occasionally of the cervical sympathetic chain.

Clinical features consist of sensory, motor, and trophic changes that occur in any segmental distribution. Areas of pain, localized deep tenderness, and muscle spasm are usually present and result in variable degrees of limitation of neck movement. The pain may be reflexly referred to visceral and somatic structures that have the same segmental nerve root supply, or it may arise from lesions of the cervical spinal cord and of the brain, in which case it follows no definite nerve root or segmental pattern. Irritation of the cervical sympathetic nerves may give rise reflexly to dilatation of a pupil, loss of balance, circulatory changes, palpitation, or nausea.

The etiology in a large percentage of cases is traumatic, whiplash injuries being a common cause. Most injuries result in a sprain of ligamentous or capsular structures, subluxations, anteroposterior narrowing of the inter-vertebral canals, and subsequent nerve root irritation. Roentgenograms should include oblique views for delineation of foramina.

Therapy depends upon the character and locus of involvement. Diathermy followed by traction usually affords a marked degree of symptomatic relief. Other forms of heat are often helpful. Cortisone given orally may aid in some instances. Calcareous deposits in the supraspinatus or other tendons may respond to hydrocortisone-procaine injections or may require deep x-ray therapy.

Remedies for Epilepsy

In cases of epilepsy, it is a good plan to eat a bear's testes, or those of a wild boar, with mares' milk or water; or else to drink a wild boar's urine with honey and vinegar, that being the best which has been left to dry in the bladder. The testes, also, of swine are prescribed, dried and beaten up in sow's milk, the patient abstaining from wine some days before and after taking the mixture. The secundines, also, of a she-ass are recommended, more particularly when it is a male that has been foaled: placed beneath the nostrils of the patient, when the fits are likely to come on, this substance will effectually repel them.*

Prophylaxis of Posttransfusion Hepatitis

A. HÄSSIG, M.D.*
Berne, Switzerland

From a recent epidemiological survey on the mortality of posttransfusion hepatitis in Switzerland, Stampfli[1] was led to the grave conclusion that the administration of a single unit of blood or plasma carries a mortality risk due to hepatitis alone which equals that of childbirth. This finding demands our fullest attention and sadly documents the limited success of all prophylactic methods which have so far been designed to suppress this serious complication of blood transfusions. We think it appropriate, therefore, to review the labour devoted to that problem in the past by the Swiss Red Cross Blood Transfusion Service, to define present policies and, if possible, to formulate some guidelines for the future.

In 1949 the newly founded Central Laboratory of the Transfusion Service initiated the production of dried plasma in Switzerland. An intensive study of the problems of hepatitis transmission became mandatory almost at once. To begin with, the plasma from 20 to 30 whole blood donations was pooled to batches of six liters. Follow-up studies[2] revealed the incidence of hepatitis among the recipients of this preparation to be 2.2% relative to the number of units administered. American reports prompted us to subject the plasma to ultraviolet irradiation prior to lyophilization. Technical reasons necessitated a simultaneous increase of the batch size to 20 liters, or 50 to 70 blood donations. The effects of the irradiation were not spectacular. The incidence of hepatitis among the recipients of irradiated dried plasma remained at 1.1% relative to the number of units administered.[3] It was manifestly indefensible to continue the distribution of such a preparation to the medical profession.

At the same time, however, several serologists fortunately reported that plasma containing only agglutinating anti-A- and anti-B-antibodies could be administered to recipients with these blood groups without any risk. Hemolytic transfusion reactions occurred only when the anti-A- and anti-B-antibodies contained in the donor plasma activated complement, thus becoming active as isohemolysins.[4] These observations recorded during transfusion of blood group O to group A or B recipients and concerning the different effects of hemolyzing and non-hemolyzing blood-group antibodies furnished the basis for the production of single-donor dried plasma, which can be administered irrespective of the recipient's blood group. From 1955 onward, the Swiss Red Cross Transfusion Service has produced only single-donor dried plasma which is tested solely for the absence of isohemolysins, whereas no consideration is given to the isoagglutinin titer.[5] This preparation has proved safe as to hemolytic reactions. The risk of hepatitis transmission equals that of whole blood. It established itself rapidly and is still frequently used.

---

*From the Central Laboratory of the Swiss Red Cross Blood Transfusion Service in Berne, Switzerland.

Fractionation

The fractionation of plasma to albumin and γ-globulin by means of the alcohol technique developed by Cohn was initiated soon after the production of dried plasma. As to the risk of hepatitis, albumin was already unsurpassed at that time, since it could be made hepatitis-proof by pasteurization at 60°C for 10 hours. Thus it was evidently desirable to evolve methods permitting a similar treatment of plasma. The problem was the selective removal of the heat-labile globulins. It was successfully solved in 1954 by Nitschman and Kistler[6] by total desalting of plasma with ion exchange resins. The "pasteurized plasma protein solution" consisting of albumin and the heatstable globulins was thus inaugurated, gained favor rapidly and proved to be hepatitis-proof. In the meantime, the laborious original version of Cohn's alcohol fractionation method was simplified and made less costly.[7] In order to isolate the γ-globulin contained in the original pasteurized plasma protein solution we abandoned the total desalting procedure in 1958. Pasteurized plasma protein solution was replaced by a 4% albumin solution which was introduced as "pasteurized plasma protein solution II". This preparation has largely supplanted dried plasma and was subsequently introduced in many countries under the general name of pasteurized plasma protein fraction.

In 1957 the basic concept behind the preparation of single-donor dried plasma was applied to that of fraction I.[8] The fractionation procedure was transferred from the pool to the individual bottle. In this way, a fraction-I preparation originating from two donors only was obtained, which is very effective in fibrinogen deficiency states and especially in patients with type A hemophilia. The risk of hepatitis transmission equals that incurred with two units of whole blood. In hemophiliacs it has proved to be surprisingly low; of 90 hemophiliacs who have received some 4,000 units of this preparation over the years, a single patient has suffered one minor episode of hepatitis. More recently we have replaced this two-donor antihemolytic factor preparation by a more active concentrate which is obtained by cryoprecipitation of plasma from eight donors. This antihemolytic factor concentrate, which is based on the procedure developed by Pool, is also lyophilized and thus suitable for prolonged storage.

Screening of Donor

All approaches designed to pick out the carriers of the virus and to exclude them as donors have been exploited to the full. From 1952 on, all donors with a history of infectious hepatitis have been excluded as donors of whole blood, plasma and fraction-I preparations, irrespective of the silent interval following their jaundice. Their plasma is employed for the production of albumin and γ-globulin.

Over the years we have tested all methods which might detect virus carriers by biochemical signs of liver dysfunction. The bilirubin level and the various serum lability tests proved unsuitable for the detection of anicteric hepatitis, the falsely positive and negative results being much too frequent. At one time we hoped to achieve better results by the systematic screening of the serum transaminase levels, especially that of glutamic pyruvic transaminase.[9] It is generally accepted that this enzyme is a valid indicator of subclinical liver damage. Unfortunately, results obtained in the Netherlands 10 suggest that the transaminase screening is of scant value for the prophylaxis of posttransfusion hepatitis. Apparently, contact carriers of the hepatitis virus without clinical or biochemical signs of disease are a more important source of infection than was hitherto assumed. Nevertheless, we have retained the transaminase screening, since it does undoubtedly detect liver damage in the early stage among the donors, who may then receive adequate treatment. The glutamic oxaloacetic-transaminase screening test developed by Rencher and Beeler[11] has proved to be simple, cheap and suitable for mass screening. If the reaction is dubious or positive, we determine the glutamic oxaloacetic-transaminase and glutamic pyruvic transaminase activities quantitatively. Blood showing activities in excess of 20 I.U. is reserved for plasma fractionation. Donors with glutamic oxaloacetic-transaminase and/or glutamic pyruvic transaminase activities exceeding 40 I.U. are referred to their family physician for further examination and treatment.

Conclusions

Altogether, then, the results of prophylactic measures designed to minimize the risk of posttransfusion hepatitis remain disappointing. For this reason, every physician who intends to treat a patient with whole blood, plasma or fraction-I preparations must weigh the expected benefits most carefully against the possible damage. Furthermore, since a fatal outcome of posttransfusion hepatitis is nearly always associated with severe underlying disease, especially preexisting liver damage, gastrointestinal afflictions or malignancy, it becomes mandatory to evaluate the prophylactic effects of repeated large doses of γ-globulin in high-risk patients belonging to these categories. If recent reports suggesting a limited value of such measures are confirmed by further studies, an attempt should be made to reduce the risk of posttransfusion hepatitis in high-risk patients by the exclusive use of washed erythrocytes.

Anger as Therapy for Rheumatoid Arthritis

The great physician Rhazes was summoned to Transoxiana to attend the Amir Mansur, who was suffering from a rheumatic affection of the joints which baffled all his medical attendants. On arriving at the Oxus, Rhazes was so much alarmed at its size and the small and fragile appearance of the boat in which he was invited to embark that he declined to proceed further, until the King's messengers bound him hand and foot, threw him into the boat, and carried him across by force.

On reaching Bukhara he tried various methods of treatment on the Amir without success. Finally he said to him, "Tomorrow I shall try a new treatment, but it will cost you the best horse and the best mule in your stables." The Amir agreed and placed the animals at his disposal. Next day Rhazes brought the Amir to a hot bath outside the city, tied up the horse and the mule, saddled and bridled, outside, and entered the hot room of the bath alone with his patient, to whom he administered douches of hot water and a draught which he had prepared "till such time as the humours in his joints were matured. Then he went out, put on his clothes, and, taking a knife in his hand, came in, and stood for a while reviling the Amir, saying, 'Thou didst order me to be bound and cast into the boat, and didst conspire against my life. If I do not destroy thee as a punishment for this, my name is not Muhammad ibn Zakariyya!' The Amir was furious, and, partly from anger, partly from fear, sprang to his feet." Rhazes at once fled from the bath to where his servant was awaiting him outside with the horse and the mule, rode off at full gallop, and did not pause in his flight until he had crossed the Oxus and reached Merv, whence he wrote to the Amir as follows:

"May the life of the King be prolonged in health and authority! Agreeably to my undertaking I treated you to the best of my ability. There was, however, a deficiency in the natural caloric, and this treatment would have been unduly protracted, so I abandoned it in favour of psychotherapeusis, and, when the peccant humours had undergone sufficient coction in the bath, I deliberately provoked you in order to increase the natural caloric, which thus gained sufficient strength to dissolve the already softened humours. But henceforth it is inexpedient that we should meet."

The Amir, having recovered from his anger, was delighted to find himself restored to health and freedom of movement, and caused search to be made everywhere for the physician, but in vain, until on the seventh day his servant returned with the horse and mule and the letter cited above. As Rhazes persisted in his resolution not to return, the Amir rewarded him with a robe of honour, a cloak, a turban, arms, a male and female slave, and a horse fully caparisoned, and further assigned to him a yearly pension of 200 gold dinars and 200 ass-loads of corn.*

In-Vivo Studies of Cellular Proliferation*

The Use of Mitotic Figures

H. P. WAGNER, M.D.†
H. COTTIER, M.D.‡
Berne, Switzerland

THE QUANTITATIVE EVALUATION of cellular proliferation, differentiation, transformation, migration and death promises to open up new perspectives in physiology and pathology. Vast efforts have been made in the past, particularly during the last decade, to improve and refine methods for investigation of the above mentioned processes, both *in vitro* and *in vivo*. It has been clearly realized that although many problems of cellular kinetics may be approached by studying *in-vitro* systems or by working with experimental animals, it will undoubtedly be necessary to do *in-vivo* studies on human beings if a precise knowledge of such features as the time parameters guiding cellular proliferation in man is one's objective.[8,16] Since information of this kind appears highly desirable in hematology, oncology, radiology, immunology and many other specialties, it may be appropriate to discuss briefly to what extent *in-vivo* studies of cellular kinetics are practicable in man.

The development of high resolution autoradiography[1,3,11] and the introduction of specific deoxyribonucleic acid precursors such as tritiated thymidine (T^3H)[4,17,18] have led to such a rapid increase in experimental means that we have chosen to limit this discussion to methods based on the evaluation of mitotic figures. This limitation will, of course, center the present consideration on techniques apt to investigate the proliferative characteristics of cells within a given cell line or cell system, disregarding other important aspects of cellular kinetics such as migration, cell death, etc.

Definition and Description of a Cell System

Before making an attempt to characterize the importance of mitotic figures for *in-vivo* studies of cell proliferation within a particular cell line or cell system, a short description of a hypothetical and greatly simplified cell sys-

tem will be given to illustrate some of the methodological limitations discussed later (Figure 1).

There is no generally accepted definition of the term "cell system" or "cell line." Obviously a cell system or cell line within a living organism represents a functional unit satisfying clearly defined needs, at least under physiological conditions.

The Cell Compartments

A cell system may be divided into several compartments, each compartment containing a class of cells distinguished from other cells in the system. The distinction may be based on function, morphology and location.[12] If functional criteria are used to subdivide a proliferative cell system the following typical compartments may be distinguished:

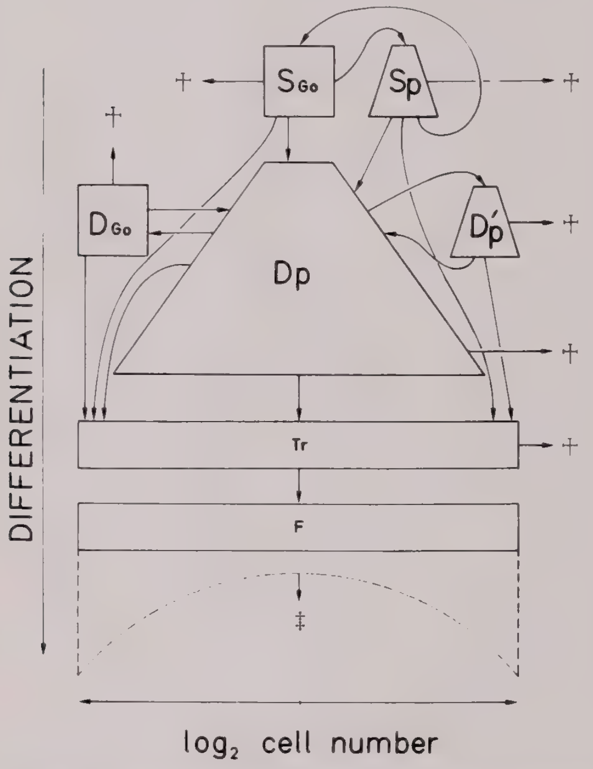

Fig. 1—Hypothetical scheme of a proliferating cell system. S_{G_0}: G_0 compartment of stem cells. S_p: generative compartment of stem cells. D_{G_0}: G_0 compartment of differentiating and proliferating cells. D_p: generative compartment of differentiating and proliferating cells. D_p': generative compartment of partially differentiated cells which do not continue to differentiate during proliferation. T_r: transitional compartment. F: functional compartment. ‡: functional compartment if cell death occurs at random. †: cell loss due to cell death.

—G_0 compartment(s) consisting of cells which do not actually proliferate but retain their ability to do so if stimulated.

—generative compartment(s) consisting of cells which may be in at least four different stages of the cell cycle:

G_1: postmitotic = presynthetic phase.

S: deoxyribonucleic acid synthesis phase usually equated with the period during which cells incorporate specific deoxyribonucleic acid-precursors.

G_2: postsynthetic = premitotic phase.

M: mitotic phase.

—the transitional compartment formed by cells in transition from proliferation to maturity.

—the functional compartment with functional (= mature) cells.

The end cell compartment comprises all cells in a cell system which have lost the ability to divide.

It should be clearly realized that compartments defined by functional criteria are not necessarily identical with those defined morphologically: thus G_0 cells and cells of a generative compartment may not be distinguished on morphologic grounds; and cells of one morphologically defined compartment may belong to two or more generative compartments.

Parameters of Compartments

In order to describe a cell system containing several compartments, information on the following parameters is needed:[12]—the relative or absolute size of the compartments,—the transit times (=time elapsed between entering and leaving a compartment),—the fluxes (=number of cells passing a particular compartment boundary in a particular direction per unit of time) and—the birth and death rates (=numbers of cells dividing or dying per cell number and unit of time in a given compartment).

Since not all cells do behave in exactly the same way and since at least some of the parameters enumerated can be expressed only in the form of distributions rather than absolute values, a complete description of a cell system is very difficult. The question therefore arises, whether at least one or the other of the parameters just enumerated were amenable to assessment in the intact human organism. If, within a given cell system, certain proliferative characteristics remain more or less constant from individual to individual, an accurate description of a cell system might gradually be realized. With this admittedly very optimistic view in mind, the relative reliability of a few methods used to investigate the proliferative pattern of a given cell line will now be discussed.

Mitotic Figures and the Evaluation of Cellular Proliferation

The relative number of mitotic figures has long been taken as an indicator of the proliferative activity within a given cell class. As discussed below, a combined determination of the mitotic index and the mitotic time formed the basis for many classical investigations of cellular proliferation (reviewed by Leblond and Walker, 1956). These methods do not require the *in-vivo* administration of radioactive materials for labeling purposes nor do they necessitate repeated sampling over prolonged periods of time.

The introduction of autoradiography and the availability of T^3H made it possible to investigate more accurately not only cell proliferation but also cell differentiation, maturation and death.[3] Although cell proliferation could now be studied without referring to mitotic figures, it soon became apparent that accurate measurements of cell proliferation *in vivo* still required the presence of mitotic figures.

Cellular Proliferation without Radioactive Compounds

Determination of the "Mitotic Index"

The mitotic index (MI), the fraction of a cell population in mitosis, is a function of the duration of mitosis (T_m) and of the average time (T) which the cells spend in the population studied: $MI = f\ (T_m/T)$ (Killmann, Cronkite, Fliedner, Bond and Brecher, 1963).

Combined determinations of mitotic indices and mitotic time have therefore been used to compute turnover times (= time taken for the replacement of a number of cells equal to that in the whole population: Leblond and Walker, 1956) and/or generation times (T_g = average duration from completion of one mitosis to completion of the following mitosis) by transforming the equation above to $T = f\ (T_m/MI)$.

One of the *major limitations* in the use of mitotic indices is related to the fact that it may be extremely difficult to assign dividing cells to a given population of cells in interphase (Leblond, 1959). This may be due to a lack of cytoplasmatic differentiation leading to an inability to establish a relation between cells in mitosis and cells in interphase. If cytoplasmic differentiation is adequate, other difficulties arise. As mentioned earlier, functional compartments are often not identical with morphologically defined cell classes within a given proliferating cell system. Furthermore, if a generative and a G_0 or end cell compartment cannot be differentiated morphologically, it will not be possible to relate the number of mitotic figures counted to the so-called growth fraction of the cell population studied, and one is obliged to determine a mitotic index for a morphologically but not functionally homogenous class of cells. This is a serious limitation since undetectable changes in the composition of such a class of cells might occur.

Even if all cells within a morphologically determined compartment do proliferate, the exact position of mitosis with respect to the morphologically defined compartment boundaries has to be known if one desires to com-

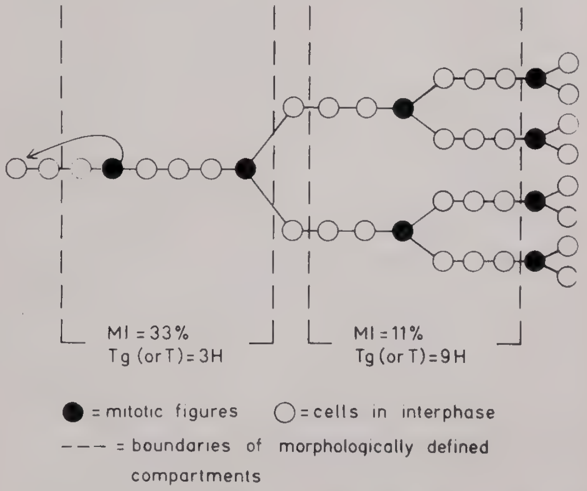

Fig. 2—The influence of the position of mitosis with respect to morphologic compartment boundaries on mitotic index determinations and computations based thereon. Assumed T_g = four hours, assumed turnover time (T) for each compartment = six hours.

pute turnover times from mitotic index and mitotic time data (Figure 2).[6]

Several other *factors may bias mitotic index* determinations: —diurnal variations of the proliferative activity and other disturbances of the steady state, —variability in the ratio of proliferating to nonproliferating cells due to sampling procedures, —loss of mitotic figures due to inadequate staining techniques, difficulties in recognizing early pro- and/or late telophases, preferential destruction and/or uneven distribution of mitotic figures on smear or squash preparations, —intracompartmental cell death.

This brief enumeration of biasing factors demonstrates well how limited the reliability of mitotic index data is for an evaluation of cellular proliferation *in vivo*. As discussed below, classic mitotic time calculations are also based on mitotic index determinations. It is therefore clearly seen that turnover and/or generation time computations from classic mitotic index and mitotic time data can be of only limited value.

Determination of the "Mitotic Time"

Mitotic time is the duration from the first recognizable prophase to the latest recognizable telophase.

Several classic methods have been used to determine mitotic time *in vivo* (Leblond, 1959; Dustin, 1959). The majority of these are based on at least two mitotic index determinations, one before and one after intervening, by chemical (e.g., colcemide) or physical means (x-rays), with the progression of proliferating cells through G_2 and M. All restrictions in the use of mitotic indices therefore apply also to classic mitotic time determinations. Incomplete blocking of cellular progression, toxic effects of the blocking agents used and inadequate timing of the second sample with respect to the administration of the blocking agent may also limit the validity of conventional mitotic time assessments.

Cellular Proliferation in vivo with T^3H

The methods to be discussed here are all based on the fact that mitotic figures represent a morphologically well-defined, short-lasting stage of the cell cycle characterized by the absence of deoxyribonucleic acid synthesis, thus permitting observation of the progression of labeled cells, after a single intravenous injection of T^3H, through this "window." The methods described require the presence of adequate numbers of mitotic figures, *in-vivo* injection of T^3H and serial sampling thereafter. They all depend on the assumptions made whenever high-resolution autoradiography and T^3H are used.[3]

Mitotic Labeling Index

This method was first described by Quastler and Sherman in 1959. Due to its short availability time of 15 to 20 minutes, intravenously injected T^3H will pulse-label all cells synthesizing deoxyribonucleic acid provided these cells dispose of the necessary enzymatic equipment to incorporate T^3H.[14] In a population of proliferating cells the cells in S which were marked by T^3H will leave S, progress through G_2 and enter M. Unlabeled mitotic figures will then be replaced by labeled ones and the mitotic labeling index, that is the relative number of mitotic figures labeled, will rise, form a "plateau" and start to fall again as soon as unlabeled cells which were in G_1 at the time of T^3H injection enter into mitosis. Theoretically the mitotic labeling index should then fall to zero and, later on, when the initially labeled cells divide again, it should rise to form a second "wave." As a rule, an analysis of the mitotic labeling index variation after a single injection of T^3H permits us to evaluate the duration of G_2 and S, especially if the majority of daughter cells continue to proliferate upon completion of the first division, T_g and the duration of G_1. In addition, information regarding the distribution of G_2, S and generation times of individual cells may be obtained; furthermore, it is possible to detect the presence of reutilization of labeled deoxyribonucleic acid.[20]

The results obtained by an analysis of mitotic labeling index data are not influenced by factors that bias mitotic index determinations, such as loss of mitotic figures, variations of the ratio of proliferating to nonproliferating cells, position of mitosis with respect to the morphologically defined compartment boundaries and intracompartmental cell death. They are influenced, however, by straggling (= deviation in time from a "rigorously-timed orderly progression" of cells through mitosis[9]), by disturbances of the steady state, by the difficulties arising from the inability to assign mitotic figures with minimal cytoplasmic differentiation to a given population of cells in interphase, and by the inability to clearly distinguish, morphologically, between mitotic figures belonging to cell populations with different proliferative characteristics.[15,20] Another limitation of this method is observed if a morphologically homogenous class of cells is composed of a proliferating and relatively large pool of G_0 cells: if, upon completion of mitosis, all proliferating cells enter the G_0 pool, and if, on the other hand, G_0 cells are triggered at random to enter G_1, no or only a minimal second wave will be found in the mitotic labeling index curve.

Midprophase-Midtelophase Time

Although rough estimates of mitotic time can be obtained by extrapolating the steepest slope of the initial rise of the mitotic labeling index after a single injection of T^3H, the best estimates of mitotic time *in vivo* are based on an analysis of the variation of separate pro- and telophase labeling index curves after pulse-labeling with T^3H.[2,10] From the experimentally determined mean "midprophase-midtelophase time" it is possible to compute mitotic time either graphically or mathematically. This method requires a precise morphologic definition of prophases and telophases and necessitates the existence of a rather constant ratio between the relative numbers of pro-, meta-, ana- and telophases.

Median Grain Count per Labeled Mitotic Figure

This method was first used in combination with mitotic labeling index determinations.[5,20] It is based on the observation that after a single injection of T^3H the mean or median grain count per labeled mitotic figure (MGC/LMF) varies with time in such a way that initially two peaks, representing periods of maximal deoxyribonucleic synthesis rate during the S phase, appear. As a rule, the second peak is only half as high as the first, indicating that daughter cells with half the amount of deoxyribonucleic label have recycled and are dividing. The time interval between the two peaks of the MGC/LMF curve can therefore be taken as a measure of T_g.

Besides being biased by the limiting factors enumerated while referring to the mitotic labeling index method, this technique is influenced by the autoradiographic efficiency[3] and by the fact that grain counts, particularly if more than 30 to 50 grains per cell are seen, become inaccurate. It is evident that this method will not furnish any information on the duration of single cell cycle phases. It will, however, permit one to evaluate roughly the rate of T^3H-incorporation during the S phase.

Conclusions and Summary

It has been shown that the more laborious methods of cell proliferation *in vivo*, developed during the last decade, necessitating the evaluation of mitotic figures, the *in-vivo* administration of radioactive deoxyribonucleic precursors and serial sampling thereafter are more reliable than any method based on mitotic index determinations. In particular, a combination of serial mitotic labeling index (MLI) and mean or median grain count per labeled mitotic figure (MGC/LMF) determinations after a single T^3H injection has proved to be a powerful tool in the assessment of cellular proliferation.

These methods, obviously, cannot be used for clinical purposes, except perhaps for a few, highly selected cases where such a study may be justified as long as one can hope to find, within a well-defined cell system, a certain constancy of essential proliferative characteristics from individual to individual.

If such a constancy does exist, it should be possible to gradually accumulate enough information to provide a more rational basis for essential clinical topics such as cancer therapy and immunosuppression. The painstaking search for mitotic figures, therefore, has not become obsolete as yet; on the contrary, it appears more rewarding today than ever before.

Clinical Notes of Razi*

The Treatment of Pyelitis

"Abdullah ibn Sawda used to suffer from attacks of mixed fever, sometimes quotidian, sometimes tertian, sometimes quartan, and sometimes recurring once in six days. These attacks were preceded by a slight rigor, and micturition was very frequent. I gave it as my opinion that either these accesses of fever would turn into quartan, or that there was ulceration of the kidneys. Only a short while elapsed ere the patient passed pus in his urine. I therefore informed him that these feverish attacks would not recur, and so it was.

"The only thing which prevented me at first from giving it as my definite opinion that the patient was suffering from ulceration of the kidneys was that he had previously suffered from tertian and other mixed types of fever, and this to some extent confirmed my suspicion that this mixed fever might be from inflammatory processes which would tend to become quartan when they waxed stronger.

"Moreover the patient did not complain to me that his loins felt like a weight depending from him when he stood up; and I neglected to ask him about this. The frequent micturition also should have strengthened my suspicion of ulceration of the kidneys, but I did not know that his father suffered from weakness of the bladder and was subject to this complaint.

"So when he passed the pus I administered to him diuretics until the urine became free from pus, after which I treated him with *terra sigillata,* Boswellia thurifera, and Dragon's Blood, and his sickness departed from him, and he was completely and quickly cured in about two months. That the ulceration was slight was indicated to me by the fact that he did not complain to me at first of weight in the loins. After he had passed pus, however, I enquired of him whether he had experienced the symptom, and he replied in the affirmative. Had the ulceration been extensive, he would of his own accord have complained of this symptom. And that the pus was evacuated quickly indicated a limited ulceration. The other physicians whom he consulted, however, did not understand the case at all, even after the patient had passed pus in his urine."

In spite of several difficulties both verbal and material, which I have not yet been able to solve to my satisfaction, the general nature of this case seems fairly clear. The patient suffered from intermittent and irregular attacks of fever preceded by slight rigors, which, in a land infested with ague, were diagnosed and treated as malarial, though really septic in origin. Razi himself at first took this view, but subsequently, observing the presence of pus in the urine, diagnosed the case as one of pyelitis, and treated it accordingly with success.†

Electronic Data Processing in the Clinical Laboratory

A Routine System for Clinical Chemistry

R. RICHTERICH, M.D.*
H. EHRENGRUBER, M.D.*
Berne, Switzerland

THE NUMBER OF LABORATORY tests in clinical chemistry doubles every three to five years.[1-3] To balance this increasing work load automation and electronic data processing were introduced. Depending on the type of laboratory, between 10 and 40% of the total working time is used for clerical work. Introduction of electronic data processing should reduce this time substantially and free technicians for laboratory work proper.

A routine electronic data processing system was installed at the chemistry laboratory of the Children's Hospital in August 1967; in January 1968 it was extended to the major medical and surgical services. The system was designed not only to reduce clerical work in the laboratory, but also to facilitate interpretation of results and to eliminate any type of transcribing errors on the wards.

Description of the System

Electronic Data Processing

The Inselspital is a University hospital with approximately 1,200 beds and large outpatient departments. Seven routine clinical chemistry laboratories are distributed over the whole area, but they will be centralized in a new building within this next year. In 1967, 316,000 quantitative chemical analyses were performed.

The electronic data processing program was developed in close cooperation with the electronic data processing center at the University of Berne, located approximately one mile from the hospital laboratories. Punching of cards is done peripherally in the laboratories on two card punchers; processing of the punched cards is performed at the university center. A Bull Gamma 30 computer with 40,000 magnetic core positions, six magnetic tape stations, a card puncher and a printer are used. Processing is done daily at 5 p.m. and takes about 15 minutes for 1,000 tests.

---

*Department of Clinical Chemistry, Inselspital Berne, Switzerland.

Input Forms

Two input forms are used: a master card and a test card. The master identification card (Table 1) contains the administrative information on each patient. It is keypunched on the day the patient is admitted to the hospital. All master cards are filed alphabetically in a master card file. On discharge the master card is removed from the master card file. It can then be used for other purposes, such as the generation of a diagnostic index or for statistics.

The layout of the test result cards is shown in Table 2. A large number of individual cards for each test are prepared by gang-punching the test code into the test code columns. These cards are kept in a test code file.

Output Forms

Three types of output forms are used. On a "laboratory test list" results appear, sorted by tests. These forms are kept in the laboratory as a record. A "list of abnormal results" is prepared daily for each physician in charge of a ward, containing the results of all the tests performed on patients who had at least one abnormal result. Finally, "case record forms" are printed daily for each patient on whom analyses have been performed; these are cumulative and contain all the results for the patient. Whenever a new form arrives on the ward the old one is discarded.

62-67	Test code	Prepunched
68-73	Time of specimen receipt (emergencies only)	Added by keypunch operator
74-79	Test result	

Test Code

For test description and identification a test code was designed. It is alphanumerical* and consists of six code units. A first letter describes the type of laboratory, e.g., C for chemistry. The second and third letters state the component analyzed, e.g., GL for glucose. The fourth position is numerical and identifies the method used, e.g., 1 for a glucose oxidase/peroxidase procedure. The fifth letter states the system analyzed, e.g., P for plasma. The sixth letter is used for supplementary information, e.g., C for capillary. A detailed description of the code is given elsewhere.[4]

Laboratory Procedure

The laboratory procedure is shown in Figure 1. Specimens and request cards are received in the laboratory. The corresponding master card is drawn from the master card file. For each test required, corresponding prepunched test cards are put behind the master card. Patient information is duplicated from the master card into all the corresponding test cards. The date is punched automatically from a program card on the card punch. In this way a set of written and punched cards containing administrative information, test code and date is obtained automatically. After analysis has been performed the result is manually written on the punch card. No worksheets are prepared, but the test cards are used directly as work sheets. Before computer processing the results are keypunched into the card.

Computer Processing

The daily routine consists of four special purpose programs (Run 1 through Run 4) and two software sorting programs (Sort-1, Sort-2). In Run 1 the result cards are read and checked for certain types of errors, such as letters instead of numerals for the date of birth, impossible test codes, and completeness of information. An error list is then printed. The information on the correct cards is taken on magnetic tape. The records then are sorted according to the date of analysis and the type of test (Sort-1). This yields a sorted preliminary result tape.

---

*See Test Your Word Score Page 89.

In Run 2 the results are checked for normality in respect to age and sex of the patients. First the age of the patient is calculated from birth date and date of analysis. Then the result is compared with age-and-sex-adjusted normal values, which are stored on the "normal range tape." Slightly abnormal results are marked by one asterisk, markedly abnormal values by two asterisks. At the same time the age-and-sex-corrected normal range is entered. Each record with the new information added in Run 2 yields a record on the result tape.

Simultaneously, lists of daily results are produced for each test performed (Figure 2).

In Sort-2 the records on the result tape RB2 are sorted according to patient identification (i.e., ward, patient's number, patient's admission date), date and time of analysis. In Run 3 a list with the results of those patients who had at least one abnormal result (Figure 3) is prepared for each ward. In the same run the setup of tape RB2 is changed, giving a mutations tape.

In Run 4 the case record forms are produced. All the information on each patient is stored on the patient's tape, which is daily updated by combining information from the old tape and the mutations tape, thereby producing a new patient's tape. Every day a new case record sheet is printed which substitutes for the old one (Figure 4). Results are printed cumulatively, the new record sheet containing all the results of the preceding days on which analyses were performed. If analyses have been done on more than five days, then a new record sheet is started, on which a special comment not to delete the old sheet is printed by the computer.

Once a month the patient's tape is updated by a special program. Patients who have been discharged are taken off the patient's tape. Their results are printed on a monthly report list.

Advantages

Only a few electronic data processing systems for laboratory use have been described[3,5-9] though many are probably in some phase of study, development or trial. Most of these systems are using a computer within the laboratory or hospital area. Since this was impossible for financial reasons, we decided to try to use the computer of the university center. This has actually proven to be an advantage for the development and the routine use of electronic data processing. Available at these centers are experienced personnel not usually available within the hospital range. Today all

Fig. 4—Cumulative case record form.

the routine computer work is done by the personnel of the computer center, while development and programming is done at the hospital unit. Good cooperation between the hospital and the computer center is necessary for the successful implementation of hospital programs. It is important that electronic data processing for hospitals obtain priority.

Contrary to many other efforts in electronic data processing our approach has not been very costly. The whole project was developed by the authors within about three years' time. The planning phase lasted about two years and was used chiefly to study existing electronic data processing systems. It took about one additional year to design all the forms needed and for programming. No trial period was needed; the system proved practicable from the first day.

Reduction of Clerical Work

Previously the name of a patient used to be written two to five times per test and two to 100 times per hospital stay. Estimates in our laboratories have shown that approximately 30% of the whole time was used for clerical work. Now the name of the patient is written only once by preparing the master card on the admitting day, thus reducing the clerical work load from about 30% to about 10% of the total working time.

Elimination of Spelling Errors

Errors in the spelling of names and wards were previously quite frequent, but are now eliminated completely because all identification data are reproduced from a master identification card.

Reduction of the Work Load on the Ward

In most conventional systems and even in some electronic data processing systems the results are given to the ward on a type of form containing the results of one day only and are then transcribed manually on a chronological and cumulative laboratory report sheet. Depending on the hospital this transcription is done by nurses, house officers or interns.

Elimination of Transcription Errors on the Wards

It must be assumed that errors occurred at the transcription stage on wards. By using computer-printed output forms this type of error has become impossible.

Simplification of Record Keeping

In conventional systems, records of laboratory reports are kept in books or files. These systems are space-consuming and make it difficult to locate old reports. The monthly report system permits the storage of results in minimal space; in addition, the magnetic tape-stored information can be used directly for research.

Automatic Production of Laboratory Statistics

The storage of laboratory results permits an automatic production of statistics. Not only the total number of tests, but also the number of tests per ward, per age group, per day, month or year, and the number of emergency tests per ward or per disease group can easily be computed.

Improvement of Quality Control

A few attempts have so far been made to improve quality control of the results by the use of a computer.[10] We are at present engaged in incorporating quality control in our system.

Improvement of Normal Ranges

It is probable that the large number of data accumulated during the years will permit a better definition of normal ranges of laboratory results. This is probably one of the crucial areas of clinical chemistry, and we hope to use our data for this particular purpose.

Advantage to Physicians

In addition to these eight features of improvement in laboratory results and in communication of the results to the physician, particular care was taken to present the results to the physicians in a more meaningful way. This was attempted by four devices:

Comparison with Normal

Each result is compared in the computer to age-and-sex-adjusted normal values. These values are printed in the first column of the case record sheet and also in the first column of the list of abnormal results.

Abnormal Results

Abnormal results are marked. One asterisk means that a result is within the confidence limits of 0.95-0.99 and two asterisks that it is definitely abnormal and outside the 0.99 confidence limits.

Aid to Rapid Diagnosis

The daily list of abnormal results supplied to each physician in charge of a ward should enable him to see important results at one glance. These sheets do not have any permanent value but are used on only one day. They should help in rapid diagnostic and therapeutic decisions.

Case Record Form

Most published systems for electronic data processing present the results in a computer-printed form to the physician. These records are often poorly legible and not in chronological order. Care was taken to design a chronological case record form which does not differ much from the conventional form but permits easy legibility and a clear picture.

Disadvantages

The following difficulties have been experienced with the system:

Errors on Master Card

Errors on the master identification card will be perpetuated on each result card and will be stored on magnetic tape. A special correction program has to be used to correct this type of error.

Ward Identification

Difficulties were encountered in regard to the ward identification of patients. Our hospital structure has been growing over many years, and new names such as department, clinic, station, ward have been introduced indiscriminately. A clear concept of hospital organization and terminology should be obtained before electronic data processing is introduced.

Age-and-Sex-Adjusted Normal Values

The most important difficulty has been the selection of age-and-sex-adjusted normal values. In some areas, e.g., enzyme concentrations, we could rely on our own established values;[11] in other cases we had to rely on values from the literature, often obtained with slightly different methods and apparatus. It is planned to revise these normal values as soon as possible.

Conclusions and Summary

Generally, the introduction of the system has been a success. Most physicians have accepted the system without reluctance and are now considering its existence as a quite obvious and natural thing.

An electronic data processing system for clinical chemistry results is described. Processing is performed on a Bull Gamma 30 computer. Special care was taken to improve the medical significance of the results, by giving age-and-sex-adjusted normal ranges for each test, by marking abnormal results by asterisks, and by printing a daily list of abnormal results for each ward and daily cumulative case record sheets for each patient.

This is the third of a series of papers on electronic data processing in the clinical laboratory. This work has been supported by The "Schweizerischer Nationalfonds zur Förderung der wissenschaftlichen Forschung" (Projekt Nr. 3740). We would like to thank Dr. R. Hüsser, head of the computer department of the University of Berne, for his help and kind cooperation.

Children have more need of models than of critics.—Joubert

Let's be specific about Campbell's Soups... and *reducing diets*

Calorie content of Campbell's Soups

There are more than 30 million people in America who are overweight. During the next year, you probably will see more than 1,000 of them in your own practice.

One good way to help these patients is to give them a reducing diet based on ordinary eating patterns.

Campbell has prepared a sensible plan for weight control based on ordinary eating patterns. The plan consists of a patient instruction booklet and a set of menus which provide approximately 1,200 calories daily. The menus are balanced to provide the minimum daily requirements of nutrients.

To obtain a supply for your office write to:
Campbell Soup Company, Box 265, Camden, N. J. 08101

Campbell's
SOUP

No two women are quite alike...

Ovulen-21 Compack
Directions

and no other oral contraceptive is quite like Ovulen-*21*®

Each tablet contains ethynodiol diacetate 1 mg., mestranol 0.1 mg.

The progestin is distinctive, and for some women this may mean a different clinical response. The Compack® tablet dispenser is distinctive; its functional simplicity makes it virtually patient-proof. The acceptance of Ovulen-21 is distinctive... together with Ovulen®, it is more often prescribed than any other individual contraceptive product currently available.

Indication—Oral contraception.

Contraindications—Thrombophlebitis, thromboembolic disorders, cerebral apoplexy or a past history of these conditions, markedly impaired liver function, known or suspected carcinoma of the breast, known or suspected estrogen-dependent neoplasia, undiagnosed abnormal genital bleeding.

Warnings—Watch for the earliest manifestations of thrombotic disorders (thrombophlebitis, cerebrovascular disorders, pulmonary embolism, retinal thrombosis); if present or suspected discontinue the drug immediately.

British studies reported in April 1968[1,2] estimate there is a seven- to tenfold increase in mortality and morbidity due to thromboembolic diseases in women taking oral contraceptives. In these controlled retrospective studies, involving 36 reported deaths and 58 hospitalizations due to "idiopathic" thromboembolism, statistical evaluation indicated that the differences observed between users and non-users were highly significant. The conclusions reached in the studies are summarized in the table below:

Comparison of Mortality and Hospitalization Rates Due to Thromboembolic Disease in Users and Non-Users of Oral Contraceptives in Britain.

Category	Mortality Rates		Hospitalization Rates (Morbidity)
	Age 20-34	Age 35-44	Age 20-44
Users of Oral Contraceptives	1.5/100,000	3.9/100,000	47/100,000
Non-Users	0.2/100,000	0.5/100,000	5/100,000

No comparable studies are yet available in the United States. The British data, especially as they indicate the magnitude of the increased risk to the individual patient, cannot be applied directly to women in other countries in which the incidences of spontaneously occurring thromboembolic disease may differ.

Discontinue medication pending examination if there is sudden partial or complete loss of vision, or sudden onset of proptosis, diplopia or migraine. Withdraw medication if papilledema or retinal vascular lesions are found.

Since the safety of Ovulen in pregnancy has not been demonstrated, it is recommended that pregnancy be ruled out for any patient who has missed two consecutive periods before continuing the contraceptive regimen. If the patient has not adhered to the prescribed schedule the possibility of pregnancy should be considered at the first missed period.

A small fraction of the hormone agents in oral contraceptives has been identified in the milk of mothers receiving these drugs. The long-range effect to the nursing infant cannot be determined at this time.

Precautions—Pretreatment physical examination should include special reference to the breasts and pelvic organs, and a Papanicolaou smear.

Endocrine and possibly liver function tests may be affected by Ovulen. Therefore, it is recommended that such tests if abnormal be repeated after the drug has been withdrawn for two months.

Pre-existing uterine fibromyomas may increase in size under the influence of progestogen-estrogen preparations.

Because these agents may cause some degree of fluid retention, conditions which might be influenced by this factor, such as epilepsy, migraine, asthma, cardiac or renal dysfunction, require careful observation.

In breakthrough bleeding, and all irregular vaginal bleeding, consider nonfunctional causes. Adequate diagnostic measures are indicated in undiagnosed vaginal bleeding.

Carefully observe patients with a history of psychic depression and discontinue the drug if severe depression recurs.

Any possible influence of prolonged Ovulen therapy on pituitary, ovarian, adrenal, hepatic or uterine function awaits further study.

A decrease in glucose tolerance has occurred in a significant percentage of patients on oral contraceptives. The mechanism of this decrease is obscure. For this reason, diabetic patients should be observed carefully while receiving Ovulen.

Because of the effects of estrogens on epiphyseal closure Ovulen should be used judiciously in young patients in whom bone growth is not complete.

The age of the patient constitutes no absolute limiting factor, although Ovulen therapy may mask the onset of the climacteric.

The pathologist should be informed of Ovulen therapy when relevant specimens are submitted.

Adverse Reactions—A statistically significant association has been shown between use of oral contraceptives and the following serious adverse reactions: thrombophlebitis, pulmonary embolism.

Although available evidence is suggestive of an association, such a relationship has been neither confirmed nor refuted for the following serious adverse reactions: cerebrovascular accidents, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.

The following adverse reactions are known to occur in patients receiving oral contraceptives: nausea, vomiting, gastrointestinal symptoms (such as abdominal cramps and bloating), breakthrough bleeding, spotting, change in menstrual flow, amenorrhea during and after treatment, edema, chloasma or melasma, breast changes (tenderness, enlargement, secretion), change in weight, changes in cervical erosion and cervical secretions, suppression of lactation when given immediately post partum, cholestatic jaundice, migraine, allergic rash, rise in blood pressure in susceptible individuals, mental depression.

Although the following adverse reactions have been reported in users of oral contraceptives, an association has been neither confirmed nor refuted: anovulation post treatment, premenstrual-like syndrome, changes in libido, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, fatigue, backache, hirsutism, loss of scalp hair, erythema multiforme and nodosum, hemorrhagic eruption, itching.

The following laboratory results may be altered by oral contraceptives: hepatic function: increased sulfobromophthalein and other tests; coagulation tests: increase in prothrombin, Factors VII, VIII, IX and X; thyroid function: increase in PBI and butanol extractable protein bound iodine, and decrease in T^3 uptake values; metyrapone test; pregnanediol determination.

"Breathing's a snap again," he said gingerly.
(COMPLIMENTS OF DIMETAPP)

Help clear up that miserable stuffed-up feeling with Dimetapp. Each hard-working Extentab brings welcome relief from the stuffiness, drip and congestion of upper respiratory conditions for up to 10-12 hours. Yet, patients seldom experience drowsiness or overstimulation. The key to success is the Dimetapp formula: Dimetane (brompheniramine maleate)—along with phenylephrine and phenylpropanolamine, two time-tested decongestants. They get the job done . . . in a hurry.

Indications: Dimetapp is indicated for symptomatic relief of the allergic manifestations of respiratory illnesses, such as the common cold and bronchial asthma, seasonal allergies, sinusitis, rhinitis, conjunctivitis, and otitis. *Contraindications:* Hypersensitivity to antihistamines. Not recommended for use during pregnancy. *Precautions:* Until patient's response has been determined, he should be cautioned against engaging in operations requiring alertness. Administer with care to patients with cardiac or peripheral vascular diseases or hypertension. *Side Effects:* Hypersensitivity reactions including skin rashes, urticaria, hypotension and thrombocytopenia, have been reported on rare occasions. Drowsiness, lassitude, nausea, giddiness, dryness of the mouth, mydriasis, increased irritability or excitement may be encountered. *Dosage:* 1 Extentab morning and evening. *Supplied:* Bottles of 100 and 500.

Salute to Berne

Switzerland with a population only half again greater than Minnesota has five times as many medical schools. Geneva, Laussane, Zurich, Basle, and Berne as part of their universities include a medical school. The faculty of one of these has provided Minnesota Medicine with this special Berne issue. The Berne Medical School, by European standards, is not old, having been founded in 1834. Fritz de Quervain, Professor of Surgery, reviewed the distinguished history of his medical school in 1934 celebrating the centennial.* He was the magnet drawing young surgeons to Berne in the early years of this century. Among them were three Minnesotans, Carl O. Rice, George Eitel and Owen Wangensteen, who studied in Berne in the late twenties. The disease they came chiefly to see was goiter. Switzerland, and particularly Berne with its low iodine mountainous environment, was the goiter capital of the world at that time. The pervasive use of iodized salt, begun in America after the work of David Marine, reached the Swiss plateau in the thirties and ended Berne's goitrous reign.

The editors of Minnesota Medicine take pride in presenting in this issue the scientific papers from Berne and thank the authors for their contributions. Many readers of Minnesota Medicine vacationing in the Switzerland mountains and valleys will visit the capital city of Berne and its famous Medical School.

The Department of Internal Medicine

Since January 1966 this department has been reorganized. Responsibility for patient care, internal administration and teaching are divided among three heads of division (full time professors), one of them acting as chairman. Patients are admitted at random to one of the three divisions which practice all the subspecialties of internal medicine. Except for technically specialized units (intensive care f.i.) no beds are allotted to subspecialties. The latter are represented by divisions whose members have consultant functions in the clinical divisions, except for a limited outpatient practice. The house staff in charge of direct patient care is appointed to the entire department and rotates among the three divisions; a slower rotation among the three heads of division also takes place. There is an interchange between the staffs of clinical and specialistic divisions. Three staff meetings are held per week, one of them open to members of other divisions and practicing physicians, another for the department staff only, and a third one of purely administrative nature. In the two former ones patients and subjects of common interest are discussed, while regular rounds take place within the divisions.

Research is mostly done within the specialistic divisions, consisting of the divisions for pulmonary diseases (Dr. M. Scherrer), for cardiology (Dr. H. P. Gurtner), for hematology (Dr. U. Bucher) and for gastroenterology (Dr. F. Halter). Clinical pharmacology (Dr. R. Preisig) is a joint division of the departments of pharmacology and internal medicine.

While the chairman (Dr. Wyss) is mainly in charge of administrative and academic affairs, one of the other heads of the clinical divisions (Dr. Studer) runs the thyroid research laboratory, while the other (Dr. Pauli), whose main field of research was clinical acid base metabolism, is in the process of establishing an office of research in medical education.

Trigger Fingers

The article by Doctor Lenggenhager* concerns the vexing problem of the trigger finger. The diagnosis of trigger finger, based on the complaints of stiffness and snapping and confirmed by the presence of tenderness over the proximal pulley of the tendon sheath, is usually not difficult. Frequently, a nodularity in the tendon or definite crepitus can be felt as the finger is actively flexed. This may be accompanied by a locking of the nodule in the flexor sheath which requires passive extension in order to straighten the finger. Stenosing tenosynovitis in the thumb may present findings similar to those in the fingers but on occasion will present as a painful thumb, for which the cause is not obvious unless the comparative lack of motion of the interphalangeal and metacarpophalangeal joint is contrasted with the opposite side.

The etiology of the so-called stenosing tenosynovitis has been discussed from the point of view of a stenosis occurring in the tendon sheath, a combination of stenosis of the tendon sheath and thickening of the tendon, or a mechanistically induced, club-shaped swelling of the tendon where it receives pressure over the metacarpophalangeal joint during grasp. The trigger finger frequently occurs in more than one finger, and is often associated with de Quervain's disease and the carpal tunnel syndrome. In each of these conditions, one frequently finds hypertrophy and thickening of both the visceral and parietal layers of the tenosynovium and occasionally an actual inflammatory synovitis. The latter is more likely to occur in active rheumatoid arthritis, but may at times be a prodromal symptom of rheumatoid disease as well. The club-shaped swelling on the tendon at times may be peeled off as a part of the visceral tenosynovium. Often this tenosynovial hypertrophy invades the tendon fibers.

Numerous methods of treatment have been proposed for trigger finger, including the percutaneous slitting of the proximal pulley. In

No injection after all!

This penicillin produces high, fast levels—orally.

Pen•Vee® K is usually so rapidly and completely absorbed that therapeutic penicillin levels are attained within 15 to 30 minutes. Thus it can often obviate the need for penicillin injections. The higher serum levels produced generally last longer than with those of oral penicillin G.

Indications: Infections susceptible to oral penicillin G: prophylaxis and treatment of streptococcal infections; treatment of pneumococcal, gonococcal, and susceptible staphylococcal infections; prophylaxis of rheumatic fever in patients with a previous history of the disease.
Contraindications: Infections caused by nonsusceptible organisms; history of penicillin sensitivity.
Warnings: Acute anaphylaxis (may prove fatal unless promptly controlled) is rare but more frequent in patients with previous penicillin sensitivity, bronchial asthma or other allergies. Resuscitative (epinephrine, aminophylline, pressor amines) and supportive (antihistamines, methylprednisolone sodium succinate) drugs should be readily available. Other rare hypersensitivity reactions include nephropathy, hemolytic anemia, leucopenia and thrombocytopenia. In suspected hypersensitivity, evaluation of renal and hematopoietic systems is recommended.
Precautions: In suspected staphylococcal infections, perform proper laboratory studies including sensitivity tests. If overgrowth of nonsusceptible organisms occurs (constant observation is essential), discontinue penicillin and take appropriate measures. Whenever allergic reactions occur, withdraw penicillin unless condition being treated is considered life threatening and amenable only to penicillin. Penicillin may delay or prevent appearance of primary syphilitic lesions. Gonorrhea patients suspected of concurrent syphilis should be tested serologically for at least 3 months. When lesions of primary syphilis are suspected, dark-field examination should precede use of penicillin. Treat beta-hemolytic streptococcal infections with full therapeutic dosage for at least 10 days to prevent rheumatic fever or glomerulonephritis. In staphylococcal infections, perform surgery as indicated.
Adverse Reactions: (Penicillin has significant index of sensitization): Skin rashes, ranging from maculopapular eruptions to exfoliative dermatitis; urticaria; serum sickness-like reactions, including chills, fever, edema, arthralgia and prostration. Severe and often fatal anaphylaxis has been reported (see "Warnings").
Composition: Tablets—125 mg. (200,000 units), 250 mg. (400,000 units), 500 mg. (800,000 units); Liquid—125 mg. (200,000 units) and 250 mg. (400,000 units) per 5 cc.

Wyeth Laboratories Philadelphia, Pa.

ORAL PEN•VEE® K

(potassium phenoxymethyl penicillin)

Wyeth

experienced hands this is undoubtedly a safe and effective method. However, the close association of the proper digital nerves and arteries and the possibility of producing an adhesion between the tendon sheath and the tendon from the use of a tenotome suggest that this procedure might be reserved for those who are also prepared to deal with the complications this method might induce. In many instances, a simple injection of ¼ ml of local anesthetic and 5 mg of a hydrocortisone preparation or its equivalent will give relief for weeks or months. This procedure is certainly fraught with less hazard. In a persistent or unimproved trigger finger, the slitting and removal of a section of the proximal pulley under local anesthesia and tourniquet control has much to recommend it. The tendons can be pulled individually from the tendon sheath and inspected, if done with a smooth blunt instrument so as to avoid adhesions. As has been recently pointed out by Flatt, some caution is advisable in suggesting surgical release, as the onset of a metacarpophalangeal synovitis may lead to the rapid production of ulnar drift due to the lack of restraint of the flexor tendon after its pulley has been excised, especially in the index finger.

Ronald L. Linscheid, M.D.
Rochester, Minnesota

Changes in the Skin with Internal Disease

IF ONE WERE asked what systemic disorders do not have a cutaneous component, much thought would be required to answer the question. Every increase or decrease in body temperature and almost any generalized stress reaction are associated with changes in the skin. However, pallor, sweating, and temperature variations occur in too many disorders to suggest a specific etiologic factor. Instead, they go along to support the correct diagnosis. Some cutaneous signs are of diagnostic importance. Fine telangiectasis at the base of the finger nails nearly always indicates a connective tissue disorder—lupus erythematosus, scleroderma or dermatomyositis. Jaundice points to hepatic disease, and blisters with residual scarring on the back of the hands, combined with a reddish hue, suggest porphyria. Numerous other examples can be given.

The same situation holds for internal cancer. A cutaneous change, such as pruritus or urticaria, may be the first indication of a neoplasm. Yet itching and hives appear so commonly in nonmalignant disorders that only in special situations would a physician consider cancer first to explain itching or hives. Other markers are more specific. Generalized herpes zoster or acanthosis nigricans occurring for the first time in an adult almost always results from internal cancer. The report by Perry, Kiely and Moertel* in the December issue of MINNESOTA MEDICINE describes six signs that may be associated with neoplasms. There are others, too, but the report is not intended to be an exhaustive review. The conditions listed, namely, plantar and palmar keratoses, generalized plane xanthomatosis, alopecia mucinosa, pemphigoid, multiple mucosal neuroma and ataxia-telangiectasis, although not common, are unusually interesting. The physician who grasps these entities has an expanded base for his diagnostic acumen.

Tick-Borne Encephalitis

THE REPORT BY Spiess and Mumenthaler adds another country to the list of European countries in which tick-borne virus encephalitis has been recognized. In Europe, in contrast to the United States, ticks rather than mosquitoes are the important vectors of arboviruses that cause encephalitis. After severe encephalitis associated with tick bite was recognized in the eastern part of the U.S.S.R. during the 1930's, similar diseases were recognized in Czechoslovakia, Jugoslavia, Austria, Hungary, Bulgaria, Poland, Germany, Denmark, Sweden, Finland, and the British Isles. Two tick vectors are involved, *Ixodes persulcatus* in the eastern part of the U.S.S.R. and *Ixodes ricinus* in Europe. Three antigenically distinguishable, but closely related, viruses are the cause of tick-borne encephalitis, namely, Far Eastern in eastern U.S.S.R., Central European of Europe, and louping ill of the British Isles. The Far Eastern virus causes the most severe encephalitis. Generally, the disease is monophasic with signs of central nervous system involvement from the onset. Flaccid paralyses, particularly of muscles of the shoulder girdle, are common. The Central European virus usually causes a diphasic type of disease. A primary phase with influenza symptoms lasts about a week. Then, after an interval of several days when the patient feels better, a period of central nervous system involvement supervenes. Disease caused by these two viruses has also occurred after drinking raw goat's milk. Virus appears in the blood and is excreted in the milk of goats bitten by infected ticks. In the British Isles, louping ill virus is an important cause of encephalitis in sheep but only occasionally causes encephalitis in man, which resembles the Central European type.

Other members of this group of viruses cause febrile and hemorrhagic disease syndromes but not encephalitis. These are Omsk hemorrhagic fever virus of U.S.S.R. transmitted by *Dermacentor pictus* and Kyasanur Forest disease virus of Mysore State, India, transmitted by *Hemophysalis spingera*. In addition, there are members of this group of viruses which, because of their ecology, rarely come in contact with man: Langat virus of Malaya which is transmitted by *Ixodes granulatus* that apparently does not feed on man, and Powassan virus of Canada and the U. S. A. which is transmitted by *Ixodes* species that rarely if ever feed on man. Disease caused by Powassan virus has been established in only one patient, a boy who had onset of encephalitis in Powassan, Ontario, in 1958 and died. He may have been exposed by contact while hunting wild animals such as woodchucks, chipmunks, and wild mice that are involved in the infection chain that maintains the virus.

The only common tick-transmitted virus disease of man in the United States is Colorado tick fever, which occurs in the Rocky Mountain region within the geographic distribution of the spotted fever tick, *Dermacentor andersoni*. In this disease a diphasic illness resembling dengue, characterized by fever, severe general aching, and leukopenia is usually observed. Central nervous system involvement is rare. Colorado tick fever virus has not been isolated from ticks collected in Minnesota.

In the United States, four arboviruses have been recognized as a cause of encephalitis. These are Eastern (EEE) and western equine encephalitis (WEE), St. Louis encephalitis (SLE), and California encephalitis (CE) viruses. All of them are transmitted by mosquitoes. Three of them, WEE, SLE, and CE, have been recognized as a cause of encephalitis in Minnesota, usually in the period July to mid-September when enteroviruses, such as the Coxsackie and ECHO groups, may also cause meningitic and encephalitic syndromes.

Tetanus

Dr. Hans Stirnemann* extensively reviews the treatment of 217 cases of tetanus at the Surgical Clinic, University of Berne, Switzerland, during the fifty-year period 1918-1967. The disease is not common but must always be considered or proper diagnosis will not be made early, as shown in 35 "missed cases."

The intensive care of severe cases which includes tracheotomy, paralysis with curare, and respirator assistance has improved survival but has also caused complications and deaths. Tracheotomy may result in death from hemorrhage (two cases). Highly trained, motivated personnel are needed for prolonged patient support, including meticulous tracheotomy care. This study emphasizes the necessity to monitor and maintain normal blood gases and pH, avoiding the hyperventilation syndrome. The complications of stress ulcers are prevented by maintaining adequate nutrition and antacids via a small gastric tube.

We feel that high concentrations of oxygen for prolonged periods should be avoided because of potential pulmonary injury. The respirator lung syndrome is becoming more common.

Recent studies in this country have demonstrated rapid recall of antitoxin antibodies following the injection of 0.5 cc tetanus toxoid in individuals who were immunized over 10 years previously and had received no subsequent booster doses. Also, human tetanus antitoxin is now available, rarely causes any undesirable reaction and is therefore much safer than equine antitoxin (heterologous serum). Injured patients can be given a booster dose at the time of initial therapy, and individuals with grossly contaminated wounds or those having never been immunized should be given 400 units of human tetanus antitoxin in addition to the tetanus toxoid.

Both the laboratory and the clinical research has failed to demonstrate significant beneficial effects of hyperbaric oxygen in the treatment of tetanus in contrast to gas gangrene (Clostridium perfringens).

Tetanus is a continuing problem in the industrial-agricultural communities and carries a significant mortality if unrecognized or inadequately treated. Fortunately tetanus, although difficult to treat, can be completely prevented by the continuing education of the public and by active immunization.

Milk: Indications and Contraindications

It is a bad thing to give milk to persons having headache, and it is also bad to give it in fevers, and to persons whose hypochondria are swelled up, and troubled with borborygmi, and to thirsty persons; it is bad also, when given to those who have bilious discharges in acute fevers, and to those who have copious discharges of blood; but it is suitable in phthisical cases, when not attended with very much fever; it is also to be given in fevers of a chronic and weak nature, when none of the aforementioned symptoms are present, and the patients are excessively emaciated.*

Renal Clearances

THE APPEARANCE of ^{51}Cr-EDTA as an estimate of glomerular filtration rate constitutes another useful item in the armamentarium of the diagnostician of renal diseases.

The use of ^{51}Cr-EDTA would appear rather limited, however, because its correlation with standard materials used to estimate glomerular filtration rate, such as inulin, is less than that of other radioactive compounds which are more convenient to use, such as diatrizoate (Hypaque). Moreover, Hypaque labelled with ^{125}I or ^{131}I is available, and this provides great flexibility in usage because these two isotopes may be quantitated individually in mixture. Such quantitation would allow, for example, glomerular filtration rate and effective renal plasma flow to be measured simultaneously. Diatrizoate-^{125}I could be used to measure glomerular filtration rate, and *o*-iodohippurate-^{131}I to estimate effective renal plasma flow. The latter compound labelled with ^{125}I is also available. In addition, these compounds yield clearance estimates that correlate well with glomerular filtration rate and effective renal plasma flow when single injection methods are used, provided the proper compartment model is chosen. Apparently, ^{51}Cr-EDTA cannot be so used, according to the accompanying paper. Nor can ^{51}Cr and ^{131}I be easily quantitated individually in mixture.

Despite these shortcomings, ^{51}Cr-EDTA may have a place in the renal physiology laboratory. Estimates of glomerular filtration rate may be desirable when radioiodine-labelled compounds cannot be used or when sequential studies using multiple labels are to be done. Thus, any new compound that estimates glomerular filtration rate is welcome.

Save him from
RHEUMATIC FEVER

Here are two ways:

1. If your child has a bad sore throat, don't wait – it might be "strep." Call your doctor. Treatment of "strep" infections usually can prevent rheumatic fever and the heart damage it sometimes causes.

2. Give to your Heart Fund. Your Heart Fund dollars support research and community service programs which can wipe out rheumatic fever and save thousands of young lives.

GIVE ...
so more will live
HEART FUND

The Editor's Soliloquy

The Span of a Professional Lifetime

YEARS AGO YOUR Editor studied for the better part of a year at the University of Berne under the tutelage of Professor de Quervain to learn the intricacies of goiter disease. I was classified as an Austausch assistant. Accompanying me to Switzerland were my wife and two infant daughters.

Having passed the required German tests for a graduate degree, I assumed that my diligence in studying the German language while speaking to Swiss students would make my accent acceptable. For the first few weeks, however, I had difficulty adjusting my ear to the slow, throaty but tuneful C sound of the Berne-Deutsch articulation. In an effort to improve my pronunciation after listening to the medical students converse with one another, I read aloud the medical literature of the Swiss journal. A year later in Minneapolis, when I called to converse with a German who was having difficulty with English, he asked me, to my surprise and delight, where I had picked up my authentic Berne-Deutsch accent which was almost as foreign to him as the English language.

Berne, Switzerland, keystone to the surrounding mountain regions, is one of the most unique and beautiful cities of Europe, its "old-town" section lying snugly within a bend of the river Aare. Its main street, extending from the Inselspital (Island Hospital) to the Barengraben (Bear pits), has retained its original architecture for almost a thousand years; but other portions of the city, the "new-town" areas, have developed with the times and are as modern as the main street is medieval. This harmonious juxtaposition of "new" and "old" furnishes concrete evidence of Berne's historical continuity (from the 12th to the 20th century) and constitutes one facet of its charm.

Tradition has it that in 1191 patrician founders of the community went hunting and sportingly agreed to name the new settlement after the first animal they shot, which turned out to be a bear. The Old High German Bero still adorns the city seal, and the Barengraben has been one of Berne's distinctive attractions throughout the centuries. Among the city's other unique features are picturesque streets and houses of medieval vintage, enticing promenades, terraces and arcades, and especially fountains: the Bagpiper, the Standard Bearer, the Marksman, and the Ogre—each unit either historically or culturally significant.

The pervasive medieval aura of the city is most manifest in its remnants of ancient walls that retain two of their original towers: the Kafigturm (prison tower) and the Zeitglockenturm (clock tower) with its elaborate ritual of striking the hour.

Perhaps even more memorable than its scenic and cultural attractions is Berne's intangible quality of "Gemutlichkeit," one of those happy German composites, the apt grace of which is untranslatable into harsher Anglo-Saxon. Somewhat similar to the French "joie de vivre," Gemutlichkeit consists of cheeriness, kindliness, cordiality, and courtesy, all warmly blended and delivered with that "light touch" so alien to most northern cultures.

Professor de Quervain was an exceedingly energetic and gracious person, deeply religious and possessed of a high degree of intellectual integrity. In addition to several Swiss dialects he spoke five languages fluently. While

This is your life line. If you're not doing something with your life, it doesn't matter how long it is.
The Peace Corps.

PUBLISHED AS A PUBLIC SERVICE IN COOPERATION WITH THE being entertained at his lovely home with the other students in his department, I once asked him which of the many languages he preferred. Without hesitation he pronounced the Berne-Deutsch to be the most beautiful of all. It was a delight to watch him converse with his retinue of foreign visitors, each in their own language, shifting from one to the other with facility and obvious inner satisfaction. He loved a well-turned anecdote and was especially fond of the story about an English woman who pointed to one of the dwarfed cretins and remarked, "There is a typical Berne Deutscher!"

Among his students was a charming young intellectual, ever gracious and considerate to associates. A keen, eager student in most phases of medical science, he demonstrated an interest in research which led him into many phases of medical investigation in addition to his chosen field of surgery. Incidentally, he often spoke of the disadvantages of extreme specialization.

As counterbalance for the arduous mental discipline of academic and scientific pursuits this young man strongly advocated the equally strenuous Swiss sports: mountain climbing and skiing.

The name of this fellow student was Karl Lenggenhager.

Timidified by my lack of ability to converse well in their language, Karl always gave me confidence and courage when I needed it most. Perhaps because of our first names I felt a common bond: his spelled with a "K," mine with a "C." Besides encouragement he often gave me valuable tips for weekend visits throughout Switzerland—to various points of historical, national, or scenic interest.

Ten years later, in 1940, Dr. Karl Lenggenhager was appointed Chief of Surgery to succeed Professor de Quervain. One of his major interests in research pertained to the coagulation of blood and the genesis and prevention of pulmonary embolism, for which he introduced postoperative prophylaxis with heparin. He has also published numerous technical improvements in a wide field of surgery.

Professor Lenggenhager has always been a gentleman to his fingertips. By nature a modest and kindly man he has not sought fame or power for himself, but has delegated responsibilities to his associates, trusting them and supporting their theories and projects, and judiciously settling differences of opinion within his department and among the faculty.

It is through my good fortune in having known this man that a Special Issue of MINNESOTA MEDICINE has been made possible; it represents almost the span of a professional lifetime.

Carl O. Rice, M.D.

Old Doc Hess Says: Do only what is right and quit counting noses. C.O.R.

Life is short
Art is long

Judgment difficult
Experimentts perilous—Socrates

Keep your eyes wide open before marriage, and half-shut afterwards.—Benjamin Franklin

My Political Creed

I am a free citizen in a free nation.

Whoever diminishes my freedom as an individual diminishes the sum total of freedom in my country.

I am also a physician, free thus far to treat my patients to the best of my ability.

Abridge that freedom and the health of my patients is adversely affected.

These things being true, I cannot--I will not--stand idly by when these hard-won freedoms are under attack.

For I believe that the values upon which this country was founded are immutable and have not been eroded by the passage of years.

I believe that I, as a free citizen in a free land, am obligated to defend my beliefs in the ways permitted to me, and required of me, by our form of government.

Therefore, let no man seek to bar me from the political process; for it would be akin to denying my right to participate in the process that determines free government.

Lederle
DECLOMYCIN®
DEMETHYLCHLORTETRACYCLINE HCl
TABLETS (Film Co
Federal law prohibits dispensing wi
American Cyanamid Com
Lederle
You've made it one
of your specifics in acute otitis media
DECLOMYCIN
DEMETHYLCHLORTETRACYCLINE

You've made it one of your specific in acute otitis media

DECLOMYCIN acts against many strains of
H. influenzae, pneumococci and streptococci, th
most common invaders. In otitis media, where it
is difficult to isolate the causative organism, this
coverage may be important. However, some strai
may be resistant and other pathogens can be
involved.

You've found the high serum levels of
DECLOMYCIN important, too. Its prolonged acti
permits convenient 300 mg b.i.d. or 150 mg
q.i.d. administration.

When specimens are obtainable, your culture studies will indicate the usefulness of DECLOMYCIN.

Effectiveness: DECLOMYCIN Demethylchlortetracycline should be equally or more effective therapeutically than other tetracyclines in infections caused by organisms sensitive to the tetracyclines.
Contraindication: History of hypersensitivity to demethylchlortetracycline.
Warning: In renal impairment, usual doses may lead to excessive accumulation and liver toxicity. Under such conditions, lower than usual doses are indicated, and, if therapy is prolonged, serum level determinations may be advisable. A photodynamic reaction to natural or artificial sunlight has been observed. Small amounts of drug and short exposure may produce an exaggerated sunburn reaction which may range from erythema to severe skin manifestations. In a smaller proportion, photoallergic reactions have been reported. Patients should avoid direct exposure to sunlight and discontinue drug at the first evidence of skin discomfort. Necessary subsequent courses of treatment with tetracyclines should be carefully observed.
Precautions: Overgrowth of nonsusceptible organisms may occur. Constant observation is essential. If new infections appear, appropriate measures should be taken. In infants, increased intracranial pressure with bulging fontanels has been observed. All signs and symptoms have disappeared rapidly upon cessation of treatment.
Side Effects: Gastrointestinal system—anorexia, nausea, vomiting, diarrhea, stomatitis, glossitis, enterocol
pruritus ani. Skin—maculopapular and erythematous rashes; a r
case of exfoliative dermatitis has been reported. Photosensitiv
onycholysis and discoloration of the nails (rare). Kidney—rise in B
apparently dose-related. Transient increase in urinary output, so
times accompanied by thirst (rare). Hypersensitivity reactions—u
caria, angioneurotic edema, anaphylaxis. Teeth—dental staining (
low-brown) in children of mothers given this drug during the latter
of pregnancy, and in children given the drug during the neonatal p
od, infancy and early childhood. Enamel hypoplasia has been see
a few children. If adverse reaction or idiosyncrasy occurs, disconti
medication and institute appropriate therapy. Demethylchlorte
cycline may form a stable calcium complex in any bone-forming tis
with no serious harmful effects reported thus far in humans.
Average Adult Daily Dosage: 150 mg q.i.d. or 300 mg b.i.d. Sho
be given 1 hour before or 2 hours after meals, since absorptio
impaired by the concomitant administration of high calcium cont
drugs, foods and some dairy products. Treatment of streptoco
infections should continue for 10 days, even though symptoms h
subsided.

DECLOMYCIN®
DEMETHYLCHLORTETRACYCLINE

Capsules: 150 mg; **Tablets:** film coated,
mg, 150 mg and 75 mg of demethylchlorte
cycline HCl.

LEDERLE LABORATORIES, A Division of
American Cyanamid Company, Pearl River, New York

Lederle

heavenly relief
for unearthly cough

Benylin®
EXPECTORANT

Each fluidounce contains: 80 mg. Benadryl® (diphenhydramine hydrochloride, Parke-Davis); 12 grains ammonium chloride; 5 grains sodium citrate; 2 grains chloroform; 1/10 grain menthol; and 5% alcohol. An antitussive and expectorant for control of coughs due to colds or of allergic origin, BENYLIN EXPECTORANT is the leading cough preparation of its kind. BENYLIN EXPECTORANT tends to inhibit cough reflex... soothes irritated throat membranes. And its not-too-sweet, pleasant raspberry flavor makes BENYLIN EXPECTORANT easy to take. PRECAUTIONS: Persons who have become drowsy on this or other antihistamine-containing drugs, or whose tolerance is not known, should not drive vehicles or engage in other activities requiring keen response while using this preparation. Hypnotics, sedatives, or tranquilizers if used with BENYLIN EXPECTORANT should be prescribed with caution because of possible additive effect. Diphenhydramine has an atropine-like action which should be considered when prescribing BENYLIN EXPECTORANT. ADVERSE REACTIONS: Side reactions may affect the nervous, gastrointestinal, and cardiovascular systems. Drowsiness, dizziness, dryness of the mouth, nausea, nervousness, palpitation, and blurring of vision have been reported. Allergic reactions may occur. PACKAGING: Bottles of 4 oz., 16 oz., and 1 gal.

Parke, Davis & Company

"The inconvenience of a cold"

For a cold, NTz® Nasal Spray provides rapid relief of nasal symptoms. Relief starts with the first spray which opens the inferior part of the common meatus. A second spray, a few minutes later, will shrink the turbinates to help provide sinus drainage and ventilation. Dosage may be repeated every three or four hours as needed, for temporary relief of symptoms. NTz is well tolerated but overdosage should be avoided.

As a sinusitis deterrent, NTz Nasal Spray can be used to keep the nasal passages open during a cold to help prevent development of acute sinusitis – or to help prevent the acute condition from becoming chronic.

Supplied: NTz Nasal Spray, plastic squeeze bottles of 20 ml.; NTz Nasal Solution, bottles of 30 ml. (1 fl. oz.) with dropper.

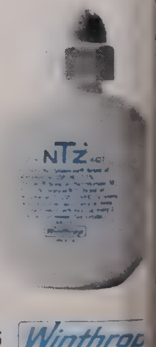
NTz is more than a simple vasoconstrictor. It contains

Neo-Synephrine® (brand of phenylephrine) HCl 0.5 per cent, the major component, virtually synonymous with fast, efficient but gentle nasal vasoconstriction.

Thenfadil® (brand of thenyldiamine) HCl 0.1 per cent, topical antihistamine for reduction of rhinorrhea, sneezing or itching. It combats the allergic reactions that may occur in colds or sinusitis.

Zephiran® (brand of benzalkonium, as chloride, refined) 1:5000, antiseptic preservative and wetting agent to promote penetration and spread of the formula.

Winthrop Laboratories, New York, N.Y. 10016 Winthrop



Curbstone Consultation

QUESTION: Occasionally the PBI and T-3 results don't jibe in women on oral contraceptives. How should we approach thyroid function in women on hormones?

ANSWER: First a few scraps of important information: (1) Most thyroxine binds to globulin in serum; less than 0.1% goes unbound, or "free." (2) PBI measures mostly the iodine attached to this globulin. (3) The amount of globulin inversely affects the T-3 value (the more globulin circulating, the less radioactive tri-iodo-thyronine "taken up"). When a woman takes birth-control pills, estrogen in the pills increases that portion of protein to which thyroxine clings, thereby forcing the PBI up and the T-3 down.

We recently went over the drug histories of 50 women on contraceptive pills who had high PBIs and low T-3s. Types of pills included C-Quens, Enovid and Enovid-E, Norinyl and Norinyl-1, Ortho-Novum, Ovulen, and Provest. Thus, all the commonly used agents exerted a thyroid effect. And a significant one, too. Values for PBI ran from 8.1 mcg.% to 21.0 mcg.% (mean 10.1 mcg.%) and for T-3 from 24% to 8% (mean 19%).

Yet when we multiplied PBI by T-3 to get a Free Thyroid Index:

PBI	×	T-3	=	FTI
(4–8 mcg.%)		(25–35%)		(100–280)

48 patients fell into the euthyroid range. From this and other studies, we are convinced the Index reliably measures thyroid status when patients have drug or disease-induced protein charges.

Up to this point we have not mentioned two other serum tests: T-4 by column chromatography and "free" T-4 by a mixed isotope dilution method. In our hands, the T-4 column test, though accurate and precise enough, has not solved the pill problem. Like PBI, estrogen sends it up. And, like PBI, drugs containing organic or inorganic iodine cause high results. Theoretically, "free" T-4 ought to be the answer since globulin changes do not influence it. But it is more expensive than a PBI and T-3 together, gives about the same information[1] and, at least in the Mayo Clinic experience, "distinguished poorly between different levels of thyroid function."[2]

New drugs take exams, too.

Today, virtually every medical school in the United States cooperates with pharmaceutical manufacturers in the clinical evaluation of new and promising drugs. Just as you might find it significantly more difficult to practice medicine without the useful new compounds made available through original pharmaceutical research in the past twenty years—prescription-drug manufacturers would find it equally difficult to obtain extensive, long-term, dependable evaluations of new therapeutic agents without the close cooperation of medical staffs and clinical facilities of medical schools and teaching hospitals. Such cooperation leads toward more effective care of more patients—the common goal of medical and pharmaceutical research—toward reduction in the cost of disease, toward increase in useful longevity.

This message is brought to you as a courtesy of this publication on behalf of the producers of prescription drugs.

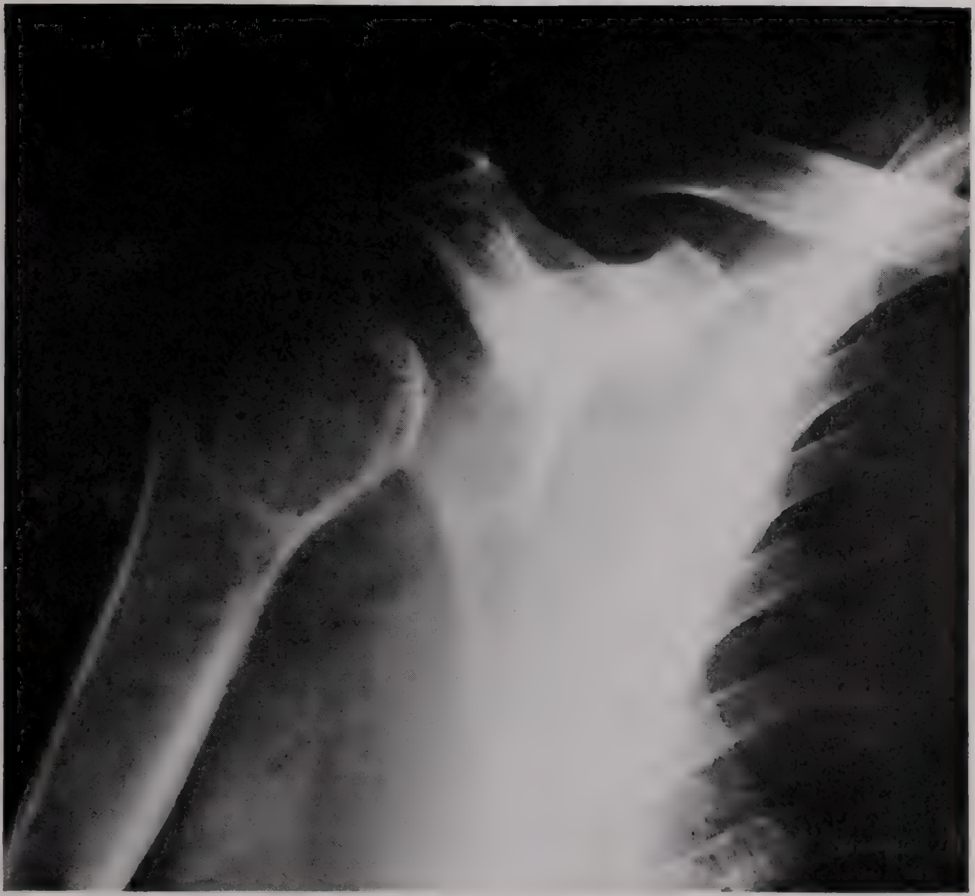
The Viewing Box

Shoulder Pain

THIS 58-YEAR-OLD MALE fell and hit his right shoulder. He complained of pain in the shoulder. Clinically the shoulder motion was limited. Roentgenograms were obtained. The anteroposterior view is shown here (Figure).

What is your diagnosis? (See next page).



Figure

Diagnosis: Posterior dislocation of right shoulder.

This case is presented because at least one half of the posterior shoulder dislocations are either missed or misdiagnosed.

The frequency with which this diagnosis is missed is largely the result of four factors: (1) the injury is rare, accounting for only 2 to 4% of all shoulder dislocations; (2) the anteroposterior roentgenogram may be deceptively normal; (3) The clinical findings are often subtle; (4) symptoms of the dislocation may be attributed to associated fractures.

Approximately one half of the cases result from convulsive episodes. The remainder are produced by a direct blow to the anterior surface of the humeral head or a force transmitted along a flexed, adducted and internally rotated humerus. The displaced articular surface of the humeral head comes to rest behind the glenoid, facing posteriorly with the humerus locked in internal rotation. The soft anterior surface of the anatomic neck hinges on the hard posterior rim of the glenoid. A deep notch in the humeral head may result. This will obliterate the second diagnostic feature to be discussed.

The following roentgen findings may be useful in the diagnosis of posterior shoulder dislocation: (1) "positive rim sign": an increase in space between the anterior rim of the glenoid and the medial aspect of the humeral head. In the normal adult shoulder this distance does not exceed 6 mm regardless of rotation or projection (36-40 inch target to film distance); (2) absence of half-moon overlap. Normally, the medial part of the head of the humerus overlaps the glenoid to form an elliptical (half-moon) shadow; (3) internal rotation; (4) associated fractures of the humeral head.

This patient exhibited the following typical radiographic findings: (1) positive rim sign (23 mm); (2) absence of the half-moon overlap; and (3) internal rotation. There is no fracture. A transthoracic lateral view (not reproduced) confirmed a posterior dislocation.

On Dropsies

All dropsies arising from acute diseases are bad; for they do not remove the fever, and are very painful and fatal. The most of them commence from the flanks and loins, but some from the liver; in those which derive their origin from the flanks and loins the feet swell, protracted diarrhoeas supervene, which neither remove the pains in the flanks and loins, nor soften the belly; but in dropsies which are connected with the liver there is a tickling cough, with scarcely any perceptible expectoration, and the feet swell; there are no evacuations from the bowels, unless such as are hard and forced; and there are swellings about the belly, sometimes on the one side and sometimes on the other, and these increase and diminish by turns.*

The surest way to corrupt a young man is to teach him to esteem more highly those who think alike than those who think differently.—Nietzsche

Dermatology

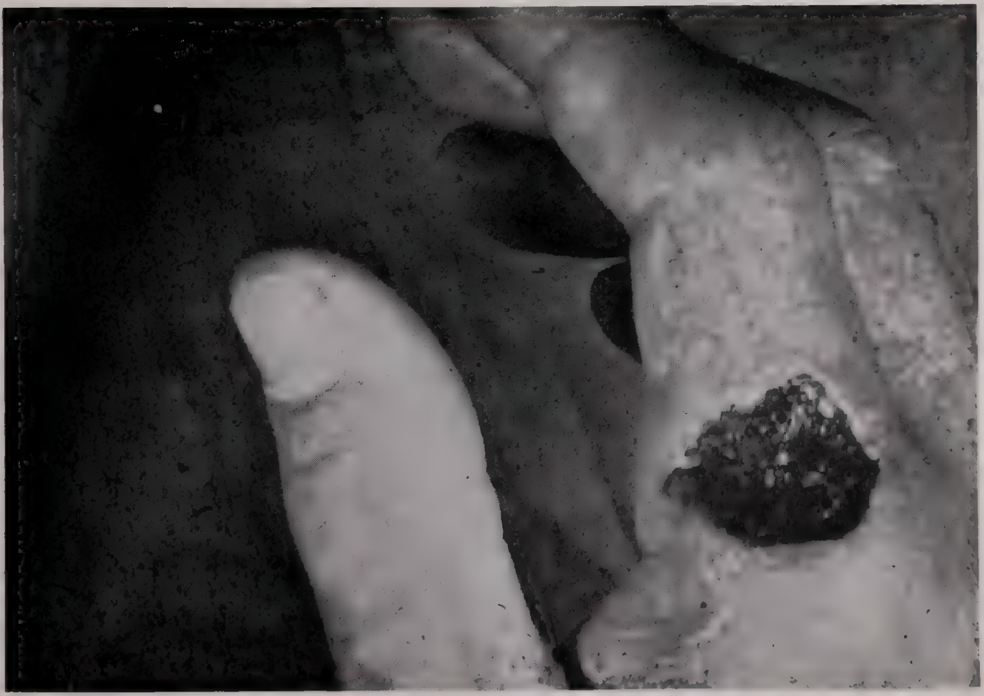
Self-Induced Eruptions

SELF-INDUCED CUTANEOUS damage varies from simple excoriations to severe and disfiguring mutilations. Generally, self-induced eruptions may be divided into two groups: neurotic excoriations and factitial dermatitis. Both are characterized by underlying emotional disturbances and refractoriness to treatment. A major point of differentiation is that the patient with neurotic excoriations will admit that he damages his skin, while in factitial dermatitis the patient denies any responsibility for the damage and may not consciously admit it even to himself.

It is generally agreed that persons who seriously damage themselves are deeply disturbed. This disturbance may range from mild neurosis to severe psychosis. Some consider these individuals as being basically hysterical, but conversion hysteria does not characteristically include self-injury or mutilation. It may be that self-inflicted damage results from guilt or aggressive feelings turned back upon the individual, with conscious satisfaction resulting from the self-injury.

Neurotic Excoriations

This heading covers patients who aggravate an existing dermatosis and also those who actually create an eruption or damage. Aggravation of dermatoses is frequently seen in acne vulgaris and in atopic or neurodermatitis.



Figure

These patients are usually of the anxious-obsessional personality type. In acne the patient may pick at his face until permanent scarring results.

Neurotic excoriations are more severe; as a rule there is no primary dermatologic disease preceding the self-inflicted damage. It must be pointed out that simple aggravation of a dermatosis and frank neurotic excoriations are not always easily separated.

Lesions of a neurotic excoriator are frequently characteristic. They occur on those areas the individual can easily reach (face, shoulders, chest, forearms, and anterior thighs). The patient usually feels there is a "core," "pimple," foreign body, or other irregularity in the skin which must be removed. At times only a diffuse itching is described. His actions are compulsive and apparently result in relief of his tension. The lesions themselves are often linear or irregular, may be superficial or deep, are usually covered by a crust or scab, and have an erythematous border. When the lesion heals there is a scar surrounded by an area of hyperpigmentation.

If an attempt is made to stop the patient's activities, tension builds up to an intolerable level (unless he is given a harmless substitute such as a lotion to apply) and resumption of the destructive behavior ensues.

Factitial Dermatitis

In this condition the patient consciously produces the lesions but will deny that he has done so. This disease usually is indicative of a severe neurosis or even an underlying psychosis. The diagnosis of factitial dermatitis is based upon location of the lesion, its clean-cut and bizarre appearance as well as the exclusion of any recognizable dermatologic diseases which might cause such changes. The artificial appearance arouses suspicion (Figure). Patients may use chemicals, heat, instruments, and nails or teeth in producing the damage. As a result the lesions usually have a distinctive appearance not seen in naturally occurring dermatoses.

Primary in this dermatosis is the patient's denial of his responsibility in producing the damage. The location as a rule is on those areas where the lesion may attract attention for sympathy, pity or monetary compensation, or where it can be used for escaping responsibility. Many of these patients are middle-aged and may have various feelings of inadequacy. This inadequacy may be real or imagined; nevertheless, the patient cannot accept it and uses this mechanism to rationalize his failure to achieve.

Treatment

In both these conditions dermatologic treatment is directed towards the induced lesions with ointments and protective or occlusive dressings to prevent further damage. At times in neurotic excoriations, superficial physchotherapy has been reported to be beneficial. However, in factitial dermatitis many observers feel these patients are often of a low intellectual level where psychiatric help even if available rarely helps. Regardless, it is considered unwise in this latter condition to uncover the patient's self-destructive behavior without psychological evaluation so that treatment may proceed with psychiatric guidance.

Tumor Conference

Diagnosis and Treatment of Malignant Testicular Tumors

THE FREQUENCY of malignant tumors of the testes is 0.5-2% of all malignancies in males and up to 4% of all malignant tumors in the male urogenital tract.[1,2] Early diagnosis significantly improves therapeutic results and thereby the prognosis and life expectancy of patients with this malignant disease which involves particularly young persons. Based upon the following case history some problems of diagnosis and treatment of testicular malignancies are discussed.

Case History

A 32-year-old engineer observed a hard swelling of his right testicle for the first time in July 1964. Four months later he consulted his physician, who advised surgical excision because he could not differentiate clinically between a growth originating from the testicle and the epididymis. At surgical exploration the tumor was clearly confined to the testis.

Pathologic Findings

Microscopically no infiltration of the epididymis and the deferent duct was observed. The histological diagnosis was embryonal carcinoma; lymphography performed 14 days after the operation did not reveal metastases in the aortic and iliac lymph nodes (Figure 1). Contrast filling of the aortic node groups was observed up to the region of L2. Some lymph nodes situated parallel to the thoracic duct at the level of Th 10/12 and Th 6/7 were also filled with contrast agent. In this region the thoracic duct was duplicated and tortuous (Figure 2). No metastases in the lungs were detectable. The gonadotropins in the urine were normal. Prophylactic radiotherapeutic treatment was performed with Co^{60}; 3234 rad were applied to the inguinal and iliac node groups on a 19 x 9 cm portal in 36 days and 3466 rh inguinal-iliac on a 16 x 9 cm umbilical portal. The usual irradiation dose of 4500 rh could not be given in both areas because of increased skin reaction. At the end of the treatment no metastases in the lungs and contrast-filled lymph nodes were observed.

Progress

Five months later a solitary metastasis in the right upper lobe of the lung was present, which increased rapidly in size during the next two weeks. Chemotherapy with an initial dose of 50 mg methylhydrazine was started on July 25, 1965. Combined radiotherapy and chemotherapy was given in 14 sessions over a period of 18 days; 250

mg of methylhydrazine was injected after each irradiation up to a total dose of 3.05 g. The lung metastasis was irradiated with high-speed electrons alternately from a 7 x 7 cm ventral and dorsal portal with a total dose of 2810 rad. On radiographic controls the lung metastasis gradually disappeared and was not detectable at the end of the combined treatment. For the next 20 months the patient did not present any abnormalities.

On April 12, 1967, he complained for the first time about substernal pain, but no pathological findings in the lungs were detected. About three months later he consulted his physician because of fever, cough and massive sputum. Fluoroscopy demonstrated pneumonic infiltration of the right middle lobe. Therapy with achromycin led to rapid clinical improvement. A subsequent radiographic control of the lungs revealed an expansivity of the right posterior hilar region at the site of the lymph nodes filled with contrast medium at the previous lymphography (Th 5-7). Oblique tomography demonstrated a moderate concentric stenosis of the right stem bronchus due to enlarged hilar and posterior mediastinal lymph nodes (Figure 3), a finding which was

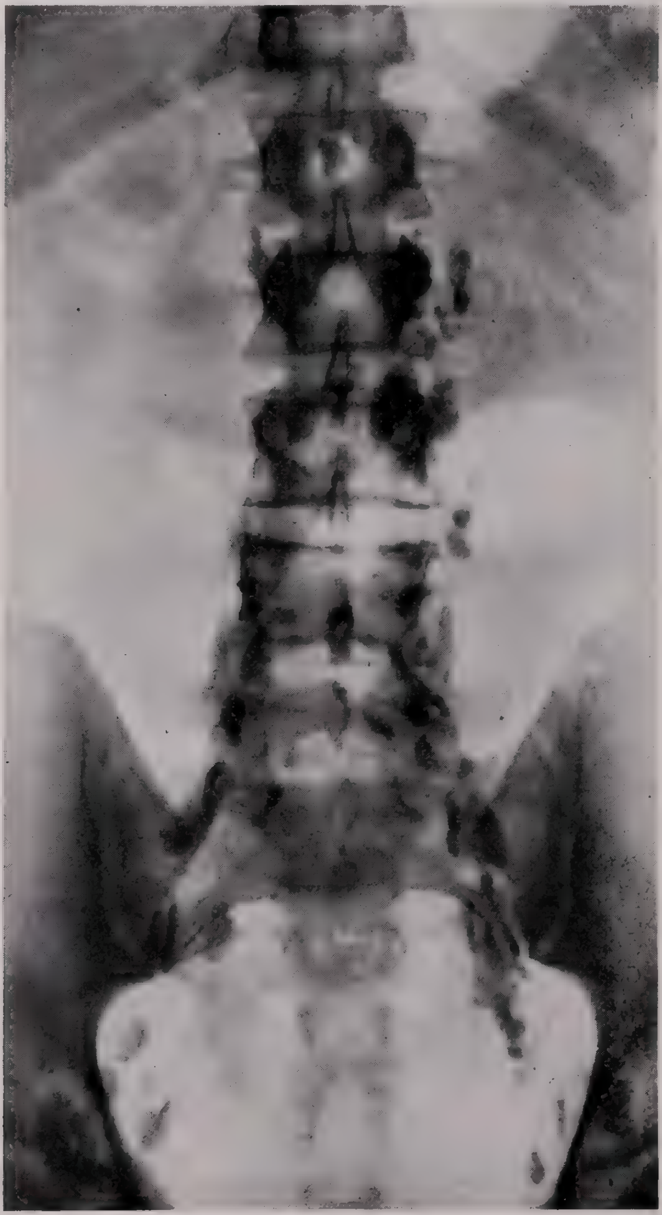

Fig. 1—Normal lymphogram of the aortic and iliac lymph nodes.

confirmed by bronchoscopy five days later. On August 31 the patient was taken to the hospital and therapeutic treatment with high-speed electrons to the mediastinal region was initiated.

Unfortunately treatment had to be interrupted on September 9 after administration of only 1240 rad, because a fistula at the level of the tracheal bifurcation between the posterior mediastinum and the esophagus had rapidly developed (Figure 4). Septic temperature was present and the general state of the patient was poor. Radiologically a mediastino-costo-diaphragmatic pleural lesion had developed on the right side of the lower posterior mediastinum.

Lymphography, cavography and urography performed after moderate recovery of the patient due to treatment with antibiotics did not show metastases within the retroperitoneal region, a finding which was confirmed at laparatomy for gastrostomy. The lymph nodes at Th 6/7 were enlarged but not contrast-filled because of complete malignant infiltration. Occlusion of the anterior branch of the thoracic duct and slight dislocation of the posterior branch were present (Figure 5).

On October 3 the esophago-mediastinal fistula was clinically closed. Roentgen-examination of the chest showed no change of the costo-diaphragmatic pleural lesion,

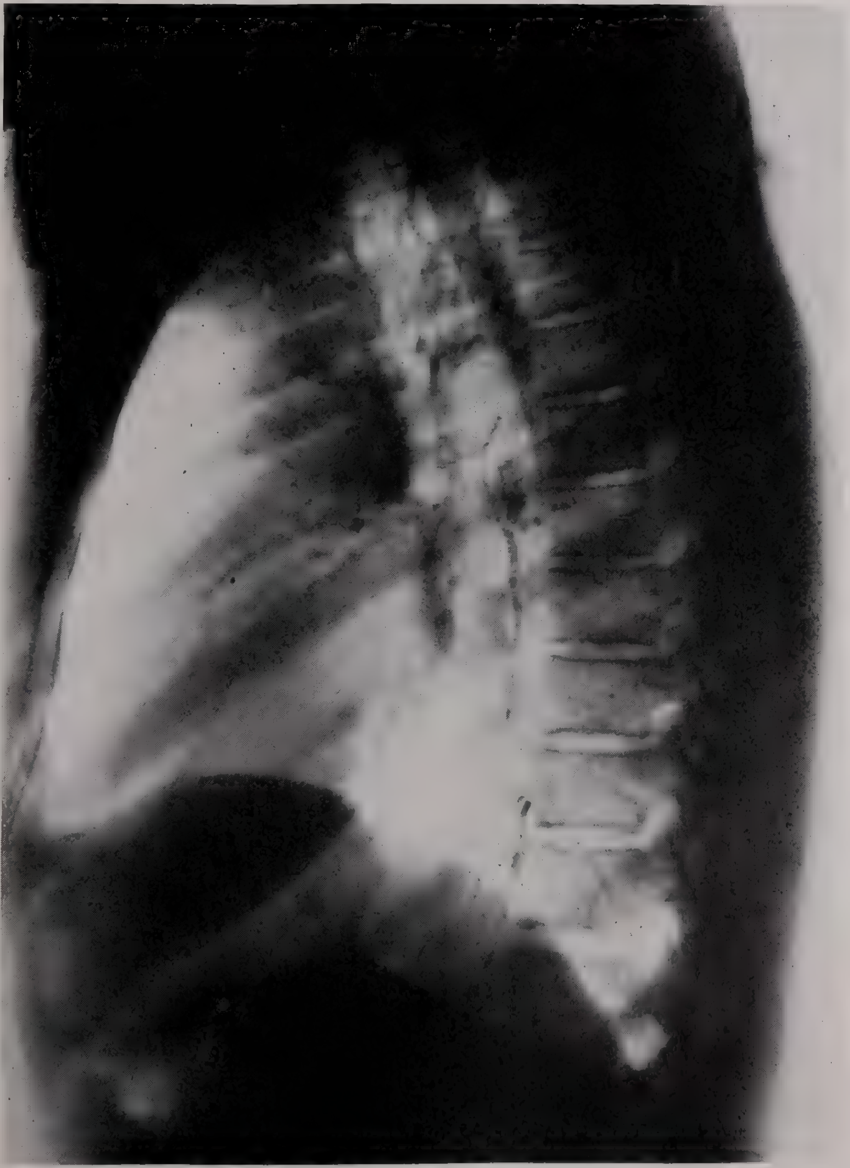

Fig. 2—Duplication and tortuosity of the thoracic duct of Th 5/7. Contrast-filled lymph nodes at the level of Th 6/7 (→) and Th 10/12 (→).

but chronic pneumonia of the right lower lobe and metastases in the left upper lobe were suspected. A first attempt to drain the mediastinal abscess was unsuccessful. As the septic condition persisted, a second drainage of the abscess was performed which resulted in an improvement in the clinical condition of the patient. The gastrostomy was then closed and the patient showed further improvement; but 20 days later acute respiratory insufficiency due to tracheal compression developed. Emergency bronchoscopy revealed complete occlusion of the right and subtotal stenosis of the left main bronchi. Removal of the occlusive tumor masses within the left main bronchus by electrocauterization slightly improved the respiratory function; but on the following day emergency bronchoscopy was again necessary and the patient died of acute respiratory failure.

The Postmortem Study

Metastases of an embryonal carcinoma with inclusion of cellular formations similar to a chorio-epithelioma in the region of the right main bronchus. Partial tumor necrosis and perforation into the bronchi, trachea and esophagus. Esophago-mediastinal fistula, 4 cm in diameter. Metastases in both lungs and pleural cavities. Posterior mediastino-costo-diaphragmatic abscess on the right side.

Diagnostic Studies

Clinical diagnosis of testicular tumors is relatively easy. A hard swelling of the testicle in a male between 20 and 50 years, producing no other symp-

Fig. 3—Concentric stenosis of the right stem bronchus (→) due to the enlarged hilar and posterior mediastinal lymph nodes.

toms, must be considered highly suspicious for malignancy. Inflammatory swellings of the epididymis are generally painful. Hydrocele of the testis can be ruled out by palpation and diaphanoscopy.*

Orchidectomy usually confirms the clinical diagnosis of malignancy. In cases where surgical exploration does not give a conclusive diagnosis, biopsy of the tumorous mass is indicated.

Histological Classification

Malignant testicular tumors comprise two categories: the germinal (96.5%) and non-germinal groups (3.5%). The germinal group included the following tumors:

---

*See Test Your Word Score Page 89.

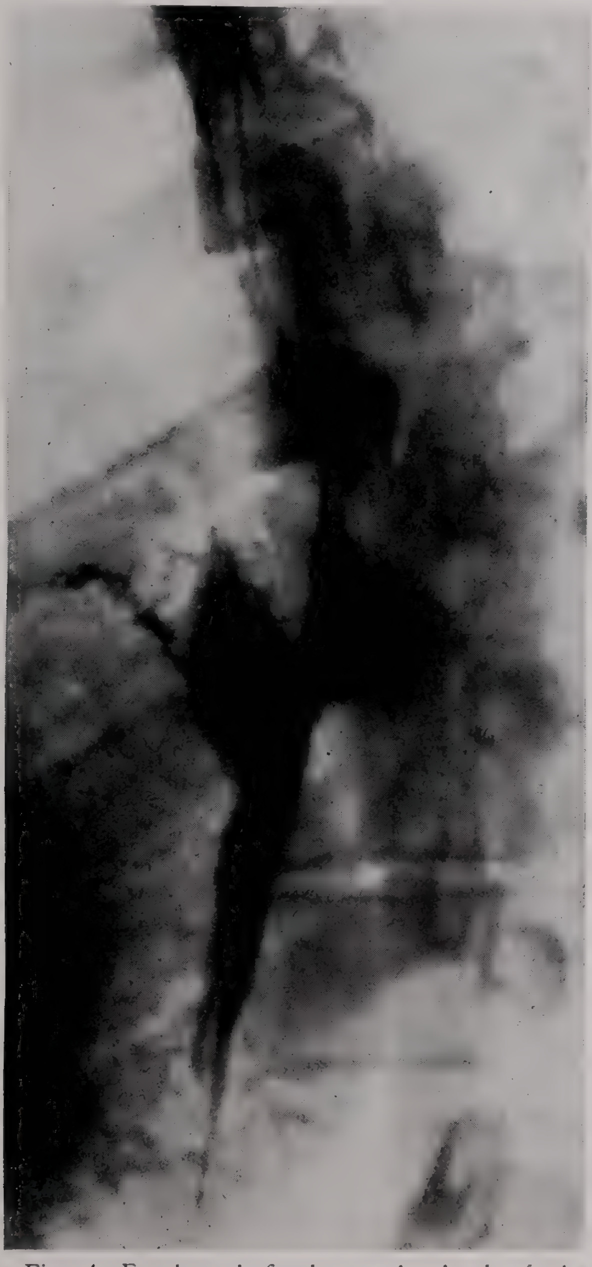

Fig. 4—Esophageal fistula at the level of the tracheal bifurcation due to malignant infiltration arising from the lymph node metastases.

Seminoma is the largest group with a relative frequency of 40%. It is the least malignant, the most radiosensitive, and the most radiocurable tumor of the testis.

Embryonal carcinoma (25%) has a consistent, highly malignant clinical behavior and shows a variety of histological pictures.

Teratoma (30%) is made up of recognizable somatic tissues corresponding to either fetal or adult stages of development. Teratoma is very often associated with either embryonal carcinoma, choriocarcinoma or both, and is then called *teratocarcinoma* (20%), the clinical behavior of which is dominated by the trophoblastic component.

Choriocarcinoma is the most malignant variety.

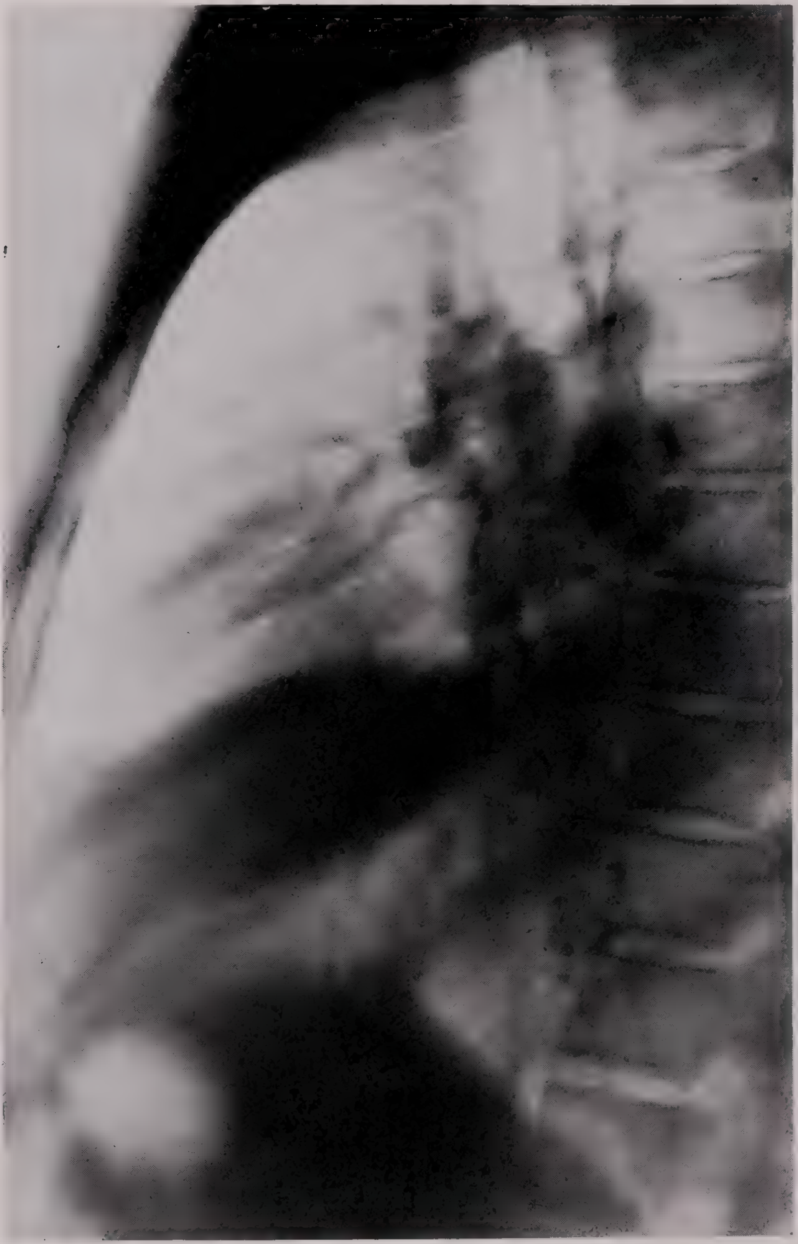

Fig. 5—Tumor metastases within the mediastinal lymph nodes at the level of Th 6/7 (→). Obstruction of the anterior branch and slight dislocation of the posterior branch of the thoracic duct.

Roentgen Studies

Evaluation of the lymphatic *metastatic spread* is important to judge therapy and prognosis. Roentgen examination of the lungs, lymphography, cavography and urography are necessary to detect clinically metastatic involvement or regional lymph nodes.

The *anatomy of the regional lymph nodes* is characterized by the fact that four to eight efferent lymph channels of the testis drain directly into aortic lymph nodes situated distal to the renal blood vessels. The lymph vessels of the right testis drain into the right latero-aortic and preaortic lymph nodes, those of the left testis into the left latero-aortic and preaortic lymph nodes. A few lymphatics arising from the medial aspect of the testis and the epididymis are closely connected with the deferent duct and enter the external iliac lymph nodes.[5]

Lymphography by injecting oily contrast material into a subcutaneous lymphatic of the foot does not visualize all the first regional lymph channels of the testicle. By injection of contrast medium directly in the efferent lymphatics of the testis during orchidectomy, one or several lymph nodes are filled at the level of the first to second lumbar vertebrae on the left side and of the first to the third lumbar vertebrae on the right side.[4,15] These lymph nodes are situated laterally to the aortic lymph nodes outlined by foot lymphography and are only occasionally demonstrated by the conventional method. Consequently neither foot nor testicular lymphography gives a complete visualization of the regional lymph nodes of the testis. Combined studies could give optimal results, but testicular lymphography is too tedious for routine use. False negative findings are therefore possible in conventional lymphography.

According to anatomical dissection studies the right latero-aortic node group contains far more nodes than the other aortic chains. Analyzing the aortic lymph node groups in 100 normal lymphograms,[12] the number of nodes demonstrated in the right aortic node groups is two to 18 with an average number of eight and is therefore by far the smallest compared to 12 of the pre- and retroaortic groups and 16 of the left latero-aortic group. In 40% of all cases the upper level of the right latero-aortic nodes filled with contrast agent was situated at L 3, and only in 10% at L 1. The classical finding of three equally developed aortic lymph node chains is therefore present in only about 25% of all cases and scarce visualization of the right aortic node group in the lymphogram is relatively common. Cavography as an additional method will reveal metastases to this node group by indirect roentgendiagnostic signs, such as compression, dislocation and infiltration.

Lymphographic Diagnosis

Lymphographic investigations of patients with malignant tumors of the testis have been reported.[2,10,13,16,18]

Seventy-four patients with malignant testicular tumors were investigated by mainly bilateral foot lymphography after unilateral orchidectomy and prior to radiotherapy. No testicular lymphograms were done. Thirty-six cases were seminoma, 16 embryonal carcinoma, 11 teratocarcinoma, four teratoma, two choriocarcinoma and five non-germinal malignant tumors. Thirty-four patients (46%) showed pathological lymphographic findings. The rate of malignant metastatic spread to regional lymph nodes was approximately 50% in embryonal carcinoma, teratoma, teratocarcinoma and choriocarcinoma, whereas one third of the seminoma group had lymph node metastases.

The high diagnostic value of lymphography for detecting malignant metastatic spread becomes evident when comparing the figures in a series of 900 cases not investigated by lymphography.[7] The incidence of lymph node metastases was 11% in seminoma, 24% in teratoma, and 30% in embryonal carcinoma and teratocarcinoma. In our case material bilateral metastases in the regional aortic lymph nodes were found in 11 patients and unilateral metastases on the contralateral side in two patients. Malignant spread to the iliac node groups was demonstrated in 10 advanced cases, five of which showed bilateral involvement. Only one patient with malignant infiltration of the scrotum had evidence of inguinal lymph node metastases.

Inguinal metastases can also be due to a reflux of tumor cells from the iliac region. Enlarged lymph nodes with filling defects were present in 31 cases and dislocation of lymph nodes and lymph vessels in 14 cases. Stasis of the lymphatic circulation was observed in 13 patients and non-filling of node groups due to malignant infiltration, leading to a collateral circulation, in six cases. Obstruction of the thoracic duct occurred occasionally.

Different histological types of malignant testicular tumors lead to identical lymphographic findings. Filling defects in lymph nodes due to metastatic deposits and slight dislocation of the normal contrast-filled lymphatic tissue are found in early forms of metastases. Extensive displacement of the remaining lymphatic tissue, complete replacement by malignant tissue, and blockage of the lymphatic circulation indicate advanced stages of malignant disease. Diagnosis of metastases in aortic lymph nodes at the level of the kidneys may be difficult because reactive hyperplasia of this group of nodes is a common finding. Reactive hyperplasia indicates a response of the lymph nodes to agents such as tumor cells or unspecific or inflammatory toxic agents especially after orchidectomy. Follow-up studies and second-look lymphograms of these lymph nodes are necessary to detect metastatic involvement at a later stage.

Accurate staging, exact planning, and control of treatment are the clinical indications for performing lymphography in cases of *seminoma*. Preoperative localization of lymph node metastases is of great importance in *teratocarcinoma* because excision of the aortic lymph nodes in unilateral metastases gives good results. Preoperative radiographic control facilitates the complete operative removal of the regional lymph nodes infiltrated by tumor. In cases of *choriocarcinoma* lymphography may give information about prognosis and therapy results in spite of the poor prognosis of these malignant tumors.

Treatment Techniques

Orchidectomy

Treatment of testis tumors entails *radical orchidectomy* as the first measure. According to the histological type of the malignancy and the extent of metastasis, different treatment techniques are employed.

Irradiation

In *seminoma* prophylactic and therapeutic irradiation of the retroperitoneal lymph nodes is given on an iliac (right or left) and an umbilical portal; both the inguino-iliac and aortic node groups are irradiated with a total dose of 4000 rh Co^{60}. In cases of positive lymphographic findings in the aortic lymph nodes additional prophylactic regional irradiation of the left supraclavicular lymph node groups with 4000 rh caes is performed. Cases of *embryonal carcinoma,* including *choriocarcinoma* and *teratocarcinoma,* are prophylactically and therapeutically irradiated with a total dose of 4500-5000 rh Co^{60} in both the inguino-iliac and aortic regions. Prophylactic irradiation[9] of the left supraclavicular region with a dose of 4000 rh caes is routinely given.

Prophylactic irradiation treatment of the supraclavicular node groups should, however, be guided to a greater extent by the results of lymphography. In a study of 336 lymphograms of our case material[11] contrast filling of the left supraclavicular nodes was present in 40%, filling of the right nodes in 5%, and bilateral visualization in 2%. Axillary lymph nodes were seen in 2.5% and cervical nodes in 3%. Lymph nodes lying parallel to the thoracic duct were demonstrated by lymphography in 15.6%, retrosternal nodes in 4.2%, hilar nodes in 4.2%, and paratracheal nodes in 5.9%. If prophylactic treatment of lymph node groups other than the inguino-iliac and aortic is planned, it should be selectively applied to the nodes demonstrated on the lymphogram. These contrast-filled node groups are in direct connection with the aortic region and are therefore directly reached by malignant metastatic spread. In the case presented, the involved posterior mediastinal lymph nodes were demonstrated by lymphography done immediately after orchidectomy. Prophylactic irradiation of the inguino-iliac and aortic regions, but not of this particular node group, was performed. Tumor metastases in the posterior mediastinum and the right hilar region were demonstrated about three years later, whereas no signs of recurrency were present in the iliac and aortic node groups.

Surgical Removal of Metastatic Nodes

Surgical excision of metastatic lymph nodes in the aortic region followed by postoperative irradiation treatment may be performed in cases of embryonal carcinoma, teratoma, teratocarcinoma and choriocarcinoma.[3,14,19,20]

Chemotherapy

Chemotherapy is applied for palliative treatment in cases with generalized metastases. In *seminoma,* alkylating substances show good results. *Embryonal carcinoma, teratoma, teratocarcinoma* and *choriocarcinoma* are treated with a combination of alkylating substances (cyclophosphamide), antimetaboliser (methotrexate) and actinomycin D or with mitramycin alone.

Results

Out of the total of 74 patients, 57 were observed for more than two years. The presentation of this relatively small number of cases compared to the large series of 900 patients reported by Dixon and Moore is justified because lymphography was used to evaluate the extent of malignant metastatic spread. A two-year survival rate seems to be sufficient to judge the value of lymphography since most patients with a lethal course of this disease succumb within the first two years.[7]

Seminoma is a highly curable tumor. The two-year arrest rate in our series is 92% compared to Dixon and Moore's 93.6%. A slightly higher survival rate was observed in cases of *embryonal carcinoma* and *teratocarcinoma* of 54.5% rsp. 72.5% compared to 41.3% rsp. 52.1%.[6]

Conclusion

Although our case material (57 cases) is about 16 times smaller than that of *Dixon and Moore* (900 cases) the increase in the two-year arrest rate might be due to better tumor staging by lymphography. A five-year period of observation and more abundant case material are necessary to judge the actual influence of lymphography on the prognosis of malignant tumors of the testis.

Fracture Conference

A Subtrochanteric Fracture

THE CHIEF ADVANTAGE of a stable osteosynthesis is the possibility of early, pain-free, active mobilization, allowing for early full reconstitution of function of the damaged soft tissues. The results are particularly impressive in fractures of the forearm and the femur, as well as in intra-articular fractures.

The bone healing following an osteosynthesis depends upon the stability of the fixation and the viability of the bone fragments. Frequently these two basic prerequisites are not fully appreciated and failures result.

Every open reduction and internal fixation carries the danger of infection.

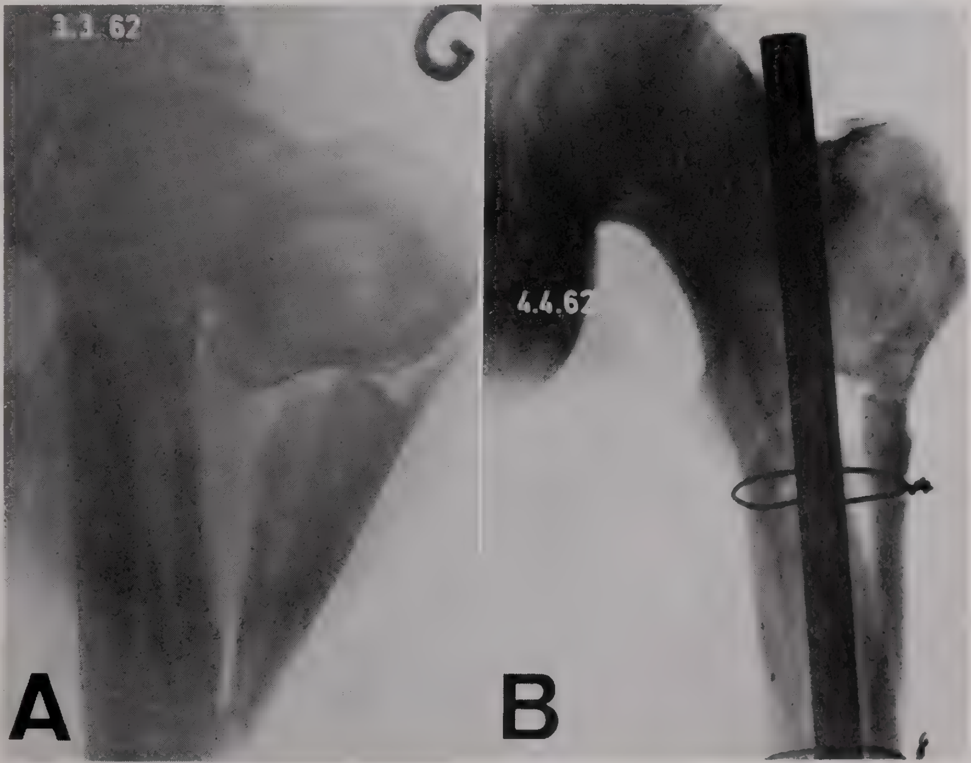

Fig. 1—(a-left) Intertrochanteric fracture; (b-right) Intramedullary nail and wire.

When one electively undertakes a procedure which involves a calculated risk, then one is obliged to obey all the basic principles in order to be as certain as possible of success. Only when an operation can assure a better result than non-operative treatment is the surgeon justified in undertaking an operative intervention.

The following case of a subtrochanteric fracture which had been operated upon seven times within five years, until union was finally obtained, illustrates well that a method should be employed only when one can be certain of success.

Case History

On March 3, 1962, a 24-year-old telephone fitter sustained a comminuted subtrochanteric fracture of the left femur (Figure A) in a ski accident. On March 4 this was treated with intramedullary nailing and a wire-cerclage (Figure B). On October 23 the metal was removed. On December 3 the patient sustained a spontaneous refracture (Figure C). On December 17, 1962, a Rush-nail was employed to secure internal fixation (Figure D). The nail was removed on November 8, 1963, with sound union of the fracture but with a marked external rotation deformity of the leg. Because of this, on August 16, 1964, a corrective intertrochanteric osteotomy was performed. This went on to non-union (Figure E). On June 15, 1965, one screw was removed and a cancellous bone graft inserted.

On August 30, 1966, the patient came under the care of an orthopedic surgeon (Figure F). The patient complained of pain in the left hip joint and was unable to bear weight on the left leg which was 3 cm shorter with very atrophic thigh musculature. The rotation deformity had been corrected; but in its place the patient had a considerable varus deformity and a pseudarthrosis where the intertrochanteric osteotomy had been carried out. On October 22, 1966, the final procedure was undertaken. This consisted of decortication, removal of the plate, and stabilization of the pseudarthrosis with a condyle plate and compression. At the same time an axial correction was made which consisted of 25° of abduction and 10° of internal rotation.

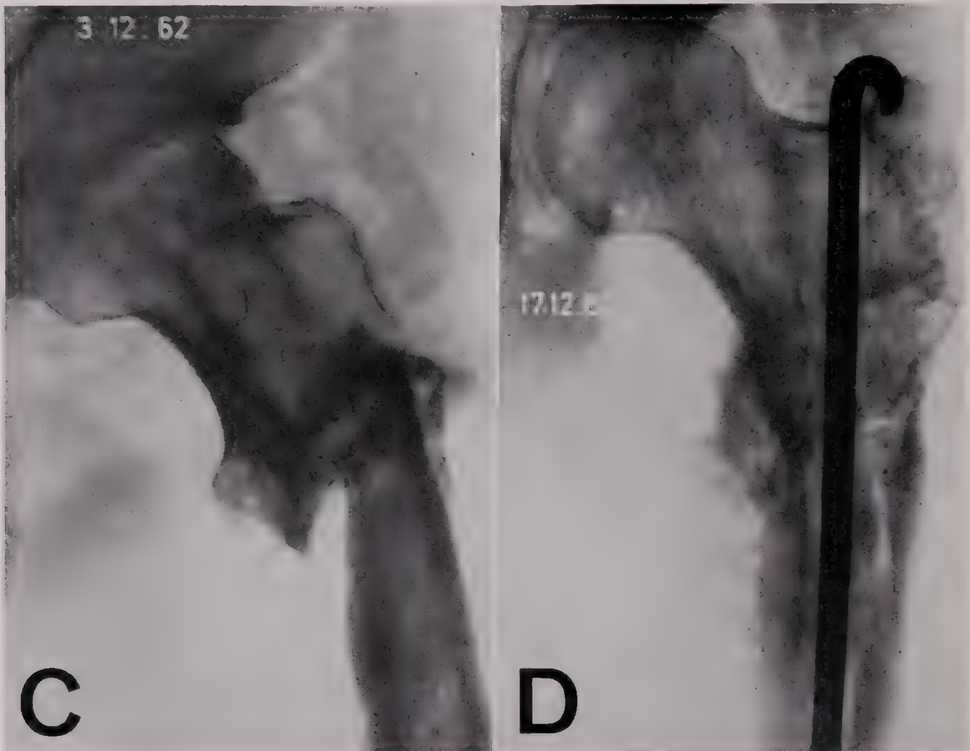

Fig. 1—(c-left) Refracture after removal of the nail; (d-right) Internal fixation by means of a Rush-nail.

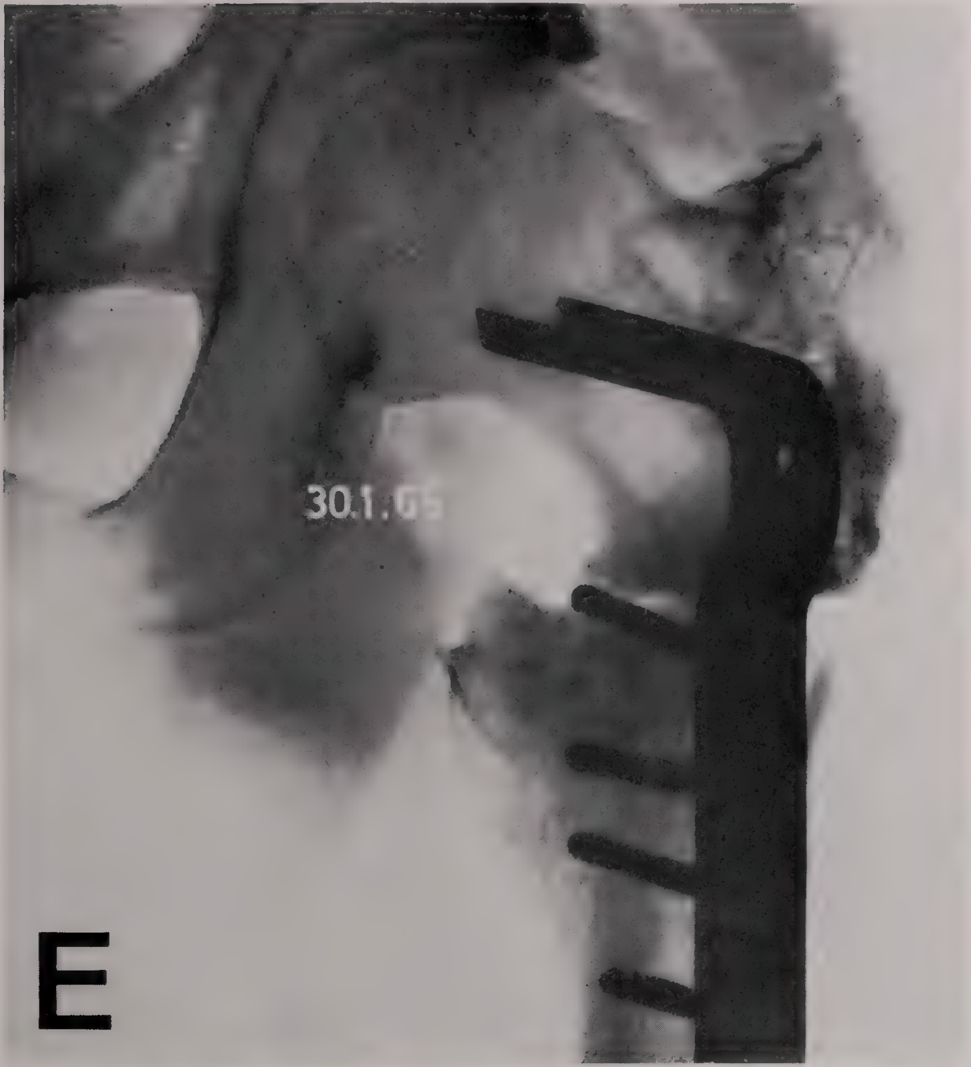

Fig. 1—(e) Intertrochanteric osteotomy with a screw in the osteotomy line.

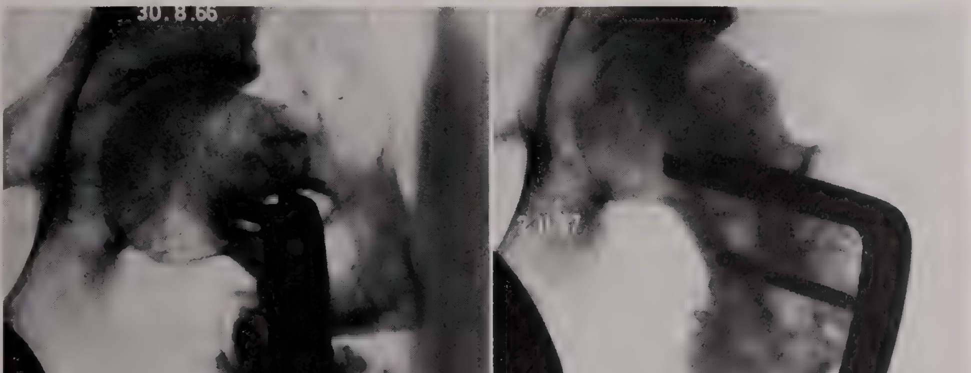

Fig. 1—(f-left) Non-union after intertrochanteric derotation osteotomy and removal of the screw in the osteotomy line; (g-right) end result one year after application of a right-angle compression plate.

At follow-up one year later, on November 2, 1967, the femur had consolidated and maintained the desired correction (Figure G). The patient was free of symptoms, had no disability, and was able to perform his previous work. The left leg was 1 cm shorter. The hip movements were: flexion/extension right 50/180, left 80/180; abduction/adduction right 120/60, left 115/65; external rotation/internal rotation right 30/30, left 40/10.

The treatment of this case took five and one-half years. It consisted of seven operations; and 76 x-rays had been taken. During this period the patient was totally incapacitated for 12 months.

Discussion

This case illustrates that, initially, all principles of a stable osteosynthesis were not observed. In sharp contrast stands the quick healing of the pseudarthrosis with correction of the deformity once a stable osteosynthesis had been carried out finally. One must say that the patient was particularly lucky that in the course of the seven operations he did not develop osteomyelitis.

Operative Indications

In a comminuted subtrochanteric fracture an open reduction and internal fixation are indicated only if it is possible to carry out such a stable osteosynthesis that after two weeks the patient can be ambulant and able to bear some weight on the extremity.

Intramedullary Nailing

An intramedullary nail cannot stabilize a subtrochanteric fracture, and the use of concomitant wire-cerclage frequently leads to partial bone necrosis.

Removal of the Metal

At the time of metal removal the bone was not fully consolidated and creeping substitution had not fully occurred. This led to the inevitable refracture. If incomplete consolidation is encountered at the time of metal removal, new internal fixation must be employed at that time in order to prevent refractures.

Rush-Nailing

A Rush-nail secures only an adaptation-osteosynthesis. When one employs a Rush-nail, reduction must be absolutely perfect and maintainable; otherwise deformities such as this will result.

Removal of the Metal

The fracture had consolidated, but a marked external rotational deformity was present. A corrective osteotomy should have been carried out immediately.

The Corrective Osteotomy

The surgeon had the indications for such an osteotomy, but unfortunately his technique left much to be desired. The blade of the plate, for the most part, was not in the femoral neck, which considerably diminished its holding power. The fragments were not accurately reduced and were not brought under compression. Furthermore, one screw had been inserted into the osteotomy fissure itself.

The Removal of the Screw and Cancellous Bone Graft

The loose screw which had been placed in the osteotomy fissure was removed and replaced with cancellous bone. In the presence of an unstable osteosynthesis and a pseudarthrosis, grafting alone could not be expected to lead to consolidation.

Decortication, Corrective Osteotomy, Compression Osteosynthesis

The procedure of decortication has been recently revived by Judet, but had already been described in 1936 by Naughton Dunn as the "shingling operation." It is particularly useful in secondary procedures and will substitute, as in this case, for cancellous bone grafting. The condyle plate was employed here as a tension band and the osteotomy was brought under compression. This time the blade of the condyle plate was placed axially in the centre of the femoral neck, and absolute rigid fixation with compression was obtained. The compression of over 100 kg led to a rapid healing of the pseudarthrosis, a phenomenon which we have already observed in hundreds of pseudarthroses treated only with stable osteosynthesis and compression without additional bone grafting, as long as we were dealing with a vascularized pseudarthrosis.

Summary

This case illustrates that the operative treatment of femoral fractures is a difficult intervention and that a stable osteosynthesis is difficult and can be achieved only when the basic principles, namely anatomic reduction and viability of the bone fragments are adhered to.

Mail-Order "Health"

No other country in the world begins to approach our national use of direct selling by mail. The public has amazing confidence in products so advertised. . . . The quacks with their nostrums, the miracle makers who can bring new sexual vigor to old men, grow hair or make it "permanently" vanish, develop the bust, cure every ill from cancer to hemorrhoids, produce pills to make skinny people fat or fat people skinny, persist in their efforts, but we believe we have made the going considerably tougher. . . . The promoters of these schemes always think up a new wrinkle when we put them out of business, and it is amazing the diversity and the novelty of the schemes that are involved.*

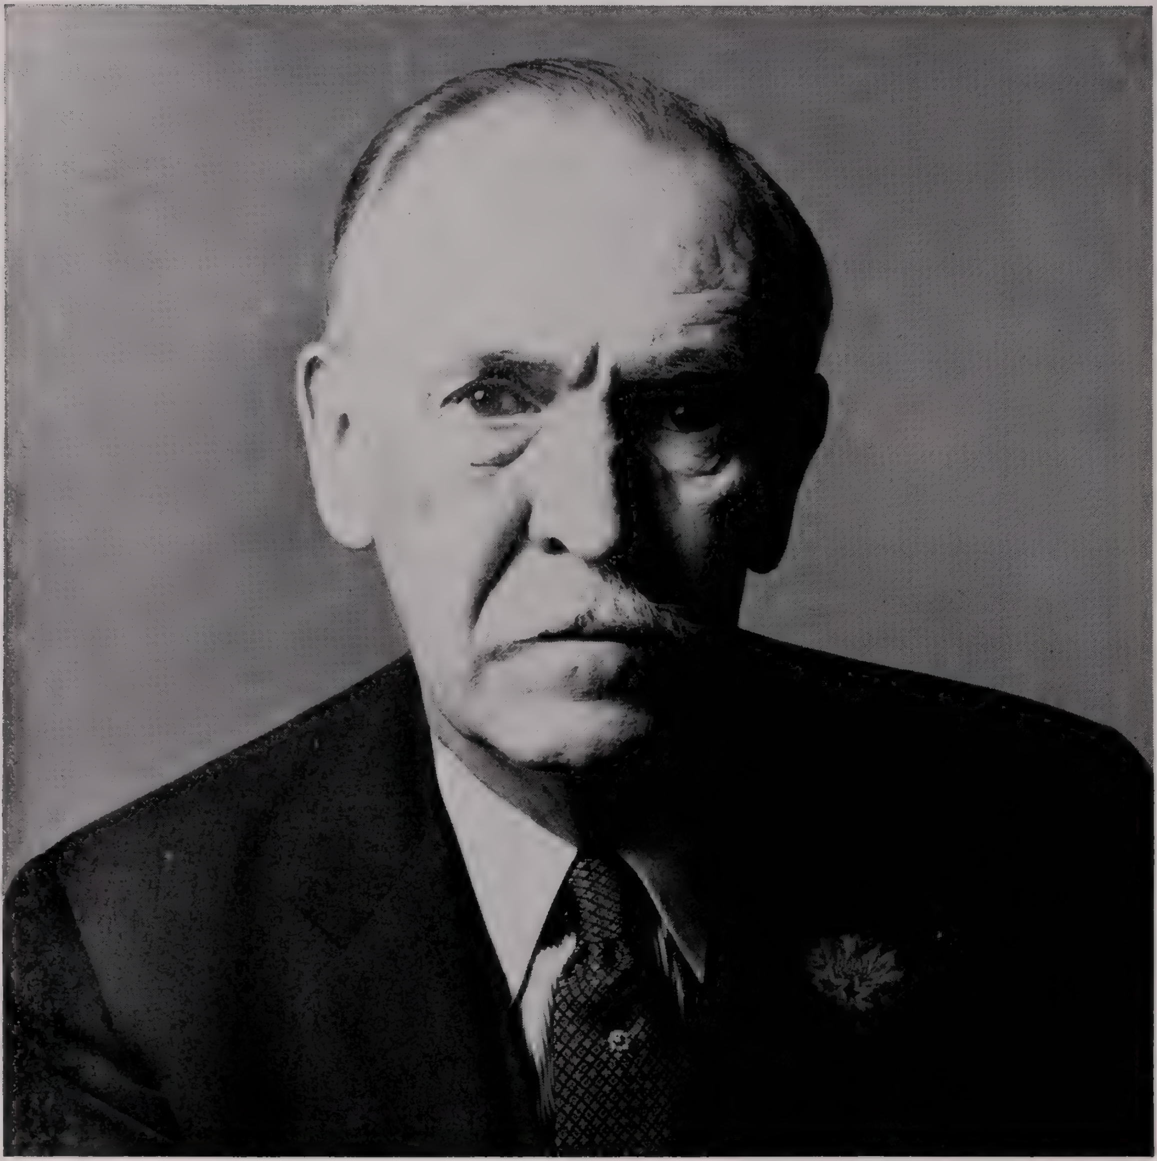
Gourmet But Not Gourmand

Great suppers do the stomach much offend,
Sup light if quiet you to sleep intend.
—Regimen Sanitatis Salerni

Editor's note: With economy and directness the School warns here that overeating breeds insomnia. This couplet should be memorized by gourmands—unless they intend to stay up all night.

Help the Needy!



A patient of advancing years may appear to "have everything," but may well be in need—*medically*. You know the symptoms. He's tired most of the time. Though there's nothing wrong with him organically, he suffers from general malaise. Lassitude has become his way of life . . . vague aches and pains his major concern.

Such a patient has entered the "Mediatric Age"—that stage of his life in which he's an ideal candidate for MEDIATRIC. This preparation provides the anabolic benefits of gonadal steroids, plus a gentle mood uplift and the nutritional support he's apt to need. MEDIATRIC is intended to help keep him more alert and active, and relieve general malaise . . . to help restore that sense of physical and emotional well-being that the elderly *deserve* to enjoy.

The estrogen component in MEDIATRIC is PREMARIN® (conjugated estrogens-equine), the orally active, natural estrogen so widely prescribed for its physiologic and metabolic benefits. The combination of estrogen and *methyltestosterone* can help maintain anabolic balance to forestall premature degenerative changes related to estrogen deficiency. MEDIATRIC also supplies a small amount of *methamphetamine HCl* to provide a gentle mood uplift, and nutritional supplements specially selected to meet the needs of the aging.

CONTRAINDICATION: Carcinoma of the prostate, due to methyltestosterone component.
WARNING: Some patients with pernicious anemia may not respond to treatment with the Tablets or Capsules, nor is cessation of response predictable. Periodic examinations and laboratory studies of pernicious anemia patients are essential and recommended.
SIDE EFFECTS: In addition to withdrawal bleeding, breast tenderness or hirsutism may occur.
SUGGESTED DOSAGES: *Male and female*—1 Tablet or Capsule, or 3 teaspoonfuls Liquid, daily or as required.
In the female: To avoid continuous stimulation of breast and uterus, cyclic therapy is recommended (3 week regimen with 1 week rest period—Withdrawal bleeding may occur during this 1 week rest period).
In the male: A careful check should be made on the status of the prostate gland when therapy is given for protracted intervals.
SUPPLIED: No. 752—MEDIATRIC Tablets, in bottles of 100 and 1,000. No. 252—MEDIATRIC Capsules, in bottles of 30, 100, and 1,000. No. 910—MEDIATRIC Liquid, in bottles of 16 fluidounces.

	Each MEDIATRIC Tablet or Capsule contains:	Each 15 cc. (3 teaspoonfuls) of MEDIATRIC Liquid contains:
Conjugated estrogens-equine (PREMARIN®)	0.25 mg.	0.25 mg.
Methyltestosterone	2.5 mg.	2.5 mg.
Methamphetamine HCl	1.0 mg.	1.0 mg.
Cyanocobalamin	2.5 mcg.	1.5 mcg.

How to turn a 14-year-old boy into a hardened criminal.

Just forget your keys in your car one day.

Tempt some fourteen-year-old boy into going for a joyride.

Oh, he could be a good kid — just weak.

And taking your car might be the first time he's ever broken the law.

But the minute he hops behind that wheel and turns the key, his life may be ruined.

He'll drive around for a few hours, endangering the life of every man, woman and child who crosses his path.

He might be caught the very first time he takes a car. Or if he's not caught by the police he'll leave your car somewhere and decide to do it again, and again, until the day he does get caught.

Teen-agers steal more than 1,000 cars every day.

The U. S. Department of Justice and your state and local law-enforcement agencies are concerned.

They know that taking a car for a joyride is just the first step.

Our prisons are filled with men who started out this way. They went on to become thieves, muggers, and even killers.

You can do something to help solve this terrible problem.

Whenever you get out of your car, even for a second, take your keys. Lock your car.

Every time you do this you may keep a good boy from going bad.

Don't help a good boy go bad. Lock your car. Take your keys.

Grand Rounds

Infantile Cytomegalic Inclusion Disease
vs.
Chronic Gastrointestinal Disturbances

E. ROSSI, M.D.*
M. KÜHNI, M.D.*
Berne, Switzerland

UNTIL QUITE RECENTLY autopsy findings or the difficult demonstration of cells with cytomegalic inclusions in the urine sediment were the main means of establishing cytomegalic inclusion disease. Today diagnosis has become relatively easy and certain with the aid of complement fixation reactions with neutralization tests, and above all with the isolation of viruses from the urine. Since the clinical picture is very indistinct and permits only suspicion of the diagnosis, these tests are important. Here we shall consider mainly gastrointestinal disturbances. Chronic disturbances are fairly common in childhood, yet it is often impossible to make an etiological diagnosis.

In the past, virus diseases were held to be the cause of *acute* gastroenteritis, but the observation that the cytomegalovirus may also produce *chronic* gastrointestinal disturbances shows that virus diseases can likewise be responsible for such disturbances. Until now it has not been proved whether the presence of the virus is the cause of the symptoms or whether it is a mere coincidence. Similar problems have already been discussed in conjunction with toxoplasmosis and pneumocystis carinii. With this critical view in mind we present two cases of chronic gastrointestinal infections in which we found the triad: positive complement fixation reactions, cells with cytomegalic inclusions, and cytomegalic virus in the urine: cases in which we could exclude through further investigations other reasons for diarrheas.

---

*Children's Hospital, University of Berne, Switzerland.

Background

In 1904 Jesionek and Kiolemenoglou[5] and shortly afterwards Ribbert[7] described for the first time the disease with the characteristic inclusions in the kidneys. It was first considered a protozoan disease, until in 1926 Cole and Kuttner[1] succeeded in transplanting the cytomegalovirus over seven generations of guinea pigs. Consequently these investigators believed in viral genesis. But it was only in 1956 that viral etiology was definitely established by Rowe[9], Smith[11] and Weller.[15]

Seifert and Oehme,[10] as of 1957, found 178 reports of children and 20 reports of adults with cytomegalovirus infection. Since then it has been possible, thanks to complement fixation reactions and by the isolation of viruses, to discover the incidence of infection in large groups of the population. It has been proved that cytomegalic inclusion disease is very common and that 50% of the population have had it before the age of 30[12,13] (Table 1), though infection may often remain inapparent.

TABLE 1

Incidence of Complement Fixation Reaction for Cytomegalic Inclusion Disease in the Course of Life (Stern, 1965, London)

up to 3 months	35%
1/2 to 5 years	4%
5-10 years	15%
10-12 years	47%
15-35 years	68%
36-60 years	81%

Many authors noted an affection of the gastrointestinal tract, especially in adults, most of whom had small or larger ulcerative lesions without specific localization.[6,14] Children often suffer from chronic, sometimes bloody diarrhea, without ulcers being detectable in vivo.[2,3,4] Symptoms are extremely variable. On the one hand small ulcers may not cause trouble; on the other they may produce severe, profuse bloody diarrhea necessitating bowel resection or internal therapy.

Incidence

The incidence of infection varies according to geographical and living conditions. Table 2 shows the incidence of positive complement fixation reaction for cytomegalovirus infection in children from one year to five years of age. These data are influenced not only by geographical circumstances, but also by population density, social conditions, and severe diseases aggravating the infant's general state of health. Also, pregnant women seem to be especially subject to cytomegalovirus infection. Table 3 summarizes these factors.

TABLE 2

Incidence of Positive Complement Fixation Reaction for Cytomegalovirus Infection in Children from 1 to 5 Years

District of Columbia (USA)	15%
Paris	41%
Helsinki	69%
Egypt	85%

TABLE 3

Factors Influencing Cytomegalovirus Infection

- Geographical aspects
- Density of population
- Social conditions
- Premature birth
- Severe illnesses
  - tumors: sarcoma
    - Hodgkin's disease
    - leukemia
    - thymoma etc.
  - immunosuppressive therapy in organ transplantation
  - accidents
- Pregnancy

Etiology of Cytomegalic Inclusion Disease

Virus etiology has been established by the above-mentioned authors. The viruses measure 113 millimicrons and are relatively insensitive to the effect of interferon. They also induce little interferon. Since the virus is present in the urine and saliva, it is likely that transmission is through these excretions, but it may also be transferred through a pathologically changed placenta. It produces nuclear inclusions which usually stain acidophilic with eosin dyes. The lesions have a homogeneous central area with a hazy peripheral zone and a thin clear halo.

Clinical Diagnosis

When cytomegalovirus infection is suspected, the tests in Table 4 should

TABLE 4

Methods of Examination with a View to Establish Cytomegalic Inclusion Disease

1. Complement fixation reaction
2. Neutralization test
3. Isolation of giant cells from the urine (not from the saliva or from the gastric juice)
4. Isolation of viruses from the urine
5. Isolation of cytomegalic cells from biopsy material
6. Isolation of cytomegaloviruses from biopsy material

TABLE 5

   - g. hemolytic anemia
   - h. mental and corporal retardation
   - i. in organ transplantation (immunosuppressive therapy)

be made seriatim. Clinically two forms of infection are distinguished: congenital and acquired[8] (Table 5). It may, however, be difficult to differentiate between the two forms in practice. The two cases recorded below demonstrate the difficulty of diagnosis and the complexity of the disease.

Congenital Infection Case

Viruses may be transferred across the placenta to the fetus from a mother with viremia. The organs affected are mainly the brain, liver and blood-forming system. In some cases the mother already shows such symptoms as skin rashes, influenza-like illness, etc. In the child the main symptoms are erythroblastosis with thrombocytopenia and hepatosplenomegaly, suggestive of luetic disease, toxoplasmosis, listerosis* or septicemia. Only complement fixation reaction, virus isolation and cells with nuclear inclusions in the urine will permit a definite diagnosis. In some cases, cerebral symptoms will appear at once; in others they become manifest only at a later period. In final stages the disease is often associated with pneumocystis carinii.

In Case 1 the main symptom was bloody mucous diarrhea from the first days of life. A malabsorption syndrome was suspected. Dietetic treatment was not successful. Other findings such as corporal and mental retardation were interpreted as a result of the intestinal disturbances. Though the body was too small, it was well proportioned; therefore microcephaly was not noted. But on minute investigation retinitis pigmentosa was found, suggesting an infectious illness.

Acquired Infection Case

In the second case, that of M. P., intestinal symptoms did not appear until the second month of life. At the age of five months cutaneous symptoms completed the clinical picture. The patient developed a protein-losing enteropathy leading to severe hypoproteinemia and intermittently reappearing edema. Repeated infusions of albumin were necessary. This manifestation was quite extraordinary and has not yet been described. The cerebrum was not affected. The child was too small and showed mild hepatomegaly. Liver function tests were normal. Puncture biopsy revealed mild chronic hepatitis. Minute gastroenterologic investigations finally led to the exclusion of other causes of the chronic gastrointestinal disturbances. Since symptoms showed only after the second month of life and the cerebrum was not affected, we suspected acquired infection in this case. However, with symptoms appearing in the first weeks of life it cannot be decided with certainty just when the child was infected. Severe brain damage with deformities and the onset of severe symptoms immediately after birth suggest prenatal infection. According to the deformities the time of infection may be approximately determined.

A positive complement fixation reaction titer in the child is not in itself conclusive, given the great dissemination of the disease. Table 1 shows that a positive complement fixation reaction is quite common in the first months of life; generally the antibodies found have been passively transmitted by the mother. In children from six months to five years of age, a high titer usually signifies acute acquired infection. In older patients it may be a sign equally of previous and of new infection. Only the isolation of the virus and the cytomegalic cells from the urine or from biopsy material will establish the presence of disease. However, it has not yet been absolutely proved that the presence of the virus is really the cause of the sickness. It may be that it is of only secondary appearance.

---

*See Test Your Word Score Page 89.

Combined with Pneumocystis Carinii

A very striking combination is that with pneumocystis carinii which we observed in two of our patients.

Children with chronic diseases or cerebral damage, whatever the symptoms, should be investigated for cytomegalic inclusion disease.

Chronic gastrointestinal disturbances are among the main problems in pediatrics. The symptoms of cytomegalic inclusion disease are extremely variable. On the one hand, infection may produce mild diarrhea which soon disappears; on the other it may cause severe gastroenteritis with blood in the stools and massive loss of albumin, as in our case. Even the ulcerative form of the disease may, in some cases, be discovered only incidentally at autopsy; in other cases it can lead to diseases resembling colitis ulcerosa and finally necessitate bowel resection. When gastroenteric symptoms appear, minute examination is indicated, including a series of barium enemas, biopsies, rectoscopy, loading tests with di- and monosaccharides and with gliadin, sweat tests, bacteriological examinations, duodenal intubation with a view to detect parasites and enzymes, etc. Only when other causes are excluded and complement fixation reactions and virus isolation from the urine are positive, may diagnosis of cytomegalic inclusion disease in the gastrointestinal tract be established.

Combination with other causes, especially with coli-infections, is quite common.

Unfortunately there is no satisfactory therapy available at present. Administration of corticosteroids and measles vaccine has been recommended in order to induce higher interferon blood levels. Our patient, M. P., was given rubella vaccine because of his low gamma globulin level and consequent danger of infection, but without success.

There is no definite prognosis: the fact that 50% of the population have been affected at some time before the age of 30 suggests that many infections remain inapparent or very mild. On thorough investigation of all children with chronic diseases, congenital cerebral defects, microcephaly, septicemia and hemolytic anemia in the neonatal period, the cytomegalovirus has often been demonstrated to be present.

Case Reports

Case 1, born June 28, 1966

Pregnancy and birth normal. Weight at birth 2,600 g. Very large placenta. The infant had difficulty in sucking, did not progress satisfactorily and appeared ill. At four weeks of age diarrhea started with bloody, mucous stools, and enlargement of the spleen and liver was noted. Various diets were tried: skim milk, soya milk, elimination of disaccharides and gliadin—with no success. The child showed developmental retardation; he had intermittent fever attacks due to bronchitis and otitis associated with febrile seizures.

Physical Examination: November 6, 1967

Severe dystrophy. Weight 7,000 g, length 71.5 cm, head 43.5 cm, all distinctly below the third percentile. On the skin, especially on the face, a strange reddish exanthem, slightly scurfy and spotty. The infant showed psychomotor retardation and corresponded developmentally to a child of nine months. Muscular system hypotonic. Skull slightly turricephalic. Otitis media on the right side. Ocular fundus with fine pigmentation from the back pole to the peripheral zone as a sign of retinitis pigmentosa. Bronchitis.

Laboratory Findings

Skin and liver puncture biopsies excluded reticulosis. Hemoglobin 10.5 gm. Hypochromia, white cell count and thrombocytes normal. Liver enzymes and bilirubin normal. Xylose and fat resorption, sweat test normal. Washermann reaction and examination for toxoplasmosis negative. Roentgenograph of the skull did not show any intracerebral calcifications. In the stools temporarily pathogenic coli 0 126 K 71 B 16. Lumbar puncture: 64/3 cells, 53/3 mononuclear and 11/3 polynuclear. Albumin 29 mg, glucose 50 mg percent. Cytomegalic antibodies in the serum 1:80. Cytomegaloviruses in the urine. Cytomegalic antibodies in the mother 1:40.

Clinical Course

Diarrhea persisted when coli-bacilli had disappeared from stools subsequent to treatment. Further dietary and antibiotic treatment was not successful. Diarrhea reappeared intermittently, often associated with new outburst of skin rashes.

Case 2, born April 27, 1966

Family history: an older brother was suffering from an itching eczema-like papular rash and often had infections until the age of two. Finally he had generalized edema, pleural effusion, ascites, and lost up to 0.5 g/die albumin in the urine. In the hospital he developed symptoms of bowel obstruction, finally necessitating laparotomy. Exitus after a few days. Diagnosis then was: nephrotic syndrome.

Personal history: pregnancy and birth normal. Intermittently reappearing diarrhea since the age of two months. Repeated bronchitis. At five months he developed a strange itching maculobullous exanthem. Edema on the extremities led to the diagnosis of hypoproteinemia.

Physical Examination: October 4, 1967

Cushingnoid appearance (after therapy with corticosteroids). Length 71.5 cm, weight 9,850 g, both far below the third percentile. On the lower abdomen and on both legs numerous red spots measuring up to 4 cm, slightly prominent and with signs of scratching. Liver 3 cm below the right costal margin. Abdomen notably protruding.

Laboratory Findings

Hemoglobin persistently too low, near 9.8 gm. Leucocytes between 6,700-18,900. Intermittent eosinophily up to 12 percent. No lymphopenia. Thrombocytes near 235,000. Xylose, saccharose, lactose, glucose and fat resorption normal. Duodenal intubation: no parasites, amylase and lipase normal. Sweat test normal. Biopsy of small intestine and rectum normal. Stool: no parasites, bacteriologic examination normal. Heavy loss of albumin into the intestine: after injection of 50 u Ci $\mathrm{Cl_3Cr^{51}}$, 10.5 % ($n = 1$) appeared in the stool seven days later. Notable elevation of the albumin turnover up to 462 mg/kg/die (normal = 0.145 %). Loss of albumin in the stool: 32.5 mg/kg/die (normal = 0). Liver enzymes (GOT, GPT, alcaline phosphatase), bilirubin and bromsulphthalein test normal. Liver puncture biopsy: mild chronic hepatitis. The most striking finding was a constant hypoproteinemia with albumin levels as low as 2.7 mg %. Electrophoresis: albumin 50 %.

Alpha 1:11%, alpha 2:22%, beta 12%, gamma globulin 5%. Pronounced diminution of immunoglobulin.

Ig A: 25 mg%	Ig M: 22 mg%	Ig G: 95 mg%
(n = 60 ± 8)	(n = 68 ± 17)	(n = 840 ± 120)

Examinations for Cytomegalic Inclusion Disease

CFR—titer in the mother 1:40. CFR—titer in the infant 1:30. Cytomegalovirus and cells with cytomegalic inclusions in the urine.

Clinical Course

Corticosteroids, antibiotics, elimination of food with animal albumin, gamma globulin, rubella vaccination did not influence the clinical picture. Severe hypoproteinemia with edema and ascites reappeared intermittently as well as diarrhea, sometimes bloody. In this course the general condition of the patient deteriorated and skin exanthem grew worse. One to two plasma infusions per week were necessary to keep the child alive.

Mountebanks

Legitimate practice soon gathered in its train the quack, and serious medication, the fake nostrum. By 1711 a Mrs. Sibylla Masters of Philadelphia was making "Tuscarora Rice" out of Indian corn and selling it as a sure cure for consumption. . . . Seneca rattlesnake root appeared in 1739 and Dr. John Tennent was awarded 100 pounds by the Virginia Colony for curing pleurisy with it. It was a popular nostrum with itinerant vendors for many years. In 1745 there came to Philadelphia (which was early a thriving medical center) a Frenchman by the name of Francis Torres, with a Chinese Stone and sundry mystic powders that, he claimed, would cure with equal ease, snakebite, cancer, toothache, gout and labor pains! Then in quick succession followed a flood of fakes and quacks—Perkins metallic tractors, galvanic wires and Brandreth's pills, and a vast company of itinerant mesmeric healers who gave out medicine, cast horoscopes, and felt head bumps.

In cities the associations of doctors could fight these imposters, but in the country and on the frontiers they had an uncontested field. Once again we see the settled town representative combating the itinerant. Connecticut legislated against these imposters in her queer old law forbidding mountebanks. Other states subsequently followed suit, so that the itinerant medical faker has always been under the eye of the sheriff.*

Success in marriage is much more than finding the right person: it is a matter of being the right person.—B. R. Brickner

Most young car thieves start your car the same way you do.

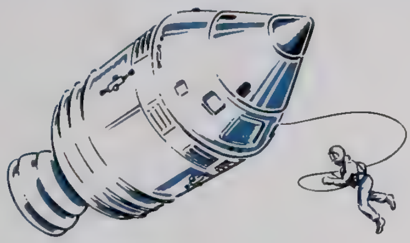
(with your keys)

Half the cars stolen last year had the keys left in the ignition. And more than half the car thieves were kids under 18. You don't have to be an "old pro" to steal a car . . . when the keys are in it.

Young car thieves need your help to steal your car. Don't give it to them.

LOCK YOUR CAR.
TAKE YOUR KEYS.

Advertising contributed for the public good.



Man in space, now fait accompli, re-emphasizes the importance of Uro-Phosphate therapy. Research into the effect of space travel on the astronaut reveals that weightlessness causes loss of bone calcium. As the bones are required to bear less and less of the weight of the body they lose calcium, increasing the calcium content of the urine. When physical activity is reduced, the acidity of the urine should be adjusted to keep increased calcium in solution . . . . a prophylaxis to prevent kidney or bladder calculi.

Uro-Phosphate®

NOW A SUGAR-COATED TABLET

Each tablet contains: METHENAMINE, 300 mg.; SODIUM ACID PHOSPHATE, 500 mg.

Uro-Phosphate gives comfort and protection when inactivity causes discomfort in the urinary function. It keeps calcium in solution, preventing calculi; it maintains clear, acid, sterile urine; it encourages complete voiding and lessens frequency when residual urine is present.

Uro-Phosphate contains sodium acid phosphate, a natural urinary acidifier. This component is fortified with methenamine which is inert until it reaches the acid urinary bladder. In this environment it releases a mild antiseptic keeping the urine sterile.

Uro-Phosphate is safe for continuous use. There are no contra-indications other than acidosis. It can be given in sufficient amount to keep the urine clear, acid and sterile. A heavy sugar coating protects its potency.

Dosage:

For protection of the inactive patient 1 or 2 tablets every 4 to 6 hours is usually sufficient to keep the urine clear, acid and sterile.

2 tablets on retiring will keep residual urine acid and sterile, contributing to comfort and rest.

A clinical supply will be sent to physicians and hospitals on request.

WILLIAM P. POYTHRESS & COMPANY, INC., RICHMOND, VIRGINIA 23217

Manufacturers of Ethical Pharmaceuticals

When the pink pill for U.R.I. symptoms speeds into action, someone somewhere breathes easier.

You provide prompt and continuous relief from symptoms of U.R.I. when you prescribe Novahistine Singlet. Novahistine Singlet is formulated to quickly relieve the fever and the aches and pains that so frequently accompany upper respiratory infections. And these continuous-release tablets provide a vasoconstrictor-antihistamine formulation to shrink swollen membranes and reduce congestion of the turbinates and sinuses.

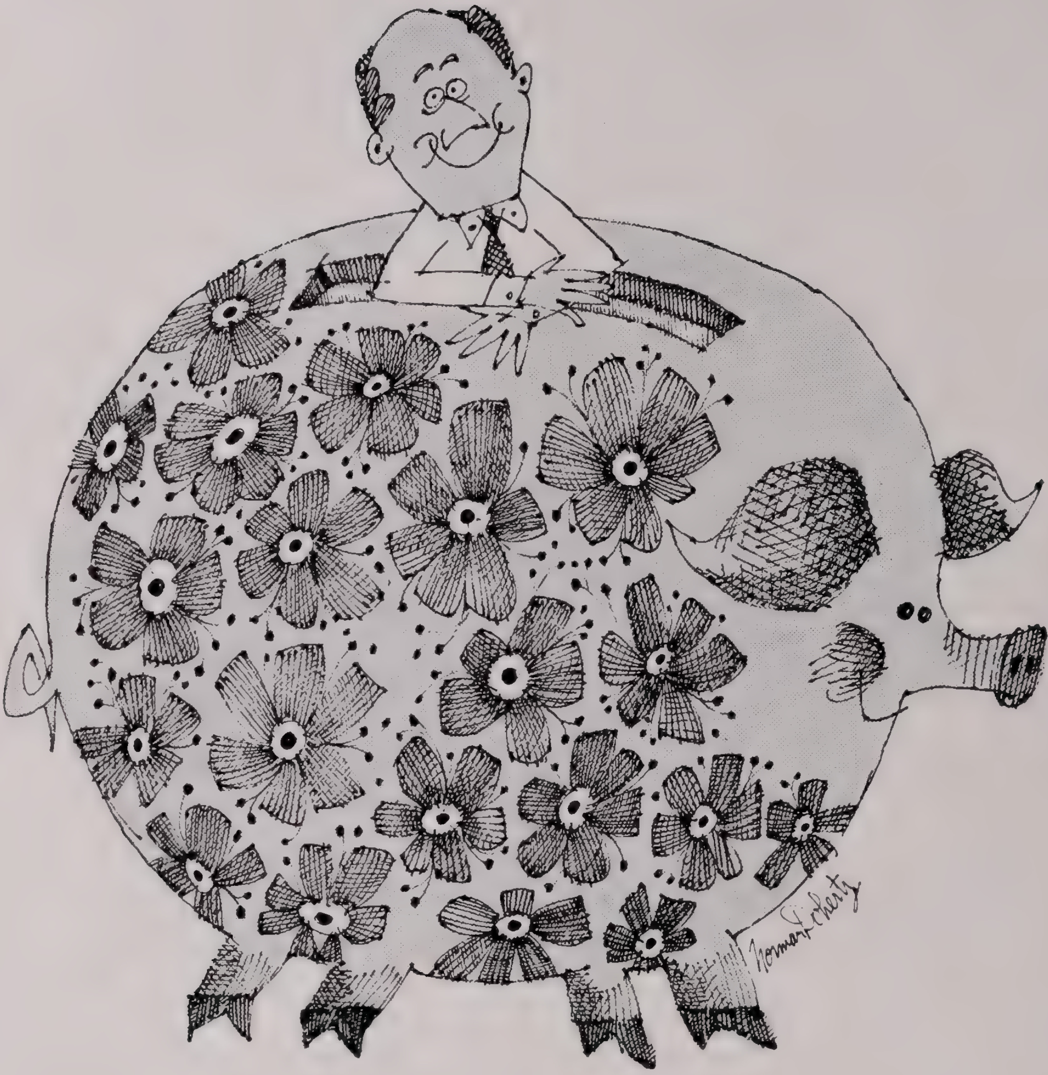
A total daily dosage of 3 or 4 tablets will normally provide the continuous relief your patient expects. Use with caution in patients with severe hypertension, diabetes mellitus, hyperthyroidism or urinary retention. Caution ambulatory patients that drowsiness may result.

PITMAN-MOORE Division of
The Dow Chemical Company,
Indianapolis, Indiana

Novahistine® Singlet decongestant-analgesic

(Each tablet contains: phenylephrine hydrochloride, 40 mg.; chlorpheniramine maleate, 8 mg.; acetaminophen, 500 mg.)

DOW



The first thing to save for your old age is you!

Everyone dreams of a pleasant retirement. And practical people save for it. But what good are plans and dreams if you aren't around to enjoy them? Be smart and have a complete health checkup every year. 1,400,000 people living today are cured of cancer. And a yearly checkup could save many thousands more. Plan now to have a future. Make an appointment today for your health checkup.

Allergic Reactions to Penicillins[*]

Advances in Understanding and Management

THE IMMUNOCHEMICAL mechanisms responsible for allergic reactions to penicillin in man have been the subject of numerous experimental investigations over the past ten years and have considerably advanced our knowledge on the mechanism of drug allergies. The interest in penicillin allergy stems from two main considerations. On one hand, allergic reactions to penicillins still represent a considerable nuisance in medical therapy. It may have been expected some years ago that other antibiotics would soon replace penicillins in therapy and thereby reduce penicillin hypersensitivity to a minor problem. But penicillins continue to represent about 30% of all administered antibiotics and their elimination from our therapeutic arsenal is less than ever predictable. With cumulative exposure of the population and with increasing use of penicillins and penicillin-like antibiotics for non-medical purposes, the absolute number of hypersensitive patients also appears to be rising. Allergic reactions to penicillin make up today about half of all allergic reactions to drugs in various countries of the world—as well in the United States as in Europe or in Russia. Penicillin is presently by far the most frequent cause of anaphylactic shock in man.[1]

A second reason for interest in penicillin allergy is because it provides a very suitable model to study the mechanism of immunological reactions and of drug allergies in man. In particular, the fact that the chemical structure of the responsible antigenic determinants may be known and various types of immunologically active reagents prepared enables us to study at the molecular level the mechanisms involved in the initiation or prevention of allergic reactions. It also becomes possible to follow the interplay of several types of immunoglobulins of the same specificity. However, continued research has indicated that even from one single relatively simple molecule such as penicillin, a large number of different antigenic† determinants originate. For that reason, the picture of the immunological response of man to penicillin has become increasingly complicated. Despite earlier hopes that the response of man to penicillins would be in fact a response to one or a restricted number of antigenic determinants it is now apparent that the immune response to penicillins involves a large variety of antigenic determinants and several types of immunoglobulins, yielding a complex picture and making interpretation difficult.

Allergic Reactions

In this paper we propose to review briefly the main clinical and immunological forms of allergic reactions to penicillin, the molecular mechanisms involved in the formation of penicillin antigens, as well as the consequences

which recent advances should have on penicillin therapy and the attitude of the practitioner.

Forms of Immune Response

Various forms of immune response to penicillin in man have now been identified, only some of which will lead to clinical allergic manifestations. Contact with benzylpenicillin either in therapy or through hidden ways (e.g., milk, mycoses) induces in man various types of immunoglobulins with different biological and pathogenic properties and specific for quite a number of different antigenic determinants. It is not surprising therefore that several clinical forms of allergic manifestations to benzylpenicillin may be recognized. These clinical forms have different immunological features, and some of the confusion and discrepancies in this field are sometimes due to a natural desire for oversimplification.

A more precise analysis of the immunological features accompanying the various clinical forms of penicillin allergy has permitted us to understand why sensitization is much more frequent than allergic manifestations and why a prediction on the outcome of penicillin administration in a sensitized individual may be difficult. Immunological follow-up of allergic patients had also demonstrated the variability of individual responses and the importance of time in the evolution of the immune response. Accordingly, the immunological status of a patient cannot be established without taking into account various factors and applying simultaneously several types of immunological investigations.

Clinical and Immunological Forms of Allergic Reactions

Allergic penicillin reactions fall into several main groups, each of which has a different immunological pattern (Table 1).

TABLE I

Clinical and Immunological Features of Untoward Penicillin Reactions

Type	Interval	Symptoms	Specificity	Antibodies
No clinical reaction	Variable	None	BPO	IgM, ev. also IgE !
"Anaphylactoid" shock (iv. injection)	0-5′	neurological and sensoral	none	none
Anaphylactic shock	5-120′	collaps, B.P. ↓	Minor BPO	"Reagins" (IgE)
Immediate and accelerated urticaria	2-24 h.	urticaria	BPO	"Reagins" ↑ IgG → "clearing"
Serum-sickness-like disease	1-3 wks.	urticaria, fever arthralgias, etc.	BPO Minor	"Reagins" ↑ IgG → "clearing"
Chronic recurrent urticaria	variable	urticaria	Minor (?)	"Reagins"
Exanthema	5-10 days	morbilliform exanth.	BPO Others (?)	Delayed hypersensitivity IgM (?)
Hemolytic anemia	variable	anemia, Coombs +	BPO Others?	IgG, IgM (?)

"Immediate," "Accelerated" Reactions and Anaphylactic Reactions

"Immediate" reactions have a sudden onset, occurring within seconds or up to an hour after penicillin administration. They are usually followed by recovery but may end in death. The symptoms resemble those of anaphylactic shock in animals. There may sometimes be attenuated symptoms only, e.g., palpitation, vertigo, dizziness, perspiration, tingling of the tongue, ill-defined malaise, etc., which may subside or develop into severe vasomotor collapse. They may sometimes be followed by signs of cerebral damage.

The true anaphylactic shock with cardiovascular collapse should not be mistaken for the rather frequent "pseudo-shock" or "anaphylactoid shock" due to the accidental intravenous injection of procain penicillin or of large penicillin crystals. In such cases the onset is often noticed during the injection, with auditive and visual hallucinations and anxiety dominating the clinical picture. There is generally no real cardiovascular collapse.[3] So-called "accelerated" urticarial reactions occurring from one hour up to one to two days after penicillin administration are now usually classified together with sudden or immediate reactions. The character of the immediate reactions indicates that antibodies must be present in the patient as the result of previous exposure to penicillin. Such exposure may have been a decade or more previously.

"Late" Allergic Reactions

Strictly *cutaneous manifestations* of various types: generalized urticaria, erythemas and morbilliform exanthemas, erythrovesicular eruptions ("id-reactions"), and some rarer types, e.g., erythema nodosum, purpura, erythema multiforme, fixed drug eruptions, acute necrotic epidermolysis, periarteritis nodosa. Exfoliative dermatitis seldom occurs but may be fatal.

Serum-sickness-like reactions which usually combine urticaria and other skin lesions, fever, polyadenopathy, joint swelling and pain, sometimes angioedema. The latter often occurs separately but as an immediate reaction. The term of "late" reaction refers only to the delay between penicillin administration and the onset of the clinical manifestations; this does not indicate whether the manifestations are due to an immediate-type (antibodies) or a delayed-type (sensitized lymphocytes) mechanism. Erythematous and urticarial reactions are the most frequent, the latter accounting for more than half of the total penicillin reactions. In late reactions there may not have been any previous exposure to penicillin and the reaction occurs only after some days (usually five to 14) following commencement of a series of penicillin administration, during which time anti-penicillin antibodies and sensitized lymphocytes may have been formed.

Contact Dermatitis

Local application or exposure to penicillin may cause dermatitis. It is seldom accompanied by allergy to penicillin of the immediate type, although this is not excluded. It is usually observed among nurses and physicians handling penicillin preparations, and among workers in the pharmaceutical industry exposed to penicillin during manufacture. It also occurs frequently in patients exposed to prolonged local penicillin treatment, the risk of sensitization being particularly high when the drug is applied to macerated skin.

Other Rare Reactions

Acute psychotic syndromes ("anaphylactoid reactions"), pachymeningitis, gangrene and intestinal hemorrhage, temporary or permanent renal damage, liver necrosis, myocardial damage, acute pericarditis and isolated eosinophilias have been described. In certain individuals large doses of penicillin appear to induce hemolytic anemia by an immunological mechanism. The possibility that symptoms like nausea, vomiting, anorexia, convulsions, diarrhea, glucosuria, anuria, myocarditis, etc. may be toxic side effects of penicillin rather than caused by previous sensitization has been suggested.[1]

Antibodies and Immunological Tests

Humans in contact with penicillin may respond immunologically by the formation of antibodies, among which skin-sensitizing and hemagglutinating antibodies have so far been identified. Their properties, as characterized up to now, are shown in Table 2.

Skin-sensitizing Antibodies

7S gamma globulins have been reported to possess at least two different specificities: those that can be identified by skin test with the penicilloyl-polylysine antigen[4,5] and those identified by skin test only with benzylpenicillin. The existence of skin-sensitizing antibodies of various other specificities is demonstrated from skin test and passive transfer results with various penicillin fractions[6]; but the specific antigenic determinants reacting with

these antibodies are not yet definitely identified. Skin-sensitizing antibodies specific for the major penicilloyl antigenic determinant are mostly associated with immediate and early urticarial reactions ("accelerated reactions") which arise within the first 48 hours after renewed penicillin administration (Table 1). Penicilloyl-polylysine skin-testing frequently reveals the presence of these antibodies (Table 3) and appears more reliable and safe than passive transfer (Prausnitz-Küstner).

Skin-sensitizing antibodies specific for the minor penicillin G antigenic determinants have been held responsible[7] for the majority of "sudden" anaphylactic reactions and can be detected through skin testing with benzylpenicillin. A positive skin test with benzylpenicillin seems more indicative of a potential anaphylactic reaction than a positive skin test with penicilloyl-polylysine. However, there is little doubt that one may also observe anaphylactic reactions due mainly or entirely to penicilloyl-specific skin-sensitizing antibodies, so that both major (penicilloyl) and minor determinants may be involved in anaphylactic reactions to penicillin. Skin testing with crystalline benzylpenicillin is of supplementary value to skin testing with penicilloyl-polylysine. Together they serve to detect both minor and major determinants.

The above considerations relate to early ("accelerated") urticarial reactions and "immediate" anaphylactic manifestations. The so-called "late" allergic penicillin reactions, including serum-sickness-like reactions, begin days

or weeks after penicillin therapy and are eventually not all associated with skin-sensitizing antibodies. This is especially true for late morbilliform exanthemas (Table 3).

In serum-sickness-like cases, on the other hand, the association with skin-sensitizing antibodies of penicilloyl specificity, detected by penicilloyl-polylysine skin test is very frequent (Table 3). Sensitization may, of course, arise during the course of penicillin therapy in previously non-sensitized individuals. Initially negative skin tests do not therefore exclude the possibility that "late" penicillin reactions will occur. On the other hand the relatively high percentage (5-10%) of patients without history of allergic reactions to penicillin found positive in penicilloyl-polylysine skin testing does not detract from the value of the penicilloyl-polylysine skin test, as such patients appear to possess in fact a latent penicillin allergy (see below).

Hemagglutinating Antibodies

7S or 19S immunoglobulins occur frequently with skin-sensitizing antibodies in sudden ("immediate") anaphylactic, early urticarial reactions and serum-sickness-like reactions.[8,9] High titers of hemagglutinating antibodies are also observed when penicillins and 6-amino-penicillanic acid are injected into rabbits. These antibodies have usually been found to be specific for the penicilloyl determinant. Significantly higher titers of hemagglutinating antibodies are found in patients with a history of penicillin hypersensitivity than in those without, or who have never received penicillin previously. It appears that such antibodies are merely an indicator of the immunological response and not the cause of penicillin allergy.

There is often no direct correlation between the amount of hemagglutinating antibodies and the results of skin testing. Hemagglutinating antibodies may be also found in patients without clinical allergy to penicillin; they are usually specific for the penicilloyl determinant but also for other antigenic determinants. With an especially sensitive hemagglutination technique, it has been claimed that anti-penicilloyl antibodies are found in 97-100% of the population of New York. It must be noted, however, that the titers found in more than 60% of normal people investigated are rather low. As the hemagglutination is observed in such cases only with the help of a high colloidal diluent (dextran-serum mixture) which favours non-specific hemagglutination, the conclusion that nearly 100% of the people possess "natural" anti-penicilloyl antibodies would still require confirmation by some other technique.

In some individuals with penicilloyl-polylysine positive skin tests who do not develop immediate anaphylactic reactions upon injection of penicillin there are high titers of hemagglutinating antibodies.[9] It has therefore been suggested that the hemagglutinating antibodies may act as "blocking antibodies," competing for antigen with the skin-sensitizing anti-penicilloyl antibodies, preventing or slowing down reactions due to tissue-fixed skin-sensitizing antibodies (SSA). In this view, a low hemagglutinating titer associated with a positive skin test to penicilloyl-polylysine would favour an immediate anaphylactic reaction on subsequent penicillin administration, due to the lack of "blocking" antibodies. On the other hand, a high hemagglutination-titer and a positive penicilloyl-polylysine reaction would then render unlikely the occurrence of an immediate anaphylactic reaction on subsequent penicillin injection, but would be compatible with an accelerated urticarial reaction.

Clinical Experience

Clinical observations support the experimental results and empirical conclusions in regard to the immunological mechanisms outlined above. It has thus been shown that patients with a past history of penicillin allergy and negative skin tests to both major and minor determinants experienced no immediate anaphylactic or accelerated urticarial reactions on subsequent penicillin treatment, suggesting disappearance of antibodies. It cannot be excluded, however, that some of these patients had never been sensitive in the first place. Patients with positive penicilloyl-polylysine skin test treated with penicillin usually fail to develop immediate anaphylactic reactions, although the incidence of severe accelerated urticarial reactions is at least 10-12% versus less than 0.5% in patients with negative penicilloyl-polylysine skin tests.

In some series[5] the incidence of severe generalized reactions in penicilloyl-polylysine-positive patients under treatment with penicillin was so high (42%) that this type of experiment had to be discontinued. The fact that a majority of patients with penicilloyl-specific skin sensitizing antibodies do nevertheless tolerate penicillin injections may, aside from the presence of "blocking" antibodies mentioned above, also be explained by the quantitative balance (varying with time and from patient to patient) between the number of skin-sensitizing antibodies present, the amount of eliciting plurivalent conjugate formed in vivo from penicillin, and the amount of penicilloic acid or unreacted penicillin reacting with skin-sensitizing antibodies as a free inhibiting hapten ("inbuilt inhibition"). This aspect is further discussed in the following paragraph.

Positive skin-reactivity to penicilloyl-polylysine and/or benzylpenicillin may be evanescent and disappear with time. Thus, in patients who had allergic reactions two to two and a half months prior to testing, the penicilloyl-polylysine skin test was positive in 90%, while in patients with allergic reactions five to 10 years previously the positivity was 25-35%. A similar transient pattern is seen after skin tests with benzylpenicillin antigen. The evanescence of the skin reactivity to the two antigens need not be parallel and appears to vary markedly from patient to patient. It is probable that the evanescence of skin-reactivity is associated with decrease or disappearance of clinical sensitivity to pencillin.

Sensitized Lymphocytes

Morbilliform exanthemas seem to be, aside from contact dermatitis, the main clinical manifestation of delayed-type allergy to penicillin. Sensitized lymphocytes seem to be demonstrated by the lymphoblastic transformation test, but there appears to be no absolute correlation between this test and the occurrence of delayed skin reactions upon intradermal injection of penicillin.

Molecular Mechanisms in Penicillin Allergy

It has been widely accepted since the time of Landsteiner that sensitizing chemicals of low molecular weight may induce the formation of antibodies only when firmly, preferably covalently,* conjugated to some large carrier molecule such as a protein. This conception was established on the basis of experiments with highly reactive chemicals (e.g., dinitro-chlorobenzene). The conjugation theory has been applied by analogy to molecules which are less or not at all reactive with proteins but which are nevertheless found to be allergenic. In the early days of penicillin therapy some of the allergic reactions observed were also attributed to impurities in the relatively crude preparations. With the use of highly purified crystalline penicillins, however, it soon appeared that allergic reactions were also due to the penicillin molecule itself. According to chemical knowledge prevailing in the late fifties, penicillin did not appear to have significant reactivity with proteins and to be readily able to form stable conjugates in vitro. Our research on this problem therefore became oriented primarily on reactive penicillin derivatives or metabolites.

---

*See Test Your Word Score Page 89.

Penicillenic Acid

Penicillenic acid (Figure), a highly reactive degradation product which readily occurs in penicillin solutions, was considered for a while the main cause of sensitization to penicillins. However, the finding that antibodies induced by penicillin are mostly of penicilloyl specificity may be explained also if penicilloyl conjugates are formed by direct reaction of the penicillin molecule, without penicillenic acid as an intermediate. The penicilloyl (BPO) determinant has clearly emerged during the last years as the most frequently involved in penicillin allergy and has therefore to be regarded as a "major" antigenic determinant. On the other hand, the effective role of penicillenic acid present as an impurity in penicillin solutions and/or developing in vivo after penicillin administration in the formation of antigenic penicilloyl conjugates has now become somewhat less credible.

Reactivity of the β-lactam Ring

Various considerations have led us to believe that the direct reaction of the β-lactam ring of penicillin with amino groups is an important pathway by which penicilloyl-conjugates may be formed (Figure). Several chemical studies have indicated that penicillins may react "directly" with amino or hydroxyl groups under neutral pH and physiological conditions, forming thereby penicilloyl determinants.[2]

Whatever the respective importance of the "indirect" pathway via penicillenic acid or of the "direct" way via the β-lactam ring of penicillin to yield a penicilloyl structure, another possibility for the formation of penicilloyl groups is the reaction of penicillenic disulfide with amino groups (Figure).

With all these possibilities for its formation, it is not surprising that the penicilloyl group is a major determinant in penicillin allergy and that most of the antibodies encountered in patients undergoing an immune response to penicillin are of penicilloyl specificity.

There is evidence, however, that other antigenic determinants are also involved in penicillin allergy. On one hand, the penicilloyl group is relatively unstable and yields by successive degradation penamaldyl and penaldyl structures. On the other hand, a number of reactive derivatives such as penicillenic disulfide, penicilloic acid, penilloic acid, penilloaldehyde and penicillamine accumulate in penicillin solutions in vitro or are formed from penicillin in vivo. Skin reactions to benzylpenicillin and to derivates of penicillin

such as penicilloic acid in some patients who are not hypersensitive to the penicilloyl determinant clearly indicate that other determinants participate in the sensitization process.

Impurities

The old assumption that allergic reactions to penicillin are in fact due to impurities has been recently revived,[10] as small amounts of penicilloylated proteins appear to be present in benzylpenicillin and 6-amino penicillanic acid (6-APA) preparations. Benzylpenicillin being extracted from a fermentation medium containing various types of proteins it would not be surprising that some impurities might be carried along in the extraction and crystallization processes. However, it has not been demonstrated that the exceedingly small amount of protein impurity present in some commercial benzylpenicillin preparations is sufficient to play a major role in sensitization of man to penicillins. The assumption that a penicillin solution devoid of any protein impurity will be less sensitizing is theoretically attractive; however, our experiments in animals demonstrate that the "purified" benzylpenicillin is as immunogenic as ordinary benzylpenicillin.

Furthermore, hydrolyzed crude benzylpenicillin, still containing eventual allergenic impurities, but where the β-lactam ring is open and no longer able to form penicilloyl conjugates, does not induce the formation of anti-penicilloyl antibodies.[6] It appears therefore that the bulk of the anti-penicilloyl response is induced by the benzylpenicillin molecule itself and that "purification" of this kind will neither abolish nor markedly reduce sensitization. Another argument speaks against the assumption that protein traces have played a major role in sensitizing man to penicillin. These protein impurities come from the fermentation medium and patients should be sensitized not only to penicilloyl but also to other determinants, e.g., mycelial proteins. However, this is mostly not the case.

The situation might be different in 6-amino penicillanic acid, prepared by enzymatic degradation of benzylpenicillin. By such a procedure, much higher amounts of penicilloyl-conjugates appear in the final products; hence the bulk of antigenicity of 6-amino penicillanic acid may effectively be due to these penicilloyl enzyme impurities.

Elicitation of Reactions

Let us now proceed to the elicitation of allergic reactions to penicillins, i.e., the elicitation of reactions in individuals who are already sensitized. In recent years, experiments with various types of conjugates and haptens of known chemical structure have clearly established that the number of antigenic determinants per molecule is a decisive characteristic, determining whether a conjugate will or will not elicit an immediate-type allergic reaction in a sensitized individual. It may be stated that truly monovalent antigens never elicit immediate-type allergic reactions, bivalent antigens may elicit anaphylactic reactions, whereas Arthus reactions require a least tri-or plurivalent antigens.

Therefore only part of the conjugates formed in vivo by an allergenic drug will function as effective elicitors; whereas all conjugates formed, including the monovalent ones, may function as sensitizers. In other words, the sensitization process requires only poorly substituted conjugates. In the elicitation phase, on the other hand, monovalent conjugates will act as inhibitors because they compete for antibody-combining sites with the bi- or plurivalent conjugates. The "inbuilt inhibition" of such a system is even reinforced when the original allergen (i.e., the unconjugated drug) also has some affinity for antibody. The free benzylpenicillin molecule has some affinity for anti-penicilloyl antibodies and is capable, when present in sufficient excess, of inhibiting reactions of penicilloyl specificity. It is therefore possible to calculate and to reproduce experimentally situations where the presence of small amounts of penicilloyl conjugates will be completely masked by the excess of free benzylpenicillin. This phenomenon of "inbuilt inhibition" is certainly responsible to a large extent for the observation that penicillin may often be tolerated even in patients who have a clear-cut immediate-type hypersensitivity to the penicilloyl-group, i.e., patients with a positive skin test to penicilloyl-polylysine. It also explains the relative capriciousness of allergic reactions to penicillin, the incidence of clinical reactions being much less than that of sensitized patients.

The elicitation of allergic reactions taking several hours to develop could probably be explained merely by conjugation in vivo. On the other hand, it is somewhat difficult to assume that enough plurivalent penicilloyl conjugates are readily formed in vivo to account for the dramatic onset of anaphylactic reactions.

We have therefore become interested in mechanisms by which "ready-made" eliciting antigens of penicilloyl or other specificities might eventually accumulate in penicillin solutions.[6] Considerable experimental evidence indicates that bivalent antigens, i.e., antigens carrying only two antigenic determinants per molecule, are sufficient to elicit anaphylactic reactions, although somewhat less efficiently than plurivalent antigen. It can therefore not be excluded that simple dimers of the penicillin molecule will eventually be sufficient to elicit anaphylactic reactions in highly sensitized individuals, the more as such dimers have actually been isolated from penicillin solutions. Furthermore, several chemical mechanisms may be visualized by which penicillin and penicillenic acid might react with themselves or with their degradation products to form various types of dimers and polymers. Finally, the presence of high molecular weight contaminants (e.g., protein, carboxymethyl-cellulose) in penicillin solutions might also lead eventually to the accumulation of eliciting antigens.

Purification procedures, based on chromatographic separation on Sephadex, leave in penicillin solutions numerous compounds susceptible of eliciting immediate reactions in sensitized patients. Whether the active eliciting fractions represent mostly small polymers or dimers capable of eliciting reactions as such, or highly reactive monomeric small degradation products eliciting only after conjugation in vivo, remains the subject of future investigation. The fact that highly sensitive patients are always hypersensitive to different antigenic determinants and to several chromatographic fractions of benzylpenicillin suggests that anaphylactically reactive patients are in fact those sensitized to the largest number of possible antigenic determinants and possibly also those sensitized to determinants non-cross-reactive with penicillin itself and therefore not protected by the "inbuilt inhibition" mechanism.

Attitude of the Physician Towards Penicillin Allergy

Although the advances in immunological understanding discussed above may explain some apparently unexpected observations encountered in clinical practice, they also oblige the practitioner to revise the very simplified equation: antigen = antibody = allergic reaction. From a practical point of view, the following attitude seems to be advisable at present.

Case History

No penicillin injection or administration should be performed without thorough inquiry about previous penicillin administration and eventual allergic reactions. When allergic reactions (especially urticaria) of unknown cause are mentioned by the patient, one should be aware of the possibility of hidden contacts with penicillin (milk, cheese, vaccines, mycotic infections).

Skin Tests

By scratch-test, prick-test or intradermal injection, one may elicit in hypersensitive patients within five to 20 minutes the formation of an itching wheel surrounded by erythema. Although advised in the past by some, a prophylactic skin test with penicillin solutions does not appear to be routinely used in clinical practice. An explanation for this rejection is the fact that such tests are found positive in only 20-30% of patients with a history of penicillin allergy. The poor results achieved with penicillin skin tests are often due to the fact that the penicillin applied or injected for the test has first to form a plurivalent conjugate in situ in order to elicit an immediate local allergic reaction.

It is not surprising therefore that complete plurivalent antigens such as conjugates prepared in vitro are much more effective test reagents. A peculiarly suitable conjugate is penicilloyl-polylysine, a small polypeptide molecule with penicilloyl determinants attached. This reagent can elicit specific local wheal-and-erythema reactions in a majority of sensitized individuals but is apparently unable to sensitize normal persons. Penicilloyl-polylysine is a much more effective reagent than penicillin itself to detect hypersensitivity to penicillin. Only about a third of the allergic patients with a positive penicilloyl-polylysine skin test also present a positive penicillin skin test. Furthermore, the penicilloyl-polylysine skin test appears to be safer than the skin test with penicillin itself.

Because of the eminently variable degree of hypersensitivity encountered in practice, it is not possible to recommend for skin testing with penicilloyl-polylysine one fixed dosage. With a high penicilloyl-polylysine dose there is a risk of causing systemic reactions in very highly sensitive patients. On the other hand, less sensitive patients may remain undetected with insufficient doses of penicilloyl-polylysine. Adequate investigation of skin hypersensitivity therefore requires cautious skin testing with progressively increasing test concentrations. This requires time and is hardly practical as a routine prophylactic procedure.

Although penicilloyl-polylysine is a more efficient skin test reagent than penicillin, penicillin should not be disregarded as far as skin tests are concerned. Occasionally patients are encountered who do react to penicillin but not to penicilloyl-polylysine. Such patients are apparently sensitized to other antigenic determinants than the penicilloyl group (Table 3). Yet such rare cases are important because they seem to have a frequent relationship with severe systemic reactions (anaphylactic shock). In our opinion, the performance of a scratch-test with aqueous benzylpenicillin (200,000 units/ml), together with a saline control, is certainly advisable prior to penicillin injection or administration. Such a procedure is even mandatory when a definite suspicion of penicillin allergy is present. On the other hand, the relatively risky intradermal injection of penicillin should be reserved for specialized allergists.

Serological Studies

As related above, patients immunized with penicillin produce several kinds of antibodies. The hemagglutinating antibodies do not appear to be responsible for skin hypersensitivity and allergic reactions but are nevertheless frequently present in patients having recently undergone an allergic reaction to penicillin. The hemagglutination reaction may therefore be used as objective confirmation of the diagnosis. The practical significance of the hemagglutination test may, however, be evaluated only together with the other information available, such as the date of the last penicillin administration and the results of the skin tests.

Numerous attempts to detect penicillin allergy by other immunological tests either with the serum or the leucocytes of allergic patients have been made within the last years.[1] Promising results have been obtained with several methods (e.g., basophil degranulation test, lymphoblastic transformation test, passive transfer to monkey). At present, however, no practical, reliable and simple in-vitro test to detect penicillin allergy is available.

Conclusions

For the present, practical advice may be summarized as follows:

A detailed case history concerning penicillin administration and allergic reactions should always be taken.

If there is the slightest suspicion of penicillin allergy in a patient, the indication of penicillin should be again carefully evaluated. In many cases, penicillin is not absolutely required or may be replaced advantageously by another antibiotic. If not, a scratch-test with penicilloyl-polylysine and/or penicillin may be performed.

Whenever possible in a case of suspected penicillin allergy, and especially shortly after an alleged allergic reaction, the case should be clarified by a specialist (extended skin tests, hemagglutination, serological investigations, etc.).

In principle, patients with demonstrated skin hypersensitivity to penicillin should never receive penicillin again. In some cases, however, the indication for penicillin therapy appears mandatory. It may then be justified to attempt a desensitization; but the results are usually transitory, and such procedures require special precautions justifying a short hospitalization. Physicians may be tempted to replace ordinary penicillin G by some of the new synthetic penicillins or by cephalosporins in the hope of reducing the incidence of allergic reactions. Cross-reactions between penicillin G and any of the other penicillins or cephalosporins on the market do occur, as shown by experience, but it is true that some quantitative differences in such cross-reactions exist. However, they are very difficult to assess statistically in a significant way.

For the present, a statement indicating that such or such a penicillin is less antigenic than the others does not appear scientifically justified. The specificity of the hypersensitivity for the side chain of penicillins may vary largely from one individual to another. Possible cross-reactions are unpredictable without a thorough immunological investigation. The safety rule for the practitioner is therefore to deny any penicillin therapy to patients having presented an allergic reaction to one or the other penicillins.

Disease as Reprisal IV

Why were the Egyptians, innocent as well as guilty, smitten with boils?

The Lord was angry because Pharaoh would not let the Israelites leave Egypt.

And the Lord said unto Moses and unto Aaron, Take to you handfuls of ashes of the furnace, and let Moses sprinkle it toward the heaven in the sight of Pharaoh.

And it shall become small dust in all the land of Egypt, and shall be a boil breaking forth with blains* upon man, and upon beast, throughout all the land of Egypt.

And they took ashes of the furnace, and stood before Pharaoh; and Moses sprinkled it up toward heaven; and it became a boil breaking forth with blains upon man and beast. (Exodus 9:8-10)

Valium®
(diazepam)

To help break the cycle of skeletal muscle spasm

Six years of investigation have culminated in th recognition of Valium (diazepam) as an effective muscle relaxant—in addition to its distinctive ro as a calmative in psychic tension.

Used adjunctively, Valium acts to relieve reflex spasm of skeletal muscle due to local pathology, such as trauma and inflammation.

To break the cycle of spasm/pain/spasm
Muscle trauma or inflammation can trigger involuntary spasm or "splinting" of muscle, and the resulting discomfort further aggravates the spasm; thus a vicious cycle of spasm/pain/spasm is produced.

To help increase range of mobility
Valium helps break this cycle of reflex spasm to local pathology—with these benefits: relief of discomfort as spasm is relaxed, increased range o mobility, faster return to more normal activities.

To relieve psychic tension when also presen
When psychic tension or anxiety complicates th clinical picture of skeletal muscle spasm, the widely-recognized calming action of Valium ma also contribute to total patient management.

(Artist's conception of reflex arc.)

efore prescribing, please consult complete roduct information, a summary of which follows:

dications: Tension and anxiety states; somatic mplaints which are concomitants of emotional ctors; psychoneurotic states manifested by nsion, anxiety, apprehension, fatigue, depressive mptoms or agitation; acute agitation, tremor, lirium tremens and hallucinosis due to acute cohol withdrawal; adjunctively in skeletal uscle spasm due to reflex spasm to local thology, spasticity caused by upper motor uron disorders, athetosis, stiff-man syndrome, nvulsive disorders (not for sole therapy).

ontraindicated: Known hypersensitivity to the ug. Children under 6 months of age. Acute rrow angle glaucoma.

arnings: Not of value in psychotic patients. aution against hazardous occupations requiring mplete mental alertness. When used adjunctively convulsive disorders, possibility of increase in equency and/or severity of grand mal seizures ay require increased dosage of standard anti- nvulsant medication; abrupt withdrawal may associated with temporary increase in frequency d/or severity of seizures. Advise against multaneous ingestion of alcohol and other CNS pressants. Withdrawal symptoms have curred following abrupt discontinuance. Keep diction-prone individuals under careful rveillance because of their predisposition to bituation and dependence. In pregnancy, ctation or women of childbearing age, weigh tential benefit against possible hazard.

ecautions: If combined with other psychotropics or anticonvulsants, consider carefully pharmacology of agents employed. Usual precautions indicated in patients severely depressed, or with latent depression, or with suicidal tendencies. Observe usual precautions in impaired renal or hepatic function. Limit dosage to smallest effective amount in elderly and debilitated to preclude ataxia or oversedation.

Side Effects: Drowsiness, confusion, diplopia, hypotension, changes in libido, nausea, fatigue, depression, dysarthria, jaundice, skin rash, ataxia, constipation, headache, incontinence, changes in salivation, slurred speech, tremor, vertigo, urinary retention, blurred vision. Paradoxical reactions such as acute hyperexcited states, anxiety, hallucinations, increased muscle spasticity, insomnia, rage, sleep disturbances, stimulation, have been reported; should these occur, discontinue drug. Isolated reports of neutropenia, jaundice; periodic blood counts and liver function tests advisable during long-term therapy.

Valium® (diazepam)

2-mg, 5-mg, or 10-mg tablets, t.i.d. or q.i.d. and when skeletal muscle spasm and psychic tension interfere with sleep: add 1 tablet, h.s., to t.i.d. dosage

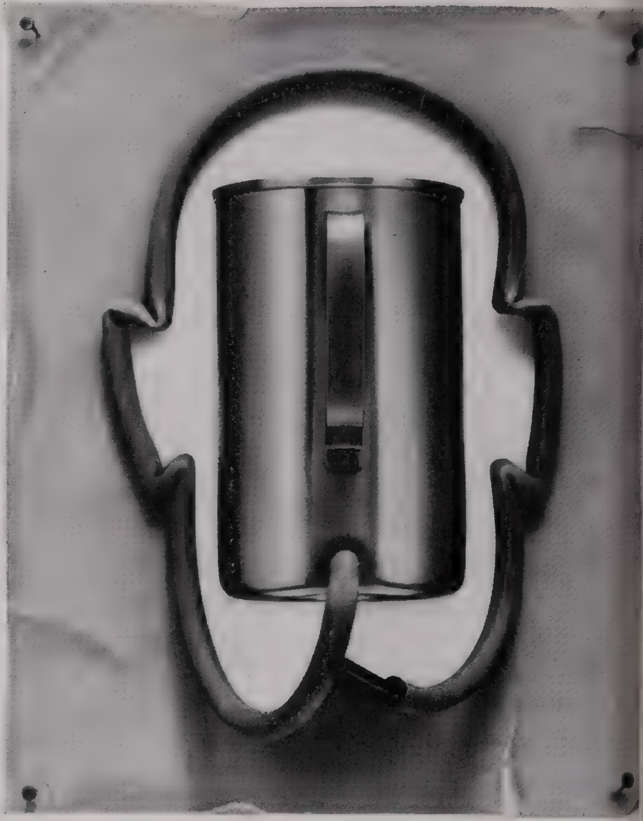
Public Enema No.1



Claim the rewards of sparing your patients the tubes and tribulations of unpleasant enemas.

Compared to enemas, Dulcolax suppositories are a gentler and simpler way to empty the bowel. Gone are the tubing, the "accidents", and the bruised egos. Just one suppository, inserted against the bowel wall, usually brings about an evacuation within 15 minutes to an hour.

In the hospital, order Dulcolax for constipation or bowel cleansing. Your patients will often prefer it to embarrassing enemas. And you can be sure nurses will appreciate the saving in time and effort.

Dulcolax tablets taken at night usually result in a bowel movement the following morning. A combination of tablets at night and a suppository the next morning generally cleans the bowel thoroughly in preparation for surgery or special procedures. Kee in mind, however, that the drug is contraindicated the acute surgical abdomen.

Dulcolax®...it's predictable

Pediatrics

The Battered Child Syndrome

Part II. Social and Psychiatric Aspects

In Hennepin County from July 1, 1963, to July 1, 1968, 123 children from 116 different families were abused (See Table 1).

The disposition of these children was as follows:*

84 Remained at home or were returned home from the hospital.
26 Were placed under the custody of the Welfare Department.
12 Were placed by the courts in a foster home with legal custody given to the Welfare Department.
12 Were placed in foster homes per parents' request.
9 Were placed in relative's home per parents' request.
7 Died.

From January, 1968 to June, 1968, 37 children from 33 different families were reported to Hennepin County Welfare Department. The source of referral primarily came from physicians (53%). The remainder of the referrals come from a social worker and a variety of other sources (Table 2). These children were more frequently abused by the mother, and then in order: the father, stepparents, consort of parent, siblings and nonrelatives (Table 3). The social and ethnic distribution appeared to reflect the general population served by Hennepin County Welfare Department (Table 4). These families are primarily low-middle or middle income groups. Only six of 123 children were previously known to social agencies in the community.

The person who beats a child can come from any socioeconomic group or any walk of life. Of thirty representative cases in Hennepin County,[1] most have had some high school education. In two cases, the parents had some

*Some may have more than one disposition, such as living at home under the custody of the Welfare Department.

college education and in one case the assailant had a graduate degree. In four cases, the assailant was mentally retarded and four carried the diagnosis of being "mentally disturbed."

The average age of the female was twenty-six and the male, thirty. The majority of the cases reviewed within the experience of the Hennepin County Welfare Department revealed that these families are from any income group, any educational level, and are frequently estranged from the community.

The assailants often have no outward signs of neurosis or psychosis. They seem overprotective, cooperative, and neat. During the interview they reveal a lack of affect. They are usually immature, demanding, hypersensitive, egocentric persons who require immediate gratification of their desires. They exhibit a propensity for impulsive aggressive behavior when their needs are not met. Often beatings are precipitated by the child defecating in the tub or in his clothes, by crying, or by goading the assailant. Often these people were the subject of beatings, neglect, and rejection themselves[2,3] and are unwilling to accept responsibility. They are purported to be jealous of the child who is allowed to be dependent, while they themselves are not allowed by society to be dependent. Thus, they tend to take their frustrations out on the child by impulsively beating him.[4,5]

There is a high incidence of pre-marital unwanted pregnancy, marital instability, sexual promiscuity, minor criminal offenses (assault and rape), and occasional alcoholism.[3] These tendencies, however, cannot be considered causes of physical abuse to children.

These child beaters are sometimes classified as having character disorders, with little guilt or anxiety about the child who is hurt and with very little reaction when the event is reported to the police. The guilty party very often is the one who seems more "normal" during the interview.[6]

TABLE 5

Reporting a Child Abuse Case*

1. Call: a. Police department or sheriff
b. Welfare department, child protection division†
2. Follow above by written reports describing history, physical examination x-ray results, etc., to police and welfare departments

*As required by Minnesota State Law
†Social worker at your hospital can do this, if one is available.

Some are overtly psychotic, especially the female with post-partum psychosis or the male who "tries to take the family with him" during a suicide attempt. He usually lives, while the child dies.[7]

Reporting Procedures

When a physician discovers a battered child he is required by law to refer the case first by a telephone call and then by writing to the local welfare and police department (Table 5). When this is done, his legal responsibilities are absolved. The department then assumes the responsibility for the reported cases and investigates, follows through and makes disposition of the cases as it and the courts see fit. Where a social worker is present in a hospital, that person can help handle the details for the physician with the police and welfare departments. However, the physician must supply details of medical findings, such as history, physical, and x-ray findings.

In one series, most of the cases which came to the attention of the police did *not* come from physicians, yet one third of them were seen by physicians. Why do we not report more? It might be due to the following three causes:[8]

1. We do not recognize the syndrome;
2. We do not know what to do if we do recognize it, due to lack of knowledge of the law or methods of reporting, or worry about lack of proof (which is not our problem);
3. We do not care (probably rare).

Case Reports

Vascular Malformations of the Dura Mater

VASCULAR MALFORMATIONS such as saccular aneurysms and arteriovenous malformations are much rarer in the dura mater than in the brain. Several reports[1,3,4,6,7,10] concerning arteriovenous malformations, especially in the tentorium, have been made. These authors also describe the characteristic angiographic finding of the frequently dilated tentorial branches of the internal carotid artery. On the other hand, the true non-traumatic aneurysm of the meningeal arteries is very rare. *New* believes, as a result of his own observations and those of *Berk*, that Paget's disease of the skull, arterial hypertension and true aneurysm of the meningeal artery are a triad, whereby the aneurysm develops in the later years as a result of the hypertension and the reduced bony support of the meningeal artery. He corroborates his opinion with the observations of *Hassler* who found histologically in 45 autopsies 19 large and 45 smaller media defects. The better support of the meningeal artery by the firm tissue of the dura could, according to his interpretation, prevent the development of aneurysm in these arteries which incidentally have the same structure as the arteries of the brain.

The combination of saccular aneurysm with arteriovenous malformation in the brain is known but not frequently seen.[2,3]

Recently we have observed a patient with the combination of a non-traumatic saccular aneurysm of the middle meningeal artery and an arteriovenous malformation of the tentorium. As the case is histologically documented it appears worth presenting, especially since we have not found a similar one in the literature.

Case Report

It concerns a 41-year-old dysplastic* male (A.F.) with cryptorchism on both sides, multiple small fibroma of the skin and pharynx, and a body weight of 100 kilograms. Since early childhood he had suffered from headache, especially in the morning, which was increased by activity. Because of visual disturbances with diplopia and repeated vomiting he entered the clinic for further study.

Physical Examination

Striking findings included a large head (skull circumference 65 cm), papilledema of about 4 diopters on both sides, and a blood pressure of 150/105 mmHg. The right eye showed a weakness of convergence. Visual field: binasal quadrant defect and central scotoma. Visus: ri 1.0, le 1.25. The other neurological findings, as well as the hematological examinations and endocrine studies, were normal. No sign of Paget's disease of the skull.

Neuroradiological Examination:

Left carotid angiogram revealed a wide and long tentorial artery (A. Bernasconi and Cassinari) which led from the carotid siphon to an arteriovenous malformation in the tentorium. The venous drainage emptied into the sinus transversus (Figure 1). Injection of contrast media into the common carotid artery, by pulling back on the needle, showed, in addition, a large saccular aneurysm on the lateral

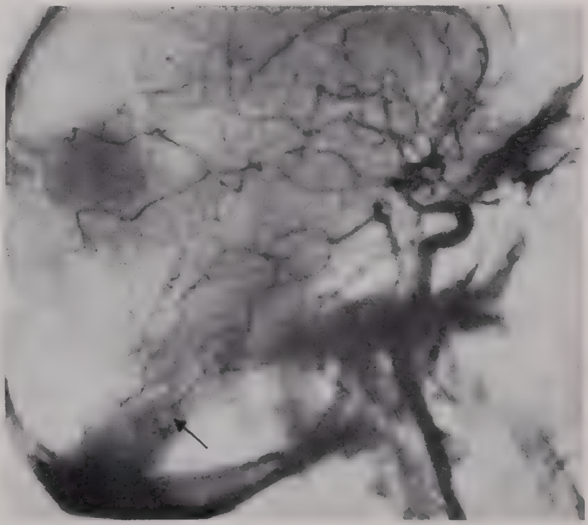

Fig. 1—Male, 41-years. Left carotid angiogram. Puncture of the internal carotid artery, lateral view of the arterial phase. Wide and long tentorial branch of the internal carotid with tortuous arterial channels at the periphery (arrow).

---

*See Test Your Word Score Page 89.

wall of the middle cranial fossa, arising from the middle meningeal artery, which was projected directly over the carotid siphon (Figure 2).

The right carotid angiogram also showed a very wide and long tentorial artery but did not disclose a definite connection between this tentorial branch of the internal carotid and the arteriovenous malformation on the left tentorial border (Figure 3).

The pneumoencephalogram, by means of fractioned lumbar injection of air, demonstrated a free passage by a normally situated fourth ventricle, aqueduct and third ventricle. The left lateral ventricle was definitely widened but not displaced.

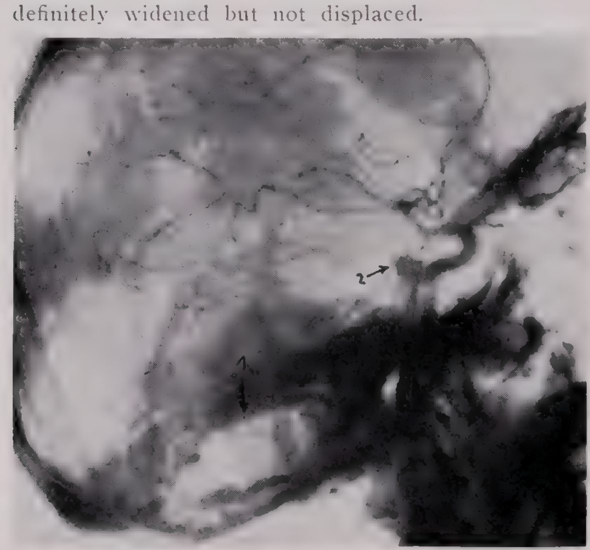

Fig. 2—Same case. Left carotid angiogram by injection of contrast material in the common carotid artery. The transverse sinus (1) is already visible because of arteriovenous shunting at the level of the malformation. As the external carotid artery is also filled, a large saccular aneurysm of the middle meningeal artery is seen in the dura of the middle cranial fossa (2).

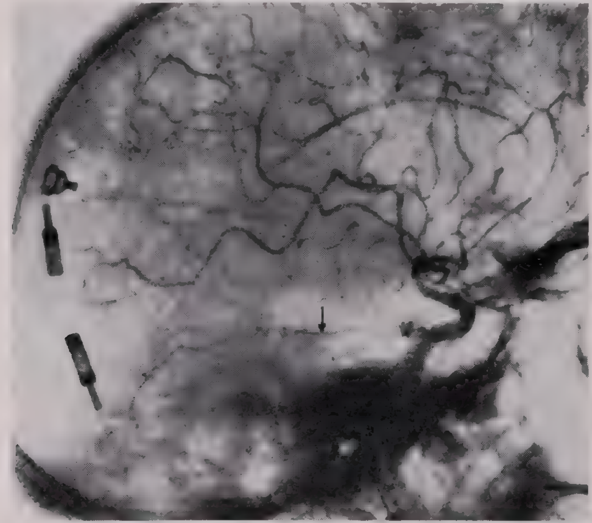

Fig. 3—Same case. Control angiography on the right side after atrioventricular shunt procedure. Large tentorial branch of the right carotid artery (arrow) without any visible connection to the arteriovenous malformation on the left side of the tentorium.

Operation:

Because of the increased intracranial pressure with marked papilledema and continuous vomiting an atrioventricular shunt (Spitz-Holter) was performed. Although the operation was simple and without complications the patient continued vomiting on the following days and became somnolent. Neuroradiological revisualization (Figure 3) did not disclose any change in the findings and there was no reason to suspect a hematoma, as the ventricular fluid was clear. A normally functioning shunt was observed. After fourteen days of assisted respiration the patient expired.

Autopsy of the Brain

The brain weighed 2,100 g and showed signs of tentorial herniation with internal hydrocephalus on the left side. The angiographically detected saccular aneurysm with a diameter of about 10 mm was found on the inner surface of the dura mater of the left middle cranial fossa (Figure 4).

Microscopic Findings:

The left middle meningeal artery was microscopically a normally developed typical arterial vessel without significant pathological changes in the wall. At the mouth of the aneurysm the intima of the arterial wall showed a diffuse fibrous thickening. The internal elastic lamella was mostly very well developed and wavy, but here and there widely split and interrupted. The outer wall showed a mild degree

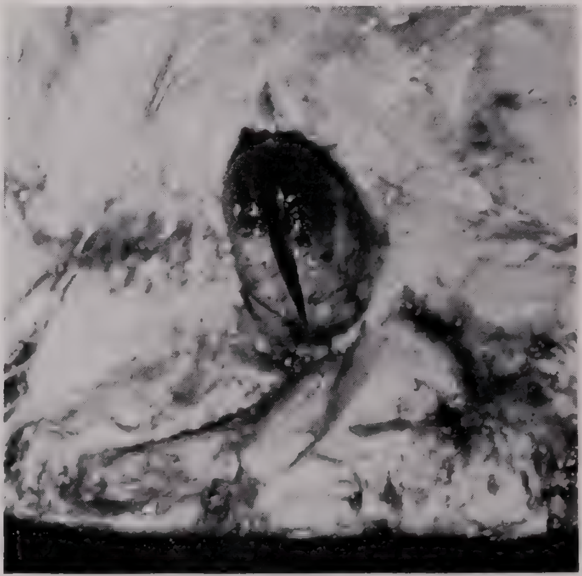

Fig. 4—Macroscopic appearance at autopsy (Nr. 366/67). Saccular aneurysm on the inside of the dura of the middle cranial fossa. The aneurysm has been opened.

of fibrosis and hyalinosis.

This vessel led into a dilated saccular aneurysm with a very thick, vasculated wall surrounded by dura. The intima was moderately cellular, showing diffuse fibrous thickening with slight hyperplasia of the smooth muscle. The internal elastic lamella was broken up and consisted of layers of varying thickness widely interrupted and distorted in some places. A medium was not distinguishable. The outer wall layers were moderately fibrous and partly hyaline.

The left tentorial branch of the internal carotid artery was a moderately thick-walled vessel of the arterial type with intact structure. The endothelium was missing in a few places.

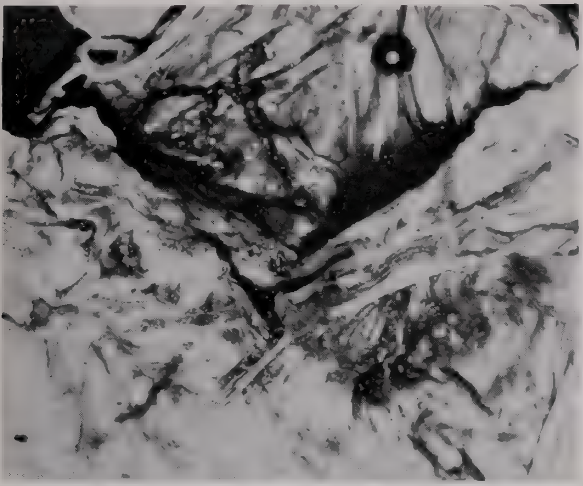

Fig. 5—Macroscopic appearance of the arteriovenous malformation in the left tentorium at autopsy. Superior longitudinal sinus with thickened wall (arrow).

The intima showed marked diffuse as well as plaque-like fibrous thickening. The internal elastic lamella was slightly reduplicated in several places. In microscopic sections from the region of the radiologically localized arteriovenous shunt between the A. Bernasconi and the left sinus transversus (Figure 5) one could recognize a saccular dilated vessel with a moderately, partly concentric, partly locally thickened, somewhat edematous wall. In the middle and outer layers the internal elastic membrane was interrupted, folded, broken up and in places hardly distinguishable. In the surrounding area were several smaller vessels of arterial, venous and transitional type, as well as slit-like cavities lined with endothelium without a true wall. The findings correspond to an arteriovenous malformation.

The microscopic picture of the macroscopically thickened confluens sinuum showed a dilated vessel with fibrous thickening and vascularization of the wall, with very little smooth muscle.

Comments

The question whether or not a direct causal connection exists between the arteriovenous malformation of the dura, size of the skull, increased intracranial pressure and remarkably increased brain weight is of special interest.

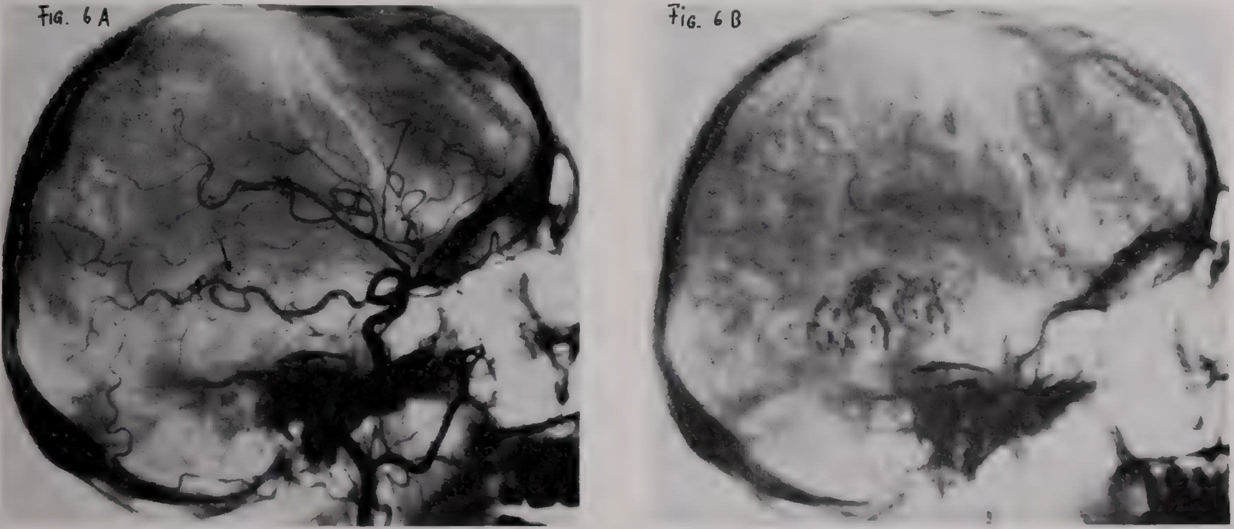

Fig. 6—Female, 28 years. Left carotid angiogram by puncture of the common carotid artery. (A—left) Lateral view of the arterial phase. Pathological vessels arising from the posterior cerebral artery (arrow). (B—right) Contrast retention in the wide sinusoids of the tumor. The contrast-filled cavities remain unchanged over a long period. Cavernous angioma of the tentorium.

A hydrocephalus with arteriovenous malformation of the dura has been described by *Newton* et al. and *Van der Werf*. Considering the wall changes of the confluens sinuum pointing to an increased load, it does not appear impossible that a long-lasting increase in pressure on the venous side could act as a chronic block resulting finally in a hydrocephalic enlargement of the left lateral ventricle.

A further, very rare vascular malformation of the dura is the cavernous angioma, which is well known in the cerebrum (*Russell* and *Rubinstein, Zülch*). The angioma has no extra development of supply vessels and the vessels of these cavernous angiomas of the cortex usually show up very weakly or not at all in the angiogram (*Krayenbühl* and *Yasargil, Tönnis* and *Schiefer*).

The following case report concerns an angiographically detected and histologically verified cavernous angioma of the dura:

Case Report

A 28-year-old housewife was taken ill with headache after the birth of her first child. Examinattion did not reveal any important neurological defect. Because of suspicion of post-partum sinus thrombosis she was sent for angiographic study

Angiographic Finding

The left carotid angiogram revealed a tumor (5x3x3 cm) above the tentorium and the left petrous bone (Figure 6 a-b). The pathological vessels arose from the posterior cerebral artery; the tentorial branch of the internal carotid artery was very thin and played only a small part in tumor vascularization. Already during the arterial phase large cavities containing contrast material were seen in the tumor and remained visible more or less unchanged until the last venous phase, without the appearance of a tumor stain as in cases of meningiomas. Veins could not be distinguished in the angiogram.

Operation Finding

The patient was operated and the tumor removed (Dr. Reichenbach). It sat with a broad surface on the tentorium, sharply separated from the brain and surrounded by a capsule. During removal massive arterial bleeding occurred, especially from the attachment of the tumor to the tentorium. The patient recovered completely from the operation.

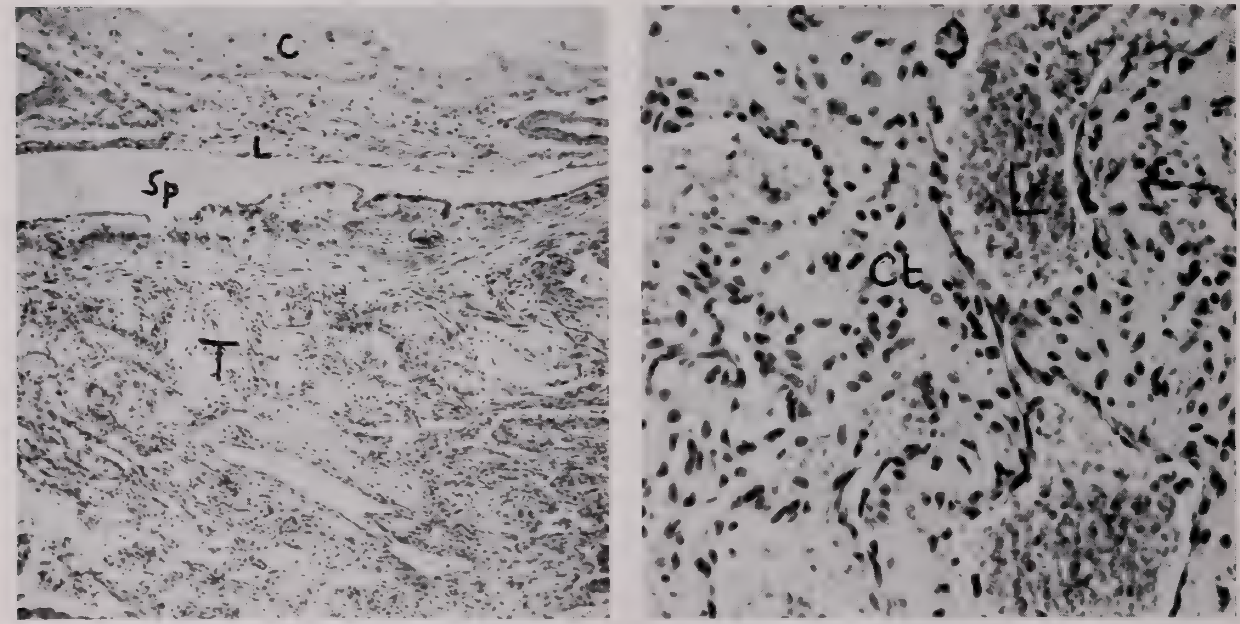

Fig. 7—Same case. Microscopic appearance of the tumor (cavernous angioma of the tentorium). Prot. Nr. 22487/67, Department of Pathology, foto Dr. Kraus-Ruppert.

A—left C = cortex cerebri.
L = leptomeninges.
Sp = subdural space.
T = cavernous angioma. (H and E, x 25)

B—right Between connective tissue (Ct) blood-filled lacunes with endothel (L). (H and E, x 100). Structures characteristic of a meningioma could not be found in the tumor.

Pathologic Findings

Histologically the tumor consisted of moderately and poorly cellular connective tissue containing many dilated sinusoidal vascular spaces, lined by a layer of flat dark cells. The outer surface of the leptomeninges was turned toward the tumor (Figure 7). Histologically it was a cavernous angioma without any indication of a meningioma.

McCormick and *Boulter* have collected three cases from the literature and have reported two additional cases detected by chance at autopsy. No angiographic examinations had been made.

Summary

Both the presented cases illustrate that essentially the same vascular malformations can occur in the dura as well as in the brain; they are, however, considerably rarer in the dura mater.

A case of combination of saccular aneurysm and arteriovenous malformation of the dura mater and a case of cavernous angioma of the tentorium are reported. Both patients were examined angiographically and histological studies were made.

To The Young Practitioner

Need I remind you of the importance of punctuality in your engagements, and of the worry and distress to patients and their friends which the want of it occasions? One of my old teachers always carried two watches, to make quite sure of being exact, and not only kept his appointments with the regularity of a chronometer, but took great pains to be at his patient's house at the time when he had reason to believe he was expected, even if no express appointment was made. It is a good rule; if you call too early, my lady's hair may not be so smooth as could be wished, and if you keep her waiting too long, her hair may be smooth, but her temper otherwise.*

He whose blood is red, whose muscles are hard, whose sleep is sound, whose digestion is good, whose posture is erect, whose nerves are steady has a good bank account in life.—Calvin Kendall

in cerebrovascular disorders

Arlidin increases blood flow

Arlidin decreases cerebral vascular resistance, increases cardiac output, helps maintain mean arterial pressure.

Arlidin helps control vasoconstriction, vasospasm, and ischemia.

Arlidin may thus relieve symptoms of cerebrovascular insufficiency, such as vertigo, lightheadedness, and mental confusion.

Arlidin also increases blood flow to the eye and inner ear to help manage ischemic disorders of those organs.

Arlidin is well tolerated and relatively free of severe adverse reactions.

DOSAGE: Usual effective dosage ½ to 1 tablet t.i.d. or q.i.d.; increased, if necessary, to 2 tablets t.i.d. or q.i.d. Parenterally, 0.5 cc. by subcutaneous or intramuscular injection; increased gradually to 1 cc. one or more times daily, as needed. SIDE EFFECT: Occasional palpitation. PRECAUTIONS: Use with caution in the presence of a recent myocardial lesion, paroxysmal tachycardia, severe angina pectoris, thyrotoxicosis. CONTRAINDICATION: Acute myocardial infarction. SUPPLIED: Tablets, 6 mg., scored; bottles of 100 and 1000. Parenteral, 5 mg. per cc., 1 cc. ampuls (5 per box); 10 cc. multiple-dose vials (1 per box). CONSULT PRODUCT BROCHURE.

Berne—Queen of Swiss Cities

GUIDO SCHMEZER, Ph.D.*
Berne, Switzerland

EVER HEARD OF SWITZERLAND? — no not Sweden. Sweden is a different European country, although often confused with Switzerland by Americans. Sweden is farther north and has only one national language. We have four.

So you know Switzerland? William Tell, cheese, chocolate, watches, yodels—but please don't say leather pants! Leather pants are definitely Bavarian or Tyrolian; in Switzerland they are worn only by foreign tourists.

I am not going to tell you about Switzerland —I just wanted to make sure that you get your bearings: small Alpine democracy jammed between France, Germany, Austria and Italy.

The capital of Switzerland is Berne—so we Bernese are capitalists. But Berne is also a community—so we are also communists. The result: we are neutral.

Have you got a map within easy reach? If it is a world map, you will probably find only a very tiny patch of color representing Switzerland, and in the middle of this patch a microscopic dot indicating Berne. If the map is larger, Zurich and Geneva might also be designated, maybe even Basel and Lugano. Berne is only the fourth largest of these cities, yet the most important of all of them. This is confidential. Don't tell the others. They are jealous.

To make you understand and fully appreciate the importance of our city, I feel obliged to give you some historical facts.

History

At school you learn that Berne was founded in 1191 by a duke whose name I will not mention as you will forget it anyway. In later years you come across historians who tell you that even before that year there had been a settlement in that place, and that 1191 is only the date when the settlement was enlarged.

The same uncertainty can be noted concerning the name. It is said that the city was named by the above-not-mentioned duke after the first animal he killed on the spot: a bear. So Berne is the city of the bear. It could also be the Germanized Italian place-name Verona; however, let's not waste time on this insignificant problem!

By the way: we spell it Berne, and the pronunciation is not "burn," but "bairn." So if you want to impress the Bernese, try to pronounce the name properly. If you fail, never mind—we have the same troubles with American names. You will not find many Bernese who have the correct pronunciation of names like "Mojave," "La Jolla" and "Houston."

When Berne was founded, Switzerland did not yet exist. Only one hundred years later the three original cantons in what is now known as Central Switzerland concluded a pact—that was the William Tell area, you know—and initiated a confederation of states which, at the end, united 22 states. We call them cantons.

---

*The only non-medical author in this issue, is known throughout Switzerland as the Bernese contributor to the "Nebelspalter", the Swiss equivalent of "Punch". He is also the author of several very popular books about Berne and the Bernese, the unique character of which will—we trust—be obvious to our American colleagues having read his introduction. P. Lundsgaard-Hansen, M.D.

The canton of Berne, then a republic, joined the Confederation in 1353. Soon it became obvious that Berne, a mighty and thriving city, had the wisest statesmen and the best military leaders and was therefore predestined to take the helm of the young nation which, at that time, was not a real nation but just a loose organization of independent cantons with some common interests and many common enemies.

Now let us skip about four centuries and open the history book at the chapter dealing with the French Revolution and its consequences. The revolutionary ideas had also taken root in Switzerland and arrayed the governed classes against the governing class. It was a most unpleasant time, with crowds shouting "To the gallows with the aristocrats!" and, therefore, when Napoleon's armies invaded Switzerland in 1798 they did not meet much resistance because the Swiss were weakened by inner strife. So, for the first time in history, the proud city of Berne was occupied by an enemy. Besides the freedom of the citizens the French also took away their arms, their watches and the state treasure, which did not make them very popular; but in later times the Bernese regained most of the money by exploiting French tourists. Crime never pays.

Napoleon tried to give Switzerland a new constitution. His various experiments were not very successful, and later he had to give them up entirely because he was too far away, exiled to the small island of St. Helena. The Swiss did not miss him much and now tried themselves to find a new way of coexistence. The constitution of 1848 finally established national unity and made of the former Confederation of States a Federated State. This constitution, totally revised in 1874, is still effective today.

In the same year—1848—the newly created National Council ("House of Representatives") and the Council of States ("Senate") had to choose the seat of government. Zurich, Berne, Lucerne and a few minor cities claimed it. Berne got it. Why?

Because of Berne's centuries-old leading role in Swiss politics, because of the most substantial contribution of Bernese statesmen in drawing up the constitution, and because of its geographical location near the border-line between the French and the German-speaking parts and its importance as a mediator between two cultural components.

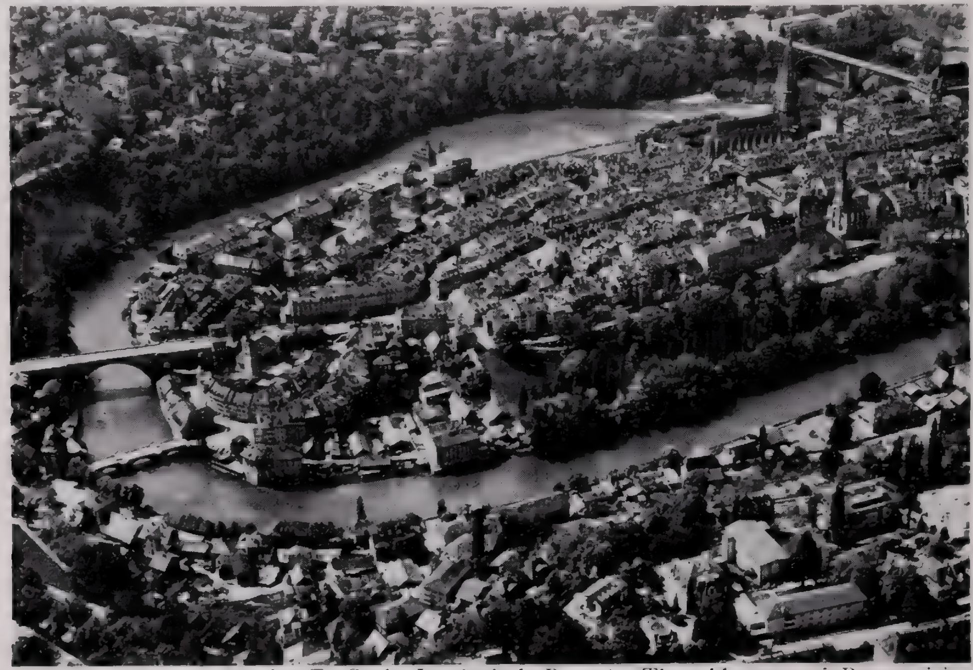

Fig. 1—(Photograph by E. Grob, Inselspital, Berne). The old town of Berne rising above the bend of the river Aare, viewed from the North. The longitudinal axis is formed by the main street terminating onto the Nydegg bridge, to the left of which (outside the picture) the Rose Gardens and the Bear pits are sited. The transverse axis links the Cathedral with the ancient Town Hall beneath its heavy roof, flanked by the Old Catholic Church.

The result of that vote naturally meant a great honor to Berne, but also a considerable burden for a city of then some 26,000 inhabitants who now had to provide the necessary buildings for the central government.

The costly Parliament Building was inaugurated on June 5, 1857. Our great-grandfathers paid for it.

A Living Monument

Berne differs from all other cities claiming to be the loveliest in the world in that it *is* the loveliest.

You may suspect me of boasting now. If you have never been here, I can understand. But if you have ever looked down from the Rose Gardens—a public park—onto the old part of Berne, you will share my feelings, unless your idea of urban beauty is closely connected with concrete and steel constructions, neon lights and noisy traffic.

The View from the Rose Gardens

A peninsula is formed by a wide bend of the river Aare which, coming from the Bernese Oberland, decided here to change its course but found the place so lovely that it formed several loops before departing towards the Jura Mountains, the Rhine and the sea.

The Old Town

This half-island—seen on Figure 1—rises some 120 feet above the river and contains what we call the Old Town. The broad and sunny main street curves gently down through its center, accompanied by somewhat narrower side-streets, all of them converging near the vertex of the river bend. At this point there used to be a ferry, the only place to cross the Aare until the beginning of the 13th century.

What makes the Old Town so charming and unique is the fact that here a medieval town has preserved its original character without becoming a lifeless museum or a mere showpiece for tourists. The narrow gray sandstone houses huddled together to form large, irregular blocks mostly date from the 18th century, but the layout of the streets is still the same as it was 800 years ago. The city planners of 1191 must have been very farsighted, for the width of the main street—80 feet—is the same as of New York's Fifth Avenue, which was built considerably later. And this antique part of the Swiss capital is, as I have already said, by no means a museum, but on its ground level a thriving shopping center and in its upper regions a favorite residential section interspersed with offices of all kinds.

The Arcades

This is the moment to say a word about the arcades. You must know that Berne, from its origin, was a market town. It had no specific market place; the farmers from the surroundings sold their produce in the streets. At the beginning arcades projecting into the streets gave them shelter; later the arcades became an integrated part of the sandstone houses occupying the front of their ground floor and were mainly used by craftsmen who liked to work outdoors, and today they have become a public thoroughfare serving as sidewalks—but what sidewalks! Just take a leisurely stroll through the approximately five miles of Bernese arcades. Never mind the weather—you are sheltered from rain and snow as well as from extreme heat. Look at the varied styles of their vaulting and pillars, at the wood and stone benches under the arches and realize that you are enjoying a prerogative dating back to imperial times: the right to walk on private ground which must be maintained by the house owners.

The main street arcades are lined with restaurants and shops of every kind and price category, from modern supermarkets to old-fashioned antique shops. In the arcades of the side-streets you will admire the beautifully carved doors of private homes with knockers beside electric bells, and in certain places you can still see craftsmen at work.

Knockers and Electric Bells

Knockers and electric bells: this is a good symbol for our Old Town. We preserve the old without refusing the new. For you must not think that life in these medieval looking houses is medieval; once you have opened the heavy door and climbed up a spiral staircase—if you do not prefer to take the elevator—you will find apartments offering you every comfort. It is not forbidden to modernize the interior of

Old Town buildings; only the renovation of the exterior is subject to very rigid regulations, because the city authorities are determined to protect the beauty of Old Berne, and the Bernese voters who adopted those regulations agree with them.

Other Tourist Attractions

There is one danger threatening all sightseers in Berne: they are often so absorbed in enjoying the arcades that they miss the other architectural and artistic beauties of the city. So if you ever come to Berne don't forget to step into the street from time to time. You will, for instance, discover that the Bernese are passionate flower lovers. They applied flower power long before the Hippie era by decorating their windows with thousands and thousands of geraniums. You will also chance upon some most admirable fountains with sculptured figures: a town messenger, a flag-bearer, a marksman, a bagpiper, an ogre, a woman personifying justice—to mention only a few of these world-famous fountains mostly dating back to the 16th century.

Clock Tower

Speaking of world-famous sights we must

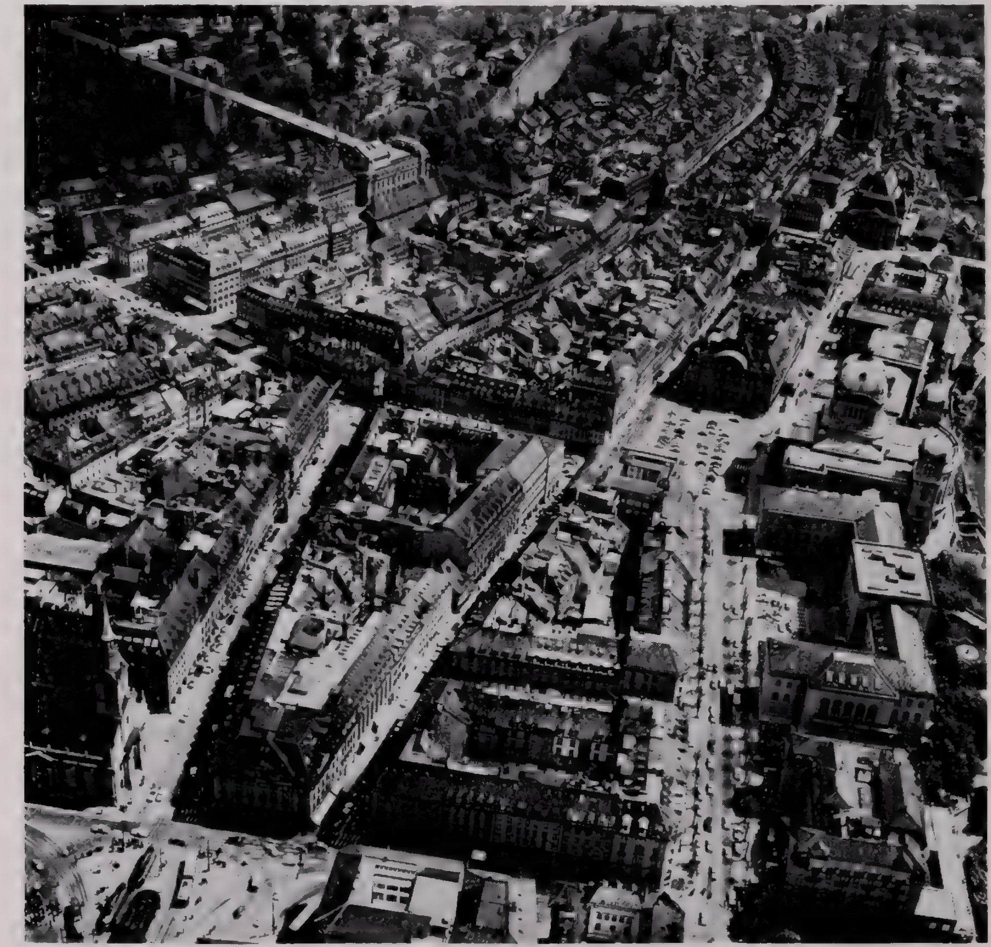

Fig. 2—(Photograph by E. Grob, Inselspital, Berne). Air view of the center of Berne seen from the West. Lower left corner: Central Railway Station Square. Taking the main street past the baroque church of the Holy Spirit, the reader arrives at the Prison Tower and, proceeding further, at the famous Clock Tower. From there he may go on towards the top of the picture, with the Cathedral on his right hand, and reach the Nydegg bridge (upper margin of picture). Crossing that bridge, he will arrive at the Bear Pits. Proceeding along the second street departing from the Railway Station Square, the visitor reaches Parliament Square with the Federal Palace under its dome, flanked by the Federal Administration buildings.

The Inselspital (University Hospital) is located some ¾ of a mile west of the Railway Station Square.

not forget the Clock Tower, probably the most photographed object of Berne. It is one of the two gate-towers marking the growth of the city (the other, some 300 yards farther west, being the Prison Tower). Its most remarkable features are a figure-play and a calendar clock which were constructed in 1530. Every full hour Father Time, turning an hourglass, a crowing rooster, a jester and a procession of little bears make a crowd of camera-equipped tourists scream with delight. Even the Bernese stop sometimes at that corner and enjoy the display of an ingenious mechanism more than 400 years old.

Bear Pits

Another "must" for foreign visitors are the Bear Pits. You will find them when you walk down the main street and cross the river on the Nydegg bridge (completed 1844). Immediately after crossing the bridge turn right and you are at the place where we keep our beloved heraldic animals. These amiable creatures perform all kinds of tricks to obtain a carrot or a fig or some other fruit, and the young ones, of course, are just darlings!

Cathedral

The most outstanding building in the old section is the Cathedral. Its first stone was laid in 1421; about a century later its main body—all made of sandstone—was completed; but the tower, the highest in Switzerland, did not reach its present height until 1893. Stained-glass windows and choir stalls carved out of oak wood deserve a closer look, and the Last Judgement sculpture above the main portal containing 238 individual figures is one of the country's most valued art treasures.

By the way: the Cathedral is a Protestant church. About 77 percent of the 170,000 inhabitants of Berne are Protestants, 21 percent Roman Catholics.

As it is not my intention to give you a lecture on the history of Bernese art and architecture, I just mention that we have also a Town Hall and many other public buildings deserving your attention—not to forget the Parliament Building (Federal Palace, as we call it patriotically) and the many other structures humming with federal, cantonal and municipal officials.

A Modern City

Once you have left the arcades you will discover that not everything in Bern is made of sandstone. High bridges span the Aare valley and connect the Old Town with green residential districts, and towards the west the city expands with new business streets and modern settlements which attract city planners from all over the world as they demonstrate that great numbers of families can live close together without losing their privacy and contact with nature, or, if I may put it this way, that giving up Beverly Hills does not necessarily mean Manhattan.

In industrial areas at the outskirts not only chemical products and chocolate and other foodstuffs are made, but also electronic equipment, printing presses and other such high precision machinery important for export.

Education and Culture

From kindergarten to university all opportunities to acquire a good education are offered in Berne. Museums—among them the world-famous Museum of Natural History—and libraries are abundant. Concerts are always sold out, and beside the venerable Municipal Theater we have also a number of "underground stages" established in large cellars of the Old Town where experimental plays and cabaret performances are given.

Famous names of outstanding writers, artists and scientists are closely connected with Berne. I mention only Albert Einstein who, in the peaceful atmosphere of the Old Town, worked on his theory of relativity, and James Fenimore Cooper who spent the summer of 1828 in Berne while writing his Leather-Stocking Tales.

In one special field Berne is leading in Switzerland: dialect theater. You must know that High German is not our native language; like all other cities and regions in Switzerland we have our own local dialect, the Bernese, and High German has to be learned at school before we are able to read books and write letters.

Now the Bernese are so fond of their mother tongue that they preserve it like their

Old Town. In no other Swiss region are there as many dialect poets and writers and dramatists as in the capital, and Bernese radio plays are very popular all over the country. The same love of native culture applies to costumes and folklore and yodeling; but if you expect to hear yodels under the arcades you will be disappointed, for this audible display of happiness would be incompatible with the Bernese mind.

The Bernese Mind

If you ask the Swiss from other cantons what they think of their Bernese confederates they are likely to answer: "Oh well, they are certainly very industrious and efficient and reliable, but awfully slow and dull."

If you believe this, you are the deplorable victim of a most unfair misinterpretation of our general behavior.

It is true that, compared with Italians or Mexicans, the Bernese are somewhat less extraverted. They do not dramatize their feelings; they often do not even show them.

Should this composure lead to the conclusion that they are dull? Knowing the Bernese I can assure you that this would be extremely wrong. Among themselves, in their families or with friends they can be very cheerful and witty. Their sense of humor is well developed, and their jokes are full of irony, both philosophical and self-directed, but never offensive. They are warm-hearted without being sentimental, gay without being frivolous.

Now what about their alleged slowness? Our critics pretend that the rather low speed of our speech originates from mental slowness. They base this theory on the completely erroneous idea that a person's intellect and imagination can be measured by the number of syllables produced by his speech organs per minute. I maintain on the contrary that those who speak very fast cannot think over what they are saying. So this so-called Bernese slowness is in fact a sign of wise consideration: no word leaves the mouth unless it is well considered.

History has proved that this reluctance to say or do anything before it has matured in the mind is one of the best Bernese qualities. Thanks to this attitude the State of Berne has steadily grown through the centuries and united French-speaking Switzerland with German-speaking Switzerland; thanks to it revolutions and strikes are unknown here, and thanks to it the Bernese is always as good as his word.

Some say that we are unsociable. We certainly do not jump at every stranger, telling him our private story within the first five minutes, but we welcome every visitor who comes to Berne, and once we have made sure that he is neither a criminal nor a silly prattler he will soon realize that our hospitality is sincere and our friendship reliable.

A Final Word

Rereading what I have written I fear that you get a wrong impression of the Bernese. While everything I said about the beauty of the city is absolutely correct, my passionate love of Berne may have carried me away into shameless bragging. Sorry! Believe me, the Bernese are modest and unpretentious. We are not the Texans of Switzerland, although our state is, like Texas, the second largest of the country. We are proud of Berne, the Queen of Swiss cities, but we show our pride only on very rare occasions.

This article is one of them.

Placebo Diagnosis

Partly because most patients so demand a diagnosis of organic disease, partly because they are inclined to be resentful against the physician who tells them the truth, and partly because it takes so much time and skill and tact to explain the real situation to them, we physicians will always be tempted to dismiss them quickly with some placebo diagnosis—some pleasant-sounding name such as clitis, ptosis, spastic colon, low blood sugar, or low blood pressure.*

To write prescriptions is easy, but to come to an understanding with people is hard.—Franz Kafka

History of Medicine

The Inselspital Berne

F. KOHLER, M.D.*
Berne, Switzerland

THE INSELSPITAL was established in 1354 by a wealthy woman of the city of Berne, Anna Seiler, in form of a foundation. This foundation was provided with a house, situated in the middle of the old town of Berne, as well as with the revenues of important land-property. The donor put the hospital, soon known as "Seilerin-Spital", under the custody and the protection of the Town-Mayor and his Counsel henceforth all through the centuries. The Inselspital has maintained the character of the foundation in spite of historical and political changes, still being an independent foundation, based on the deed of foundation of Anna Seiler, subordinate to the regulations of the Swiss Civil Code and—as to its public duties—to cantonal law.

The Seilerin-Spital

In 1528 the Seilerin-Spital moved into the premises of the Insel-Cloister which, as a result of the reformation, was unoccupied and which was formerly situated on a little island in the river Aare. From this time on the hospital has been called "Inselspital".

In 1724 a new building was set in operation at the place where the Swiss House of Parliament is situated today; but having no possibility of extension the place was left in 1884 to move into the newly-built hospital-establishment with a capacity of 320 beds (a hundred beds more than in the former building), situated outside the town. In those days this new hospital was said to be a perfect example of good hospital architecture.

The Inselspital, initially installed for "13 bedridden, poor persons", developed more and more into the central hospital of the Canton, viz., the Cantonal Hospital. Since 1805, when under the auspices of the Academy a Medical Faculty was organized, the Inselspital has the function of University-Hospital as well. In 1834, the year of the foundation of the University of Berne, the Inselspital consisted of two departments with 44 beds. Today the teaching departments have nearly 730 beds and the non-teaching departments, roughly 400 beds.

The Inselspital

Thanks to the erection of the "Anna Seiler-Haus" set in operation in 1954 and comprising 190 beds, and owing to the thorough renovation of the C. L. Lory-Haus (about 150 beds) in 1956-57, the Inselspital constituted well-equipped non-teaching divisions which, for ancient legal reasons, are not open for teaching and research-purposes. The teaching divisions, however,

---

*Director, Hospital, Berne, Switzerland.

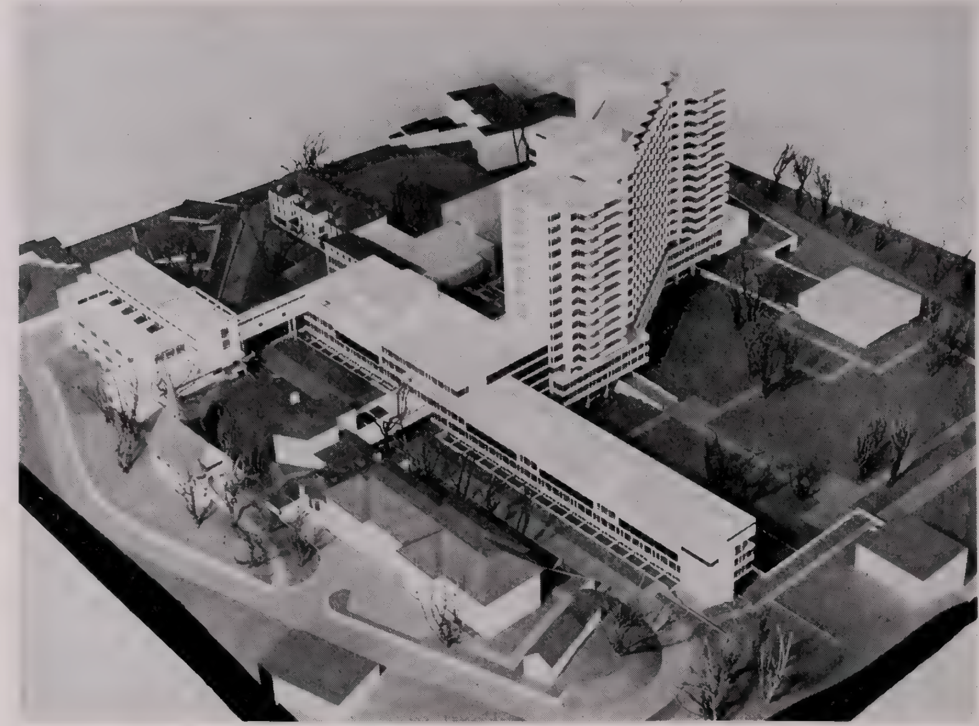

Fig. 1—Model of the new buildings 1960-1970. Ward block with the long diagnostic and treatment-building in the foreground. In the lower left the kitchen-building with kitchen, laundry, cafeteria.

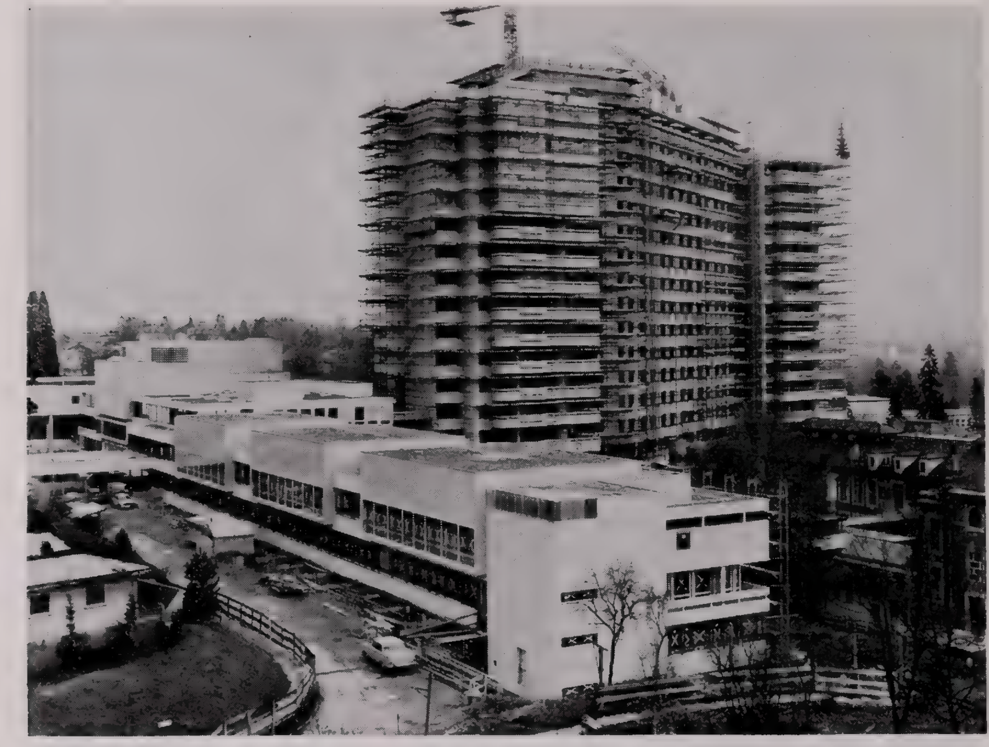

Fig. 2—The ward block is under roof (November 1967). In the foreground is the diagnostic and treatment-building, its left side having been completed in 1964.

were lodged for the most part in houses built in 1883 and 1884, representing the pavillion-type, which no longer met the standards of a modern Cantonal- and University Hospital. Thanks to the foresight of the cantonal architect it was decided in 1955 to study possible reorganization of the oldest buildings. Dr. H. C. R. Steiger, Zurich architect, was entrusted with this task, and he concluded that all the centrally situated old buildings should be razed and replaced by connected buildings forming a compromise between the one-block hospital and the pavillion-type. In the course of the following planning-period the architects Drs. Fietz and Steiger, Zurich, Brechbühl and Itten, Berne, arrived at the solution shown in Figure 1.

The total renewal of the hospital, for which a credit of 69 million Swiss francs was granted in 1958, is to be executed in three phases. After phase one it appeared that this amount would not be sufficient for a building-project of such a dimension, as the first phase—completed in 1964—had required 40 million Swiss francs. This first portion comprised the following buildings: a house for personnel; a house for nurses; a building for economic branches, with central kitchen, laundry, cafeteria for the staff; one half of the diagnostic and treatment building; and the roads, underground links, water- and power-supply for all three phases.

For the second phase the Bernese electors granted a further credit of 87.8 million Swiss francs in September 1964, including: a ward-block equipped with about 730 beds, to be occupied in 1970 (length 101 m; height 71 m) (Figure 2), and the second part of the diagnostic and treatment building, ready for use in 1969. This last mentioned building will include: an emergency department, a ward for sick prisoners, the hematological and chemical central laboratories, a diagnostic X-ray department, an X-ray therapy division, a central sterile department, and nine operating theatres.

However, there are no plans as yet for the third phase of the total renewal of the Inselspital.

Increasing Costs

The increase of old-aged people, the developments in therapy and diagnostics as well as in surgical operations, the terrific augmentation of street-accidents and last but not least, the greater trend towards hospitalization (partly due to the lack of home nurses and as a result of restricted lodging possibilities) have led to the turbulent development of the Inselspital during the years after the war. This development may be stated by the following figures:

Year	Number of patients	Number of patient-days	Number of personnel	Cost per day and patient
1940	8,384	228,818	306	8.107
1950	9,473	241,202	494	17.248
1960	12,049	303,864	948	37.984
1966	15,959	349,356	1,820	89.33

The impressive increase in the personnel sector is especially noteworthy, the number of staff within about six years having nearly doubled and the costs nearly trebled. Nobody is any longer wondering about Cantonal and University Hospitals showing big deficits; it is evident that patients in the general ward never will be able to pay the above-mentioned costs. Consequently the hospital has to meet a social obligation by assessing moderate daily rates for care and treatment. As a matter of fact the Bernese citizen, supported by the social-authorities, still enjoys today the favor of being hospitalized free of charge at the Inselspital.

Service to the Community

The Inselspital is an institution which—owing to a highly specialized staff and special medical equipment—is able to receive the most exceptional and critical cases, besides being a center for teaching and research. The teaching of medicine and the education of young doctors prevail, but the following schools governed by the Inselspital deserve to be mentioned: the school for physiotherapists, the school for laboratory technicians, the school for auxiliary nurses, and the school for nurses for chronic sick and aged persons (practical nurses).

Besides being a place where cooks can serve their apprenticeship, the hospital facilities are all the more in demand for the practical education of future house-keeping-officers and social workers. In this way the Inselspital further serves the population of our Canton, as stipulated by Anna Seiler more than 600 years ago.

SHAKESPEARE'S DOCTORS

Cerimon

" 'Tis known, I ever
Have studied physic, through which secret art,
By turning o'er authorities I have,
Together with my practice, made familiar
To me and to my aid the blest infusions
That dwell in vegetives, in metal stones;
And I can speak of the disturbances
That nature works, and of her cures; which doth give me
A more content in course of true delight
Than to be thirsty after tottering honor,
Or tie my treasure up in silken bags,
To please the fool and death." (Pericles III, 2)

Scornful of hollow prestige and venality, thus spoke Cerimon when his friends expressed surprise that he, a nobleman, should show an interest and some skill in medicine. While only an amateur rather than a certified physician, he fully qualifies as one of Shakespeare's doctors, acquitting himself as ably as any.

When a chest containing the "corpse" of Thaisa is cast ashore from a shipwreck off the coast of Ephesus and is opened, Cerimon immediately detects that the body within shows faint signs of life and sets about to revive it.

"For look how fresh she looks! Make a fire within:
Fetch hither all my boxes in my closet.
Death may usurp on nature many hours,
And yet the fire of life kindle again
The o'erpressed spirits.
The fire and cloths.
The music there! I pray you, give her air." (Pericles III, 3)

Cerimon's armamentarium consisted of warm packs, fresh air, stimulating music, and unidentified substances from his boxes, presumably stimulants.

Industrial and Forensic Medicine

Organic Solvents in Blood

Determining the Quantity

ORGANIC SOLVENTS are becoming ever more widespread at work and in the home. This means that the number of solvent intoxications will increase still further.

Although the effects of individual organic solvents on the organism have been studied thoroughly, little attention has been given to quantitative determination in blood and organs. It is true that in certain cases it was possible to explain the often relatively uncharacteristic, pathological-anatomical picture by means of chemical detection of the poison; however, for this purpose relatively large quantities of blood or organs had to be processed in order to detect the solvents that were present only in traces. Also, since the appropriate chemical methods were frequently lacking, the poison could in many cases be detected only indirectly by examination of the work premises or the accident site. This procedure may to some extent suffice for a plausible clarification of a simple case, but in complex cases such an indirect procedure, even if possible, often gives too limited or too inconclusive, unsatisfactory results. Hence legal, insurance, or industrial health questions could not always be answered satisfactorily.

Gas Chromatography

Because of its high sensitivity, gas chromatography permits the determination of small traces of organic solvents; therefore, it seemed to us a suitable method for solving the problem under discussion here. We investigated the technical possibilities and developed in our Institute a procedure which enables solvent traces to be detected in small blood samples. The procedure consists of injecting ten microlitres of whole blood without further preparation straight into the gas chromatograph. Where apparatus conditions are suitable it is even possible by this method to determine volatile physiological substances in their normal concentrations. To do this, however, one needs a special sample inlet which retains the high-boiling blood components and also a water-resistant high-efficiency column.

We designed the sample inlet in the shape of a quickly exchangeable cartridge which can be attached to the chromatograph with a gas-tight bayonet fitting. Changing and heating this cartridge takes only about a minute, thus facilitating rapid, reproducible work. We avoided another considerable difficulty—coagulation of the blood in the needle of the liquid sampler—by an additional cooling of the inlet septum.[1]

To begin with we had the commercially produced stationary phases and solid supports for the construction of the column. Three requirements for the columns severely limited the number of possible liquid phases; these were water resistance of the stationary phase, complete separation of the trace substances from the main mass of water, and the best possible resolution of the organic trace elements.

Practically speaking there remained only Carbowax, Chromosorb 102 and Porapak. In the case of Carbowax either the separation of the water or the resolution of the trace substances is unsatisfactory. The two other materials (polystyrene derivatives) separate the water very well, but detection of tiniest solvent traces is difficult as many technical solvents are only slightly polar and consequently can be eluted* only at high temperatures as relatively flat peaks, making analysis considerably more difficult.

For these reasons we synthesized (made to measure, as it were) a stationary phase for the gas chromatography. From a technical and theoretical point of view good results can be expected from a material with the following characteristics: high hydrophilic group content to separate the water from the organic components; enough hydrophobic groups of different structure to separate lipophilic organic substances; chemical resistance to water at high temperature and pressure and to a very large contact surface (very thin film on active solid support), for which reason only the use of water-resistant C-C and C-O-C (ether) bondings was suitable for our purposes. Finally, low volatility is required, so that the bleeding of the column remains relatively small, or so that tiny traces of an organic solvent can actually be detected in the background. The substance therefore has to have a relatively high molecular weight.

From these considerations we coupled relatively hydrophobic alkylphenols with the hydrophilic glycerine, using ether bondings. The high separations

---

*See Test Your Word Score Page 89.

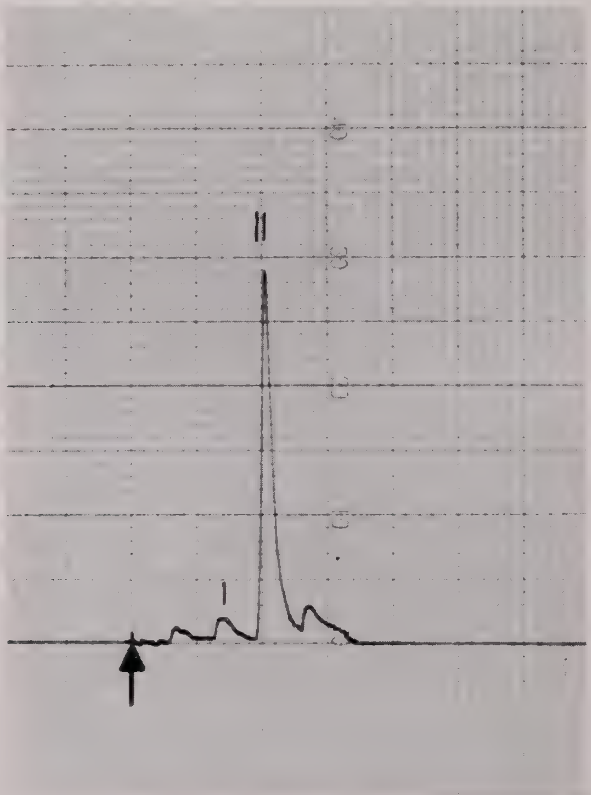

Fig. 1—Whole blood (rat). I = acetaldehyde. II = acetone.

of greatly diluted watery solutions achieved with these materials[2,3,4] subsequently confirmed our theoretical suppositions. For the time being the following proved to be the most suitable column[5] (at present being further developed): 12 feet, 3/16″, stainless steel, with 10% of a mixture of 78 parts NPGA and 22 parts ORGA on Chromosorb A, 60/80 mesh.

This resolves the technical solvents to a large extent. The chromatographed substances are eluted roughly according to their boiling points, thus making identification of the fractions considerably easier.

Clinical Application

To illustrate the analyses possible with this method we present some examples from our practical work.

Control of Physiological Substances in the Blood

Figure 1 shows a gas-chromatogram of normal rat blood, two of the peaks representing the acetaldehyde or acetone in the physiological range (ppm-range). This method is therefore also suitable for dealing with problems of metabolism. Tests in this connection are at present being carried out at our Institute.

Detection of Gasoline Intoxications

Gasoline fractions, as largely inert hydrocarbons with conventional chemical reactions, are practically impossible to detect in the micro-range, and, for this reason their detection in blood had previously been impossible. But

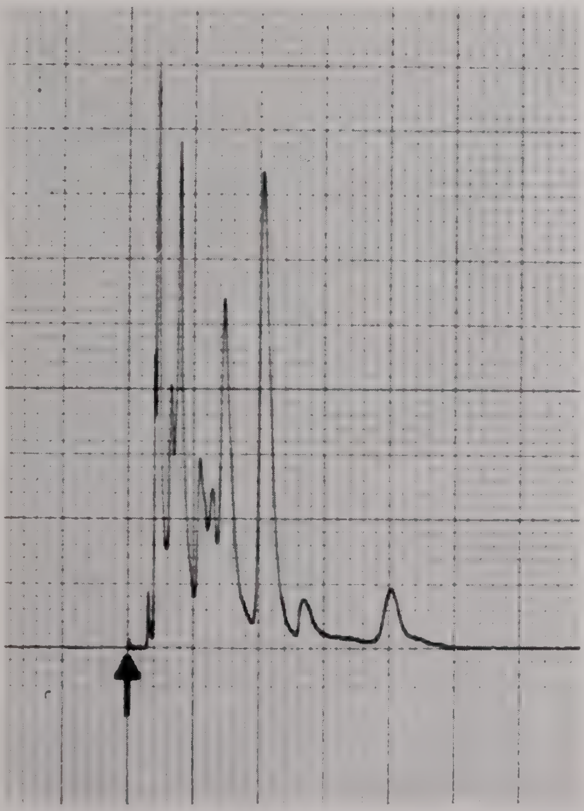

Fig. 2—Whole blood of a rat intoxicated with gasoline.

gas-chromatography solved the problem; by its application about fifteen hydrocarbon fractions, all contained in inhaled gasoline, were detected in the blood of a worker (Figure 2).

These results have been checked experimentally in animal tests when a lethal gasoline concentration (total of all fractions) of only 0.3 – 0.4 o/oo was ascertained.[6] The concentration of individual subfractions was, of course, much lower, ranging from only a few up to about fifty ppm.

Detection of Solvents in the Case of a (Compulsive) "Sniffer"

The blood of a fifteen-year-old boy was also examined by gas-chromatography because of repeated fits of intoxication and raving madness. The analysis revealed not only increased acetone concentration but also considerable amounts of chloroform, carbon tetrachloride and ethanol solvents, contained in a stain-removing preparation.

Detection of an Intoxication Caused by Paint Thinner

A young man was found dead in a storeroom for empty solvent containers. Initially the cause of death was not clear, but gas-chromatography subsequently revealed a number of solvents in the dead man's blood. They were:

0.1 o/oo	toluene
1.2 o/oo	isopropanol
1.0 o/oo	methyl-ethylketone
0.3 o/oo	methyl-isobutylketone and
0.8 o/oo	acetone

All these substances were contained in a so-called nitro-thinner, some of which was later found in a container, thus identifying the source of the poison. Whether the intoxication was due to chance exposure or to addiction could not be clarified.

We believe that these few examples clearly indicate the advantages of gas-chromatography for toxicological determination of organic solvents in the blood. With increasing experience the quantitative determination of the poisonous substances will permit an approximate estimate of the seriousness of such intoxications.

Summary

With suitable modification, gas-chromatography can be used for direct qualitative and quantitative determination of organic solvents in blood. A number of typical cases from our practical experience show that non-lethal or even physiological concentrations can also be established.

The Question in Life

There's always a big "if" in the center of life.—Consol Dealer

Laboratory Letter

Chemistry Graphs in Liver Diseases

As a measure of liver function, chemistry graphs excel. Of the twelve tests on the graph, seven—albumin, alkaline phosphatase, total bilirubin, cholesterol, SGOT, LDH, and total protein—relate in some way to the liver.

Among diseases of organ systems, few are tougher to define precisely than those of the liver. Sometimes, even after a good history, a thorough physical, x-ray studies, and a host of laboratory tests, the diagnosis still remains in doubt. Yet with certain diseases, a chemistry graph gives solid clues as to the nature of the liver process. Here are a few examples of uncommon disorders in which we have been able to help the physician interpret the graph.

Alcoholic Hepatitis

What is alcoholic hepatitis? Probably the condition that precedes portal cirrhosis. Histologically, the liver shows focal necrosis and polymorphonuclear leucocyte influx. Yet patients often do not have symptoms, though they may complain of anorexia, nausea, vomiting, and abdominal pain that can mimic cholecystitis, pancreatitis, or even appendicitis. Also they sometimes have fever and leucocytosis. Most liver function tests are normal, but the SGOT is often up in the range of 50 to 200 units. If patients drink excessively and have an unexplained SGOT elevation, most will usually show changes of alcoholic hepatitis on liver biopsy.

Subacute Hepatitis

What do you do when a non-drinking patient has the clinical picture of portal cirrhosis? Chances are, you question whether the history is valid. Yet when the patient is a middle-aged woman, it is worthwhile to consider subacute hepatitis. This disease, a sequel of viral hepatitis, smoulders for months or years and culminates in postnecrotic cirrhosis. It has a striking predilection for women over 40 (about 90% of cases). Though ultimately the diagnosis is histological, certain clinical features—intense or protracted jaundice for months or years, or signs and symptoms of liver destruction in an otherwise typical viral hepatitis—ought to make the physician seriously consider subacute hepatitis. Chemistry graphs can give you information—elevation of serum transaminase for months, a striking fall in albumin levels, and a persistent hyperglobulinemia—that you rarely see in benign hepatitis.

Biliary Cirrhosis

Though some claim that this is merely a variant of posthepatitic cirrhosis patients with "biliary cirrhosis" do have characteristic clinical features—chronic itching, insidious jaundice, xanthomas, large livers, and a predominance of women. On the chemistry graph, total bilirubin, alkaline phosphatase, and cholesterol are moderately to strikingly elevated, but other liver function tests remain normal until late in the disease. A new hypocholesteremic agent, cholestyramine, which binds bile acids in the intestine, often relieves pruritis.

These, then, are a few conditions in which chemistry graphs offer helpful information. For brevity's sake, we have not mentioned changes found in portal cirrhosis, viral hepatitis, fatty metamorphosis, infection mononucleosis, "lupoid" hepatitis, drug cholestasis, extrabiliary obstruction, and metastasis to the liver, although all may give recognizable patterns.

Richard L. Reece, M.D.
Minneapolis, Minnesota

So he'll breathe easier:

relieve anxiety while you relieve pain.

Relief of pain is usually a major goal in traumatic conditions. But often of importance, too, is alleviation of anxiety and tension that may heighten patient discomfort.

Single-prescription, non-narcotic Equagesic may effectively relieve pain. *And* ease anxiety and tension.

TABLETS

Equagesic®

(meprobamate and ethoheptazine citrate with aspirin) Wyeth®

IN BRIEF.

Contraindications: History of sensitivity or severe intolerance to aspirin, meprobamate or ethoheptazine citrate.

Warnings: USE IN PREGNANCY: Safety for use during pregnancy or lactation has not been established; therefore, it should be used in pregnant patients or women of child-bearing age only when the physician judges its use essential to the patient's welfare.

Precautions: Keep out of reach of children. Not recommended for patients 12 years old or less. Carefully supervise dose and amounts prescribed, especially for patients prone to overdose themselves. Excessive prolonged use of meprobamate in susceptible persons—as alcoholics, ex-addicts, severe psychoneurotics—has resulted in dependence or habituation. Withdraw gradually after prolonged excessive dosage to avoid possibly severe withdrawal reactions including epileptiform seizures. Warn patients of possible reduced alcohol tolerance, with resultant slowed reactions and impaired judgment and coordination. If drowsiness, ataxia or visual disturbances (impairment of accommodation and visual acuity) occur, reduce dose. If symptoms persist, patients should not operate machinery or drive. After meprobamate overdose, prompt sleep, reduction of blood pressure, pulse and respiratory rates to basal levels, and hyperventilation are reported. Give cautiously and in small amounts to patients with suicidal tendencies. Treat attempted suicide (has resulted in coma, shock, vasomotor and respiratory collapse and anuria) with gastric lavage and appropriate symptomatic therapy (CNS stimulants and pressor amines as indicated). Two instances of accidental or intentional significant overdosage with ethoheptazine and aspirin have been reported. These were accompanied by CNS depression (drowsiness and lightheadedness) but resulted in uneventful recovery. On basis of pharmacologic data, CNS stimulation could be anticipated, with nausea, vomiting and salicylate intoxication (requires induced vomiting or gastric lavage, specific parenteral electrolyte therapy for ketoacidosis and dehydration, and observation for hypoprothrombinemic hemorrhage [usually requires whole blood transfusions]).

Adverse Reactions: Ethoheptazine and aspirin may cause nausea with or without vomiting and epigastric distress, in a small percentage of patients. Dizziness is rare at recommended dosage. Meprobamate may cause drowsiness, ataxia and rarely allergic or idiosyncratic reactions. These reactions, sometimes severe, can develop in patients receiving only 1 to 4 doses. Such patients may have had no previous contact with meprobamate and may or may not have an allergic history. Mild reactions are characterized by urticarial or erythematous maculopapular rash. Acute nonthrombocytopenic purpura with cutaneous petechiae, ecchymoses, peripheral edema and fever have been reported. If allergic reaction occurs, discontinue meprobamate; do not reinstitute. Severe reactions, observed very rarely, include fever, fainting spells, angioneurotic edema, bronchial spasms, hypotensive crises (1 fatal case), anaphylaxis, stomatitis and proctitis (1 case) and hyperthermia. These cases should be treated symptomatically including, when indicated, such medication as epinephrine, antihistamine and possibly hydrocortisone. A few cases of leukopenia, usually transient, have been reported on continuous use. Rarely, aplastic anemia (1 fatal case), thrombocytopenic purpura, agranulocytosis, and hemolytic anemia have been reported, almost always in presence of known toxic agents.

Overdosage: See precautions section for management of overdosage.

Composition: 150 mg. meprobamate, 75 mg. ethoheptazine citrate and 250 mg. aspirin per tablet.

Wyeth Laboratories   Philadelphia, Pa.

Classified Advertisements

Classified advertising rates are twenty (20) cents a word; minimum monthly charge $5.00; key number, fifty (50) cents additional.

Replies to advertisements with key numbers should be mailed in care of Minnesota Medicine, 375 Jackson, St. Paul, Minn. 55101.

NINETEEN-MAN Wisconsin group located in college community of 40,000 with excellent hospital facilities is seeking additional associates in the following areas: (1) Internal Medicine, (2) General Practice, (3) Pediatrics and (4) Orthopedics. For further information please contact D. R. Griffith, M.D., Midelfort Clinic, Eau Claire, Wisconsin 54701.

ASSOCIATE urgently needed in busy general practice. Excellent clinic and hospital facilities. Salary open. Partnership after 1 year. Klefstad Clinic, Greenbush, Minn. Call collect: Lloyd H. Klefstad, M.D., Tele. 218—782-5275 or 4725.

TWO MAN GROUP needs a third general practitioner in a fast-growing West St. Paul area. Begin with salary and assume early partnership. Contact N. W. Howe, M.D., or E. J. McEllistrem, M.D., 1246 Gorman, West St. Paul, Minn. 55118 Telephone: 224-8001.

WANTED: G.P. to join clinic serving population area of 12,000. City has new hospital, new clinic building, two nursing homes, new Jr-Sr high school, new swimming pool, rich farming area in Red River Valley. Fishing and hunting nearby; metropolitan city close by. Salary open and partnership if interested. Write or call Warren Clinic, Warren, Minnesota 742-6231, area code 218.

GENERAL PRACTITIONER wanted to join well-established practitioner. New clinic building—90 miles east of St. Paul—city of 14,000. Early partnership with full hospital facilities. Ideal location. L. W. Picotte, M.D.; Chippewa Falls, Wisconsin.

GENERAL PRACTITIONERS—one or two wanted by the two local physicians and the community. Progressive, active community in Central Minn. Community has excellent schools, modern hospital-nursing home, golf course, beautiful lakes and active community organizations. For further information contact Administrator, Melrose Hospital, Melrose Minnesota, 56352. Tel. (612) 256-4231.

GENERAL PRACTITIONER wanted. Exceptional opportunity for one or two. Present Doctor leaving for V.A. Hospital. 5000 active files, 50 bed nursing home. Hospital 15 minutes, College 30 minutes. Clinic and equipment available. Contact Dr. Wm. Alcorn or John Franta, Wabasso, Minn.

G.P. AND INTERNIST for five-man clinic. New building, good hospital, city of 14,000 in heart of lake district. Good schools, junior college. Write: MINNESOTA MEDICINE—420, 375 Jackson St., St. Paul.

EXPANDING EIGHT-MAN CLINIC IN NORTHWESTERN WISCONSIN has immediate openings in General Practice, Internal Medicine and Urology. New clinic building; three accredited hospitals; large branch of the University of Wisconsin; population 33,000. Liberal first year salary, early partnership. Contact Milton Finn, M.D., 3600 Tower Avenue, Superior, Wisconsin 54880. Tel.: 715-392-8111.

GENERAL PRACTICE AVAILABLE. Retiring because of age. Fine clientele. Progressive town of 50,000 with large referral area. Excellent Hospital and University facilities. Air conditioned offices in good location. Contact T. Q. Benson, M.D., 1524 Walnut Street, Grand Forks, N. D.

WANTED: General Practitioner for staff physician on General Medical Service. Regular hours. Starting salary $14,409 to $19,771. Generous fringe benefits, including outstanding retirement program. Nondiscrimination in employment. For further information contact Chief of Staff, Veterans Administration Hospital, Des Moines, Iowa 50399.

WANTED: Young physician for association leading to partnership with four well established General Practitioners in fast growing suburb of St. Paul. Excellent clinic facilities in nearly new, partnership owned, well equipped, medical center building. Contact: A. Eugene Muller, M.D., North St. Paul Medical Center, 2579 East 7th Avenue, North St. Paul, Minnesota 55109.

THREE MAN group in North West Wisconsin Resort, State Conservation and Retirement Area needs two more physicians adequately to serve their practice. Facilities offered are three-room physician suites, X-ray and lab under AMT technician, RN-only nursing personnel. New accredited thirty-two bed hospital and forty-six bed nursing home. Deer and duck hunting, fishing within five minutes of town. Internist most needed; generalists welcomed. Will meet any reasonable salary request. Partnership after one year. Write: MINNESOTA MEDICINE—365; 375 Jackson St., St. Paul 55101.

GENERAL SURGEON interested in some general practice to associate with a 2-man partnership in a rich agricultural community in southern Minnesota. Modern hospital and new clinic building. Hunting, 9-hole golf course, swimming pool. Salary open and full partnership as soon as desired. Write: MINNESOTA MEDICINE—405, 375 Jackson, St. Paul 55101.

INTERNIST AND GENERAL PRACTITIONER wanted to join a five-man clinic group in Minneapolis. Complete laboratory and X-ray with board roentgenologist. Excellent hospital staff associations. Salary arrangement to start with, early partnership. Write MINNESOTA MEDICINE—289; 375 Jackson, St. Paul, 55101.

Law and Medicine

Procurement of Transplantable Tissues

THE NEED FOR transplantable tissues has grown enormously in the 20th Century. Through the years man has made many attempts to transplant various tissues and organs from animals and other men,[1] but it was not until 1900, when Landsteiner described the blood groups in man, that the success of blood "transplants" or tranfusions became feasible. These observations not only laid the ground for transfusion therapy, but opened the entire field of tissue transplantation.[2] The state of blood tranfusion as a routine safe procedure today is the goal for organ transplantation in the remainder of this century. To realize this goal, advances are needed in techniques in understanding and control of the rejection process, in organ preservation, and in moral and legal areas so that this new knowledge can be applied more promptly.

Source of Tissue

The sources of transplantable tissues are three: Living donors (related or non-related), cadaver "donors" and animal donors. At present, the best results with organ transplantation have been with kidneys taken from blood-related donors of compatible blood types.[3] It is in this group also that the moral and legal questions have been the least problem since the donor is able to willfully donate his kidneys. Unfortunately, the use of the blood-related living donor is limited to those who have such a suitable donor and those who require only the transplantation of expendable tissues such as blood or kidney. Fortunately, no living donor has died at operation, nor have any needed their previously donated organ. Sooner or later, however, this problem will occur.

The use of animal donors, while an attractive solution, has not yet been successful for any length of time.[4,5] When the immunology of transplantation is more advanced, animals might be the ideal source for tissues. This will eliminate the moral and legal issue of jeopardizing the life of the donor to prolong the life of the recipient. Also, since the animal is expendable, the transplantation will be scheduled at the convenience of the patient and his physicians.

At present, the human cadaver serves as the only practical source for many organs. Couch classifies cadaver tissues into two groups:[6] Critical tissues are those whose usefulness depends upon their viability, but whose viability is lost so rapidly at normal temperatures that postmortem legal procedures, tissue procurement and transplantation must be completed in a matter of minutes. In this group are the kidney, liver, heart, lung, pancreas, intestine, and most other organs; non-critical tissues are those that can be removed at leisure after death. They are subclassified into two types: viable, such as skin and cornea, and non-viable, which includes bone and artery.

Although it might seem that any hospital would have an enormous supply of cadaver donors, retrospective evaluation has implied that only seven to ten per cent[6,8] of hospital decedents could serve as suitable kidney donors, when the cause and time of death, age and conditions of death are considered.

Logistics and Legality

Of importance also are the aspects of logistics and legality of the tissue donation. It is in the procurement of critical tissues that logistic, moral, and legal problem can seriously influence the final outcome of the attempted transplantation. For here, every second is vitally important in increasing the chances for success. Difficulty surrounds the ability to remove the organ(s) from the cadaver donor before these tissues suffer the sequel of entering in a non-living environment (hypotension, hypoxia, released intracellular enzymes from other damaged cells). This means that the closer to the exact minute of "death" the donated tissues are removed, the better are the chances that they will live when placed in the body of the recipient. Today, with our automatic respirators, external cardiac pacemakers and ventricular bypasses and assist devices, it is technically impossible for a patient to die by the previously accepted criteria of heartbeat and respiration. Thus, for transplantation to serve society for maximum benefit, some expansion of our thinking in regard to the concept of death is needed.

Criteria for Death

There is no clear agreement among transplant surgeons for the criteria which indicate death. Some imply that the electrocardiograph is of great importance. Some refer to an inactive electroencephalograph as being reliable. Others leave the fixation of time of death to the physician who cares for the donor, being careful to never have the transplant team involved with the donor until after "death" has transpired. Any criterion for death that rests on a single measurement is bound to lose many otherwise good organs while the measurements are being made. These results are always dependent upon the measurement device, the personnel using the device and other extraneous factors. The electroencephalograph, for instance is cumbersome, requires trained personnel, and is not always available. The results are not completely reliable since hypoxia (a situation that adversely affects most critical tissues) and barbiturates can give a flat tracing that later may revert to normal.[9] The electroretinal response to photic stimulation may also be a reliable index of central irreversible neuronal damage, but the difficulty in performing the test is a disadvantage.[9]

Physiologic Measurements

Another problem inherent in physiologic measurements is to define a uniform period of measurement. An occasional qrs complex is often seen on the electrocardiograph 15 minutes after "death" has occurred by all other criteria. A flat electroencephalogram is virtually impossible to obtain in even the most severely damaged neurosurgical patient because the existence of "life" and muscular movement in the body are being measured. This and the changing electrical environment nearby where various motors and appliances are being switched on and off, could generate some artificial electrical activity if hours of flatness were to be necessary. Thus, in attempting to ascertain the precise minute of "death," we cannot rely on any one vital sign or set of measurements, but must consider many such observations.

This multiplicity of factors is recognized by both the law and the medical dictionaries[10,11] when they define death as being the "apparent extinction of life as manifest by absence of heartbeat and respiration" and "the cessation of life; to cease to exist; defined by physicians as a total stoppage of the circulation of the blood, and a cessation of the animal and vital functions consequent thereon, such as respiration, pulsations, etc."

Physician Must Declare Death

In the final analysis, it is the opinion of the physician that determines the time of death regardless of what instruments or methods he uses to assess the condition. Obviously, the patient who "died" while on cardiopulmonary bypass will always have a "pulsation" (from the roller pump) and respiration (from the oxygenator initially and anaerobic cellular respiration for some time thereafter) until someone decides that the patient will not revive. Then the machines are turned off and the patient is allowed to "die" even though death has already taken place long before. Thus it should be that when, in the opinion of physicians, recovery is impossible, the organs and tissues contained in the bodies of patients suffering irreversible brain damage, unsuccessful heart surgery, or other terminal situations should be available for transplant.

"Death" should be declared when it is obvious, in the opinion of the attending (and perhaps one other) physician that recovery of an acceptable degree of the central nervous system necessary for vital function is impossible, or when the patient's disease has progressed to the point that death is inevitable within a predictably short time. Then organ preservation and/or transplantation procedures should be implemented. The responsibility of predicting that death is soon to come must remain in the hands of the attending physicians, who then contact the transplant team to take over the management of the "cadaver." This is the point in space time where death must be considered to occur. The relatives and the previously attending physicians can be comforted by the concept that although the patient died, perhaps this patient's kidneys, lung, heart, valves, or other organs will live on, and in so doing, enable some other patient to enjoy life for several more years. It is the attending physician who should inform the relatives of the patient's demise, and the transplant team should discuss tissue donation with the next of kin only after the attending physician has given permission.

Disposition of Body

The techniques and knowledge are now available to "save" more than half of the younger people (age 55 is usually chosen as an arbitrary upper limit) afflicted with kidney damage. Moreover, each year new advances are being made to improve our methods and permit the transplantation of other organs and tissues. Society must make similar advances in our laws to permit the optimum use of organs for transplantation. It is unjust to allow a person's kidneys, for instance, to die just because they reside in a host whose heart or brain is severely damaged. It is even more unjust when the recipient who could harbor these kidneys may also be condemned to die if he does not receive them.

Society already considers the needs of the majority more important than the wishes of the deceased or his family to maintain a corpse intact. This is evidenced by the fact that all states have laws by which public officials can order that autopsies be performed in certain cases, e.g., where the person died as a result of an accident or is suspected to be the victim of foul play.

In the recent medical literature,[6,13,14] reference is made to the origins of American law in the roots of early common law of England wherein a corpse did not constitute property and no property rights were associated therewith. It was assumed that the next of kin had an inherent obligation to dispose of a body and a right to direct such disposal in a dignified and acceptable fashion. It should be pointed out, however, that if the next of kin failed to uphold that responsibility, provisions were made for prompt disposal of the remains. Thus the needs of society were met by the orderly disposition of the body.

Autopsy

The laws concerning the study of the bodies of dead persons vary from state to state (Table 1). These laws can be divided into three broad categories, which are autopsy or dissection, bequest or donation for anatomical study, and disposition of unclaimed bodies.

Autopsies, or post-mortem examinations, are limited to the purpose of determining the cause of death. These can be of two types. First is the case where a coroner or other public official has jurisdiction over the body because of death occurring under unusual or suspicious circumstances, e.g., to ascertain whether death occurred as a result of criminal activity. Second are the cases in which an autopsy is sought for medical purposes. An autopsy is generally performed within a few hours after death and the body released for burial shortly thereafter.

All states need enlightened revision of their autopsy, donation, and unclaimed bodies law to catch up with the expanded transplantation technology.

Today 39 of the states have specific statutory provisions governing the performance of post-mortem examinations. Although there is considerable variety of detail in these statutes, some provisions are fairly standard.

In 17 of the states, consent for performance of the autopsy must be written regardless of who gives the consent. In five more states, written consent is not required if relatives or kin consent; but it is, if consent is given by the decedent himself.

In 20 of the 39 states having autopsy statutes, the decedent may authorize an autopsy upon his own remains. In all 39 states, consent may otherwise be obtained from kin or relatives. However, from just whom consent should be sought is often subject to a great deal of doubt. One general group of statutes does provide an order of persons based on degree of familial relationship from whom consent should be sought. Many others, however, only list those from whom consent may be obtained, but do not provide any priorities among those listed. They also usually provide that consent should

be sought from the person who has assumed custody for the purpose of burial.

Donation for Anatomical Study

A bequest or donation for anatomical study is for two general purposes: first, to make tissue available for transplantation; second, to facilitate, indeed make possible, anatomical study of the human body by medical students, etc. In this instance the body may be kept for up to a year before final disposition of the remains is made.

Because it is entirely possible for persons to die without friends or relatives to see to the disposition of their body and, because some disposition must be made, most states have laws requiring certain public officials to dispose of such bodies. A waiting period is usually required before the body is made available for anatomical study.

One of the most common provisions is that if consent is being sought from a group or class of persons in the same order of priority, consent from one shall be sufficient authorization.

In spite of the fact that eleven states have no statutes relating to autopsy and that the law in many states is unclear, it is still possible to perform autopsies with little risk of liability if certain procedures or precautions are followed. States in which no statute prescribes who has custody of a body upon death have, as part of their common law, rules determining who has custody. This is almost always, first of all, the surviving spouse. Then children, parents, and other kin in that order. Since the person with right to custody is usually the only one who can maintain an action for mutilation of the body or willful interference with the right to custody, obtaining that person's consent, preferably in writing, stops him from bringing the action. Thus the important thing to determine in non-statutory situations is: who has right to custody of the body upon death?

Although many states have no statutory provision for conduction of autopsies, nearly all have cases which set precedence in determining responsibility along family lines for the custody of the body; therein lies an implied authority to grant permission or give consent to the autopsy.

Today 40 of the states have statutes whereby a person may will or otherwise donate his body or parts thereof for various medical purposes, including transplantations.

The laws of Tennessee, Mississippi, and New Jersey clearly state that a person may dispose of his body as he sees fit, and further provide that the recipient's right to possession of the body is superior to that of the surviving spouse or next of kin, and that the gift shall not be invalid if made by will, even if the will is not offered for or admitted to probate at a subsequent date.[15]

In some states, if the whole body is donated, the donee cannot claim the body until relatives have had an opportunity to provide funeral services. It is obvious that in such a situation no critical tissues could be transplanted unless organs could be removed prior to the funeral service. However, the law is unclear as to whether tissue can be removed prior to the funeral services.

All statutes which provide for donation permit donation by the decedent himself. The instrument of donation must always be in writing, and generally must be a will, with all that a will implies with respect to validity of the donation. However, some statutes provide for deeds of gift or other written authorization, and some provide that in case the will is not offered for probate or is invalid the donation of any or all of a body is still valid. Such a non-liability provision would seem to be a necessity, because if it were necessary to wait until the will was probated, the body would be of little use for study and of no value for transplantation.

In some states the statute specifically permits relatives to make the donation. Such a provision makes the law clear; but, because only the person who has the right to custody can bring an action for mutilation of the body, it is generally possible to procure tissue in the absence of statutory authorization by obtaining this person's consent.

Although most donation statutes do not specifically name eligible donees, such a listing in a statute would appear desirable to make it clear just who is authorized to study or transplant organs from the body of the deceased.

MINNESOTA

The donation of tissues, after death of the donor, is permitted in the Bequest section of the Minnesota Statutes under the definition of wills,[16] wherein it states:

> EXECUTION OF WILL. Subdivision I. Every person of sound mind, not a minor, may dispose of his estate, or any part thereof, or any right or interest therein, by his last will in writing, signed by him or by some person in his presence and by his express direction, and attested and subscribed in his presence by two or more competent witnesses.
>
> Subdivision 2. In addition, every such person described in subdivision I may by will dispose of the whole or any part of his body to a teaching institution, university, college, state board of public health, or legally licensed hospital, either for use as such institution, university, college or hospital may see fit, or for use as expressly designated therein (1935 c 72 s 34; 1949 c 160 sl) (8992-34).

In the autopsy section,[17] dissection of "dead" human bodies is permitted as follows:

> Dead bodies; dissection; when permitted. The right to dissect the dead human being shall be limited to:
>
> a) cases specifically provided by statute, or by the direction or will of the deceased;
>
> b) cases where a coroner is authorized to hold an inquest upon the body, and then only so far as he may authorize dissection;
>
> c) cases where the husband, wife, or next of kin, charged by law with the duty of burial, shall authorize dissection for the purpose of ascertaining the cause of death, and then only to the extent so authorized, provided no dissection shall be performed pursuant to this clause if there is any objection by anyone of such next of kin.
>
> Every person who shall make, cause to procure to be made, any dissection of the body of a human being, except as herein before provided, shall be guilty of a gross misdemeanor (R.L. s 4978) (10228).

Thus dissection and presumably donation of bodies or tissues is permitted providing that either the donor's will so stated and was witnessed by two competents, or a next of kin gives his permission, and no other next of kin objects. If any of these cases were to come to court, it might become apparent that the only authorization for tissue donation would have to be based upon an ante mortum will since the definition of a will in subdivision 2 as cited above speaks only of a body, and does not label it a dead body. This distinction becomes important when we attempt to define dead body in the legal terms of the Minnesota Statutes. Under definitions of vital statistics,[20] a dead body means a lifeless human body or such parts of the human body or the bones thereof from the state of which it reasonably may be concluded that death recently occurred. Obviously, lifeless means without life, and if a body is without life, no cell therein can be alive, and therefore, the only tissues that could be so harvested would be the non-viable and non-critical tissues by this definition.

Unclaimed Bodies

In regard to unclaimed bodies, it is interesting to note that all states except Idaho have statutory provision for the disposition of unclaimed bodies without a will or known desire to the contrary, the unclaimed body becomes the property of the states to be used for the advancement of medical science. This would appear to be a good source for cadaver tissues, but it is limited at present to non-critical tissues, since all states except Idaho and Hawaii require that the body be held for a given period of time from 24 hours to several months prior to being delivered to the designated medical authorities. During this holding period, efforts must be made to locate any relatives or friends that might be interested in the body.

Persons who die in Minnesota with no relatives or friends to claim their bodies cannot, at present, be considered as a source of critical transplantable tissues because of a 36-hour waiting period required before they can be made available. This is pointed out in the "Anatomical Study" section:[18]

> DELIVERY OF SUBJECT FOR DISSECTION
>
> Except as otherwise provided in section 145.15, the bodies of all persons dying within the state and not claimed for burial within 36 hours after death shall be delivered by the person in charge thereof for purposes of anatomical study. The deans of the medical college of the state shall appoint a committee to receive such bodies, which committee shall apportion the same to the several colleges according to the numbers of their students. Any body so received shall be surrendered on demand of a relative entitled to its possession. The remains of any such body, after it has answered the purpose, shall be decently buried in a public cemetery and the expense of transporting and burying such body shall be borne by the college receiving the same (R.L. s 2152) (5392).
>
> WHAT BODIES EXCEPTED
>
> No body shall be so delivered
>
> (1) After it has been regularly interred.
>
> (2) After it has been claimed for burial or cremation, by any person entitled to receive it for such purpose.
>
> (3) Without the consent of all known relatives of the person deceased.

(4) If such person in his last sickness requested that his remains be burned.
(5) If he died while detained as a witness or under suspicion of crime, or
(6) If by any provision of the law another disposition thereof be required (R.L. s 2153) (53 3).

If "purposes of anatomical study" were to be interpreted as including transplantation, penalties are provided for anyone using these "unclaimed" bodies for transplantation tissues inasmuch as[19] it is provided that:

> Every person who shall fail to comply with the provisions of sections 145.15 (what bodies excepted) and 145.16 (delivery of bodies) shall be guilty of a misdemeanor, the minimum punishment whereof shall be a fine of $25. Every person who shall use any body mentioned in sections 145.15 and 145.16 for a purpose other than that contemplated therein, or who shall remove it from the state, or in any manner traffic therein, or refuse to deliver the same upon proper demand, shall be guilty of a gross misdemeanor.

Comments

In comparison to the rest of the country, Minnesota is well ahead of the least progressive states, but somewhat behind the more forward-thinking regions. The time is ripe for change. A uniform gift-of-human-tissues act has been drafted which incorporates the best aspect of present laws,[105] recent advances in transplantation have demonstrated the need for a law which goes beyond the confines of present legal concepts. Since transplantation is now a well-established practice and a field that is receiving enormous amounts of federal funds to help its growth, and since Minnesota has its share of physicians interested in transplantation, it behooves us to alter our laws to bestow the most good upon the most people, while considering the individual rights of both donor and donee: that is, to encourage the donation of organs in numbers as great as possible, and still protect the rights of the donating individual and the sensitiveness of his relatives. In the prior act asking the next of kin of a soon-to-die donor for his tissue was a monumental and morbid task. Surprisingly many people even in that hour of grief, were able to permit the donation. To discuss the prospect of donation with a possible donor after his death has become predictable, but before he was moribund, is almost unthinkable from a psychological standpoint. This burden should be lifted from the patients and from the transplant team.

The need to move as quickly as possible, in order that the critical tissues for transplantation may have the best possible chance, militates against the filling out of forms with witnesses, signatures, statements of limitation, etc. At present, all this must be done before the anticipated transplant time.

The earlier a donation source can be predicted, the greater is the opportunity to begin tissue compatibility tests and assure the greatest possible chance for a successful transplant. Thus, potential donors might be partially evaluated long before they become moribund . . . if every patient could be considered a potential donor.

The legislation that is needed to allow the maximum number of lives to be saved by transplantation must establish that when we die, we have no further use for our bodies. This is evidenced by the rapid way they decay if not carefully preserved. Since the living population has a great stake in keeping all its members alive and healthy, and since the needs of the living take precedence over consideration for the dead as the Supreme Court of Nebraska pointed out in a 1964 case:[102]

> The right to have a dead body remain unmolested is not an absolute one; it must yield where it conflicts with the public good or where the demands of justice require subordination (Stastny vs. Tachovsky, 132 NW 2 d 317).

Therefore, it must be resolved that all efforts be made to keep organs and tissues alive and functioning. In an effort to do so, the law needs revision to allow donation of tissue automatically. If, for some religious or other reason, anyone objects to helping another human being live with a gift of his organs, the wishes of the individual donor should prevail. And, if the next of kin of a terminal patient should feel that their relative's tissues should be destroyed by cremation or burial immediately upon death, instead of living on in the body of some desperate child for 40 or 60 more years, their wishes too should be respected. When these changes in law come about, the last-minute legal aspects (which may have been useless at best, and fraudulent at worst) will be avoided. By assuming that saving a life is more valuable to society than destroying a whole body with all its parts, we place the burden of responsibility for initiating burial and the resultant destruction on those who want the tissues to be buried. The law could be written, however, in such a way as to avoid any mutilation or change in appearance and to maintain the present funeral practices.

Legislation designed to enhance the extension of life through transplantation techniques is greatly needed because of problems associated with transplantation not present under earlier medical practices. First is the need for large quantities of tissues, which are practically impossible to salvage under present legal procedures. Second is that speed is of the utmost importance in the procurement of tissues. The decision to transplant must be made before or very shortly after death; present legal procedures do not as a practical matter permit this to be done. The proposed legislation is an attempt to meet both of these needs and yet to preserve the basic rights of everyone involved.

Although much time and effort was expended by the authors to construct new legislation to accomplish all these aims, the *Uniform Anatomical Gift Act* developed by the National Conference of Commissioners on Uniform State Laws is now considered adequate on each of these points. In addition, it carries the approval of the National Conference, the National Research Council, The American Bar Association, and four states have recently enacted laws based on earlier drafts of the Uniform Act. We, therefore, suggest that the Uniform Anatomical Gift Act be enacted with all due haste, and in the form presented.

UNIFORM ANATOMICAL GIFT ACT

(Copy of final draft as approved on July 30, 1968, by the National Conference of Commissioners on Uniform State Laws)

An act authorizing the gift of all or part of a human body after death for specified purposes.

Section 1. (Definitions)

(a) "Bank or storage facility" means a facility licensed, accredited or approved under the laws of any state for storage of human bodies or parts thereof.

(b) "Decedent" means a deceased individual and includes a stillborn infant or fetus.

(c) "Donor" means an individual who makes a gift of all or part of his body.

(d) "Hospital" means a hospital licensed, accredited or approved under the laws of any state and includes a hospital operated by the United States government, a state or a subdivision thereof, although not required to be licensed under state laws.

(e) "Part" includes organs, tissues, eyes, bones, arteries, blood, other fluids and other portions of a human body, and "part" includes "parts."

(f) "Person" means an individual, corporation, government or governmental subdivision or agency, business trust, estate, trust, partnership or association or any other legal entity.

(g) "Physician" or "surgeon" means a physician or surgeon licensed or authorized to practice under the laws of any state.

(h) "State" includes any state, district, commonwealth, territory, insular possession, and any other area subject to the legislative authority of the United States of America.

Section 2. (Persons Who May Execute an Anatomical Gift)

(a) Any individual of sound mind and 18 years of age or more may give all or any part of his body for any purposes specified in section 3, the gift to take effect upon death.

(b) Any of the following persons, in order of priority stated, when persons in prior classes are not available at the time of death, and in the absence of actual notice of contrary indications by the decedent, or actual notice of opposition by a member of the same or a prior class, may give all or any part of the decedent's body for any purposes specified in Section 3.

(1) the spouse,
(2) an adult son or daughter,
(3) either parent,
(4) an adult brother or sister,
(5) a guardian of the person of the decedent at the time of his death.
(6) any other person authorized or under obligation to dispose of the body.

(c) If the donee has actual notice of contrary indications by the decedent, or that a gift by a member of a class is opposed by a member of the same or a prior class, the donee shall not accept the gift. The persons authorized by subsection (b) may make the gift after death or immediately before death.

(d) A gift of all or part of a body authorizes any examination necessary to assure medical acceptability of the gift for the purposes intended.

(e) The rights of the donee created by the gift are paramount to the rights of others except as provided by section 7(d).

Section 3. (Persons Who May Become Donees, and Purposes for Which Anatomical Gifts May Be Made)

The following persons may become donees of gifts of bodies or parts thereof for the purposes stated:

(1) Any hospital, surgeon, or physician, for medical or dental education, research, advancement of medical or dental science, therapy or transplantation; or

(2) any accredited medical or dental school, college or university for education, research, advancement of medical or dental science or therapy; or

(3) any bank or storage facility for medical or dental education, research, advancement of medical or dental science, therapy or transplantation; or

(4) any specified individual for therapy or transplantation needed by him.

Section 4. (Manner of Executing Anatomical Gifts)

(a) A gift of all or part of the body under section 2 (a) may be made by will. The gift becomes effective upon the death of the testator without waiting for probate. If the will is not probated, or if it is declared invalid for testamentary purposes, the gift, to the extent that it has been acted upon in good faith, is nevertheless valid and effective.

(b) A gift of all or part of the body under section 2 (a) may also be made by document other than a will. The gift becomes effective upon the death of the donor. The document, which may be a card designed to be carried on the person, must be signed by the donor, in the presence of 2 witnesses who must sign the document in his presence. If the donor cannot sign, the document may be signed for him at his direction and in his presence, and in the presence of 2 witnesses who must sign the document in his presence. Delivery of the document of gift during the donor's lifetime is not necessary to make the gift valid.

(c) The gift may be made to a specified donee or without specifying a donee. If the latter, the gift may be accepted by the attending physician as donee upon or following death. If the gift is made to a specified donee who is not available at the time and place of death, the attending physician upon or following death, in the absence of any expressed indication that the donor desired otherwise, may accept the gift as donee. The physician who becomes a donee under this subsection shall not participate in the procedures for removing or transplanting a part.

(d) Notwithstanding section 7(b), the donor may designate in his will, card or other document of gift the surgeon or physician to carry out the appropriate procedures. In the absence of a designation, or if the designee is not available, the donee or other person authorized to accept the gift may employ or authorize any surgeon or physician for the purpose.

(e) Any gift by a person designated in section 2(b) shall be made by a document signed by him, or made by his telegraphic, recorded telephonic or other recorded message.

Section 5. (Delivery of Document of Gift)

If the gift is made by the donor to a specified donee, the will, card, or other document, or an executed copy thereof, may be delivered to the donee to expedite the appropriate procedures immediately after death, but delivery is not necessary to the validity of the gift. The will, card or other document, or an executed copy thereof, may be deposited in any hospital, bank or storage facility or registry office that accepts them for safekeeping or for facilitation of procedures after death. On request of any interested party upon or after the donor's death, the person in possession shall produce the document for examination.

Section 6. (Amendment or Revocation of the Gift)

(a) If the will, card or other document or executed copy thereof has been delivered to a specified donee, the donor may amend or revoke the gift by:

(1) the execution and delivery to the donee of a signed statement, or

(2) an oral statement made in the presence of 2 persons and communicated to the donee, or

(3) a statement during a terminal illness

or injury addressed to an attending physician and communicated to the donee, or

(4) a signed card or document found on his person or in his effects

(b) Any document of gift which has not been delivered to the donee may be revoked by the donor in the manner set out in subsection (a) or by destruction, cancellation, or mutilation of the document and all executed copies thereof.

(c) Any gift made by a will may also be amended or revoked in the manner provided for amendment or revocation of wills, or as provided in subsection (a).

Section 7. (Rights and Duties at Death)

(a) The donee may accept or reject the gift. If the donee accepts a gift of the entire body, he may, subject to the terms of the gift, authorize embalming and the use of the body in funeral services. If the gift is of a part of the body, the donee, upon the death of the donor and prior to embalming, shall cause the part to be removed without unnecessary mutilation. After removal of the part, custody of the remainder of the body vests in the surviving spouse, next of kin or other persons under obligation to dispose of the body.

(b) The time of death shall be determined by a physician who attends the donor at his death, or, if none, the physician who certifies the death. This physician shall not participate in the procedures for removing or transplanting a part.

(c) A person who acts in good faith in accord with the terms of this Act, or under the anatomical gift laws of another state (or a foreign country) is not liable for damages in any civil action or subject to prosecution in any criminal proceeding for his act.

(d) The provisions of this Act are subject to the laws of this state prescribing powers and duties with respect to autopsies.

Section 8. (Uniformity of Interpretation)

This Act shall be so construed as to effectuate its general purpose to make uniform the law of those states which enact it.

Section 9. (Short Title)

This Act may be cited as the Uniform Anatomical Gift Act.

Better a bald head than none at all.—Austin O'Malley

Geigy

onedownmanship

Regroton® chlorthalidone 50 mg.
reserpine 0.25 mg.

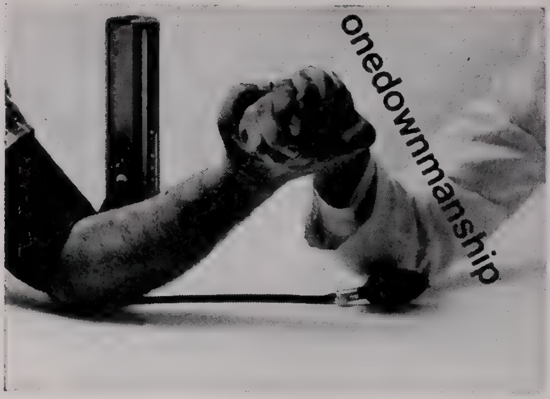
One Regroton tablet a day usually helps you and your patient bring high blood pressure down and keep it down.

Regroton produces a smooth, long-acting effect that usually reduces both systolic and diastolic pressures. At the same time it often acts to allay anxiety and nervous tension associated with hypertension.

Although Regroton is generally well tolerated, adverse reactions may occur. This drug is contraindicated in mental depression, demonstrated hypersensitivity, and most cases of severe renal or hepatic diseases. For a complete list of side effects, please see the Prescribing Information summarized on the following page.

Regroton®

chlorthalidone 50 mg.
reserpine 0.25 mg.



One Regroton tablet a day usually helps you and your patient bring high blood pressure down and keep it down.

Indications: Hypertension. **Contraindications:** History of mental depression, hypersensitivity, and most cases of severe renal or hepatic diseases. **Warning:** With the administration of enteric-coated potassium supplements, which should be used only when adequate dietary supplementation is not practical, the possibility of small-bowel lesions (obstruction, hemorrhage, and perforation) should be kept in mind. Surgery for these lesions has frequently been required and deaths have occurred. Discontinue coated potassium-containing formulations immediately if abdominal pain, distention, nausea, vomiting, or gastrointestinal bleeding occur. Discontinue one week before electroshock therapy, and if depression or peptic ulcer occurs. *Use in pregnancy:* Because chlorthalidone may cross the placental barrier and appear in cord blood and thiazides may appear in breast milk, this drug should be used with care in pregnant patients and nursing mothers. When used in women of childbearing age, the potential benefits of the drug should be weighed against the possible hazards to the fetus. Use of chlorthalidone may result in fetal or neonatal jaundice, thrombocytopenia, and possibly other adverse reactions which have occurred in the adult. Increased respiratory secretions, nasal congestion, cyanosis and anorexia may occur in infants born to reserpine-treated mothers. **Precautions:** Antihypertensive therapy with this drug should always be initiated cautiously in postsympathectomy patients and in patients receiving ganglionic blocking agents, other potent antihypertensive drugs, or curare. Reduce dosage of concomitant antihypertensive agents by at least one-half. To avoid hypotension during surgery, discontinue therapy with this agent two weeks prior to elective surgical procedures. In emergency surgery, use, if needed, anticholinergic or adrenergic drugs or other supportive measures as indicated. Because of the possibility of progression of renal damage, periodic kidney function tests are indicated. Discontinue if the BUN rises or liver dysfunction is aggravated. Hepatic coma may be precipitated. Electrolyte imbalance, sodium and/or potassium depletion may occur. If potassium depletion should occur during therapy, the drug should be discontinued and potassium supplements given, provided the patient does not have marked oliguria. Take particular care in cirrhosis or severe ischemic heart disease and in patients receiving corticosteroids, ACTH, or digitalis. Severe salt restriction is not recommended. Use cautiously in patients with ulcerative colitis or gallstones (biliary colic may be precipitated). Bronchial asthma may occur in susceptible patients. **Adverse Reactions:** The drug is generally well tolerated. The most frequent side effects are nausea, gastric irritation, vomiting, diarrhea, constipation, muscle cramps, headache, dizziness and acute gout. Other potential side effects include angina pectoris, anxiety, depression, bradycardia and ectopic cardiac rhythms (especially when used with digitalis), drowsiness, dull sensorium, hyperglycemia and glycosuria, hyperuricemia, lassitude, restlessness, transient myopia, impotence or dysuria, orthostatic hypotension which may be potentiated when chlorthalidone is combined with alcohol, barbiturates or narcotics, leukopenia, aplastic anemia, skin rashes, thrombocytopenia, agranulocytosis, nasal stuffiness, increased gastric secretions, nightmare, purpura, urticaria, ecchymosis, weakness, uveitis, optic atrophy and glaucoma, and pruritus. Eruptions and/or flushing of the skin, a reversible paralysis agitans-like syndrome, blurred vision, conjunctival injection, increased susceptibility to colds, dyspnea, weight gain, decreased libido, dryness of the mouth, deafness, anorexia, and pancreatitis when epigastric pain or unexplained G.I. symptoms develop after prolonged administration. Jaundice, xanthopsia, paresthesia, photosensitization and necrotizing angiitis are possible. **Average Dosage:** One tablet daily with breakfast. **Availability:** Pink, single-scored tablets in bottles of 100 and 1000.

Abstracts, Briefs and Commentaries

THE PYLORUS AS A BARRIER TO REFLUX

The gastroduodenal junction has been extensively studied in the past from the viewpoint of its relationship to gastric emptying, and its role as a pump and as a filter established. This paper deals with a clinical radiological study of the pylorus in 400 patients, assessing its efficiency as a barrier to duodenal regurgitation.

Results indicate that the normal pylorus is a competent structure preventing reflux during duodenal cap diastole and also during systolic contraction of a full cap. Such competence can easily be demonstrated in healthy nondyspeptic individuals and in many cases of duodenal ulcer. In the dyspepsias associated with gastric mucosal disease, especially gastric ulcer, there appears to be a breakdown in sphincter competence.

The sphincter is incompetent in 96% of active simple gastric ulcers, in 100% of combined duodenal and gastric ulcers, in 60% of duodenal ulcers, in 56% of patients with symptomatic hiatus hernia, and in 80% of X-ray negative dyspeptics. In biliary tract disease the sphincter behaves normally unless there is an associated dyspepsia, when incompetence is the rule.

These results add weight to the hypothesis that reflux of duodenal contents is abnormal and may play a part in human gastric pathology.

SERUM ENZYME STUDIES IN RELATION TO THE PANCREATITIS OF PREGNANCY

It seems to be reasonably well accepted that there is an increased incidence of acute pancreatitis in pregnancy. This is a serious disease with a high mortality rate. The condition may be due to an underlying pancreatic disturbance preceding pregnancy. This is not a universal rule. Recurrence of pancreatitis in further pregnancies is not inevitable. We have studied levels of serum amylase, lipase and anti-trypsins in the sera of normal pregnant women over the months of pregnancy. The levels of these substances are elevated in the last trimester. This is not necessarily in parallel for each of the three. The levels reach a maximum about term. The mean figure reached is at the upper limit of the normal range. Absolute levels would be greater if the extra body water of pregnancy were allowed for. We have studied a limited group of patients using the serum evocative test with secretin and pancreozymin as stimulants. The response of the serum levels following pancreatic stimulation in such subjects is also at the upper limit of the normal range or may exceed it, especially in the last trimester. Somewhat analogous changes in the levels of these enzymes occur during the menstrual cycle. This may be relevant to the changes found in normal pregnancy and to the pathogenesis of pregnancy pancreatitis.

DETERMINATION OF GASTRIC SECRETION USING A STEADY STATE TECHNIQUE AS A GUIDE FOR THE ELECTIVE SURGERY FOR PEPTIC ULCER

In order to obtain a preoperative evaluation of the gastric secretion, the steady technique by Nordgren has been performed on patients with gastric or duodenal ulcer. Some 75 patients with peptic ulcer have been investigated. Patients with duodenal ulcer often have a higher volume secretion than normal individuals. The relationship between volume secretion and acidity was, however, found to be within normal limits. Patients with gastric ulcer have normal volume secretion but often a lower acidity. This was most obvious at submaximal stimulation. We are now performing more radical surgery on patients with high secretion and less radical on patients with low secretion and low acidity. In this way we intend to get a low frequency of recurrences in combination with a low rate of postgastrectomy disturbances.

Minnesota Medicine Cover Photographs

In order to encourage more physicians to submit color slides for use on the cover of MINNESOTA MEDICINE the competition is being discontinued. The picture editor now invites all physician-photographers to send 35 mm. color slides of suitable subjects for consideration as cover pictures. The format must be horizontal because of printing limitations. Pictures highlighting Minnesota seasons, places, and activities will have an automatic advantage. No limit as to the number of slides sent will be set, but all slides should be individually identified. All slides will be returned. Physicians whose pictures are used as covers will be recognized in MINNESOTA MEDICINE. We can use many more pictures than we have received in the past.

Book Reviews

The books which help you most are those which make you think the most.—
Theodore Parker

MENIERE'S DISEASE MECHANISM AND MANAGEMENT, M. Spencer Harrison, M.D., F.R.C.P., F.R.C.S., and Lionel Naftalin, B.Sc., FC. Path., Pp. 226. Charles C. Thomas, Publisher.

This book is a comprehensive treatise on Meniere's disease, its possible causes and treatment. All related phases of basic research on the labyrinth, its structure, and function are discussed in accordance with current thinking.

The chapters are integrated essays on all facets pertinent to Meniere's disease. Three chapters in particular: "The Natural History of Meniere's Disease," "Difficulties in Diagnosis," and "Treatment," should be read by every physician who treats a dizzy patient.

The authors' aim . . . "to fit together the many intriguing pieces of research on the contents of the labyrinth in the past two decades," is attempted in the chapters on "Histopathology and Physiology and Biochemistry of the Labyrinthine Fluids." Various theories regarding origin of endolymph, and distention of the endolymphatic system are presented. An amazing bibliography has been compiled here, and I feel this book is worth purchasing for this reason alone.

A monograph on Meniere's disease fills a periodic need for otolaryngologists. Certainly in the past decades, with the development of ultramicrochemical techniques and the use of the electron microscope in the study of normal and also pathological specimens, a tremendous amount of new knowledge has accrued. The authors have done a good job of gathering all this information, organizing and contributing their own original work to it, and presenting it to the reader in an interesting fashion.

Hyman M. Paisner, M.D.
Minneapolis, Minnesota

ANATOMY FOR SURGEONS, Vol. 1, The Head & Neck, 2nd Edition, W. Henry Hollinshead, Ph.D.; Hoeber Medical Division, Harper & Row, New York, N. Y.; Price: $20.00; 634 pages; illustrations: 600.

This Anatomy of the Head and Neck is an excellent monograph for the surgeon in clinical practice. The details of complete descriptive anatomy are not included, but anatomical structures and variations are well described and beautifully illustrated with line drawings. This gives the clinical surgeon an opportunity to review the anatomy under consideration and have readily at hand the variations which might be encountered in the course of a surgical operation.

This will be particularly useful to the ophthalmologist and to the otolaryngologist. Chapter 9 deals with Surgery of the Neck which in most circumstances will probably be useful to the surgeon who does goiter surgery and neck dissections.

The illustrations are labeled in chapter sequence so that the first number indicates the chapter and the subsequent numbers indicate the sequence within the chapter. The headings and sub-headings are well placed and the type faces are large enough to be easily read without eye strain.

CALCULATION OF INDUSTRIAL DISABILITIES OF THE EXTREMITIES AND THE BACK—Second Edition—Carl O. Rice, M.D., Ph.D., F.A.C.S.; Publisher: Charles C. Thomas, Springfield, Illinois; Pages: 170; Illustrations: 148.

While admiring very much the precise and objective system of calculation which the author has evolved, it is felt that the method is so far removed from the basic principles applied to such calculations in Switzerland that Swiss surgeons will hardly be able to use it in calculating the disabilities of their patients.

The major discrepancy between the American and the Swiss system is that apparently in the United States a disability is calculated strictly on the basis of anatomical and functional defects without regard for the profession of the patient, whereas in Switzerland a given anatomo-functional impairment is evaluated on the basis of the disability it causes the patient in his individual profession.

The author has pointed out (page 83) that the physician should take the responsibility of accurately determining physical disability of an industrial member, but the Industrial Commission should establish the remunerative award in accordance with the individual's employment.

THE WEST MEDICAL CLINIC **has an opening** for a General Practice Physician. This is a five man group that conducts a practice near downtown St. Paul and also has the Airport Medical Clinic at Wold Chamberlain Field, Twin City International Airport. Both clinics have full laboratory and X-ray services with technologists covering both fields.

The Airport Medical Clinic does industrial, occupational and Aviation medicine. FAA examinations are conducted at both clinics.

The clinic located near downtown St. Paul has a practice limited principally to internal medicine, pediatrics, as well as occupational and industrial medicine. There is only a limited practice of obstetrics and no surgery.

Salary is open and opportunity for partnership is available. Write: West Medical Clinic, 539 W. Seventh Street, St. Paul, Minnesota 55102. Phone: Area Code 612-227-9341.

SURGEON; Board certified; FACS; desires part time surgical or industrial association—hours flexible. Write MINNESOTA MEDICINE 418, 375 Jackson, St. Paul 55101.

FOR SALE: Busy general practice northern Minnesota. Ideal for 1 or 2 doctors. Clinic, 14 rooms with lab. and X-ray. Good community hospital. Fine home. Will introduce. Write: MINNESOTA MEDICINE—416, 375 Jackson, St. Paul 55101.

WANTED: General practitioner to join two young general practitioners in well-established practice in suburban St. Paul. Excellent office space with lab, x-ray, and emergency room. Salary negotiable, with an association leading to early partnership opportunity. Write MINNESOTA MEDICINE 412, 375 Jackson St., St. Paul 55101.

EXPERIENCED GENERAL PRACTITIONER: Available for Locum Tenens. One or two week periods. After April 1st. Solo Practice Preferred. Write Minnesota Medicine 385, 375 Jackson, St. Paul, Minn. 55101.

RESIDENTS IN PSYCHIATRY: Vacancies for July 1, 1969. Three years approved eclectic residency program with emphasis on community psychiatry, milieu, individual and group therapy. 350 inpatients; large outpatient dept.; children's unit; excellent senior staff; affiliation with University of Iowa. Stipend $15,000 for residents with Iowa license or immediate eligibility for regular license. Stipend for foreign graduates who must have ECFMG, $12,240. Federal stipend available to physicians with four years non-psychiatric training or experience following internship amounting to $15,000 annually, of which $3600 is tax exempt. Enthusiastic and dynamic training and treatment programs that are best understood by a personal visit. Write or call W. C. Brinegar, M.D., Supt., or William Blyth, M.D., Mental Health Institute, Cherokee, Iowa.

FINANCING: We are most interested in financing medical buildings and clinics. Mortgages of $85,000 to $500,000, 18 to 20 year term. T. R. Waite Company, 700 Commerce Building, St. Paul, Minnesota. Tel. No. 227-8901.

FOR SALE AT BIG DISCOUNT: Nearly new medical equipment. Fluoradex "60" by Westinghouse—250 mill amperes—X-ray machine with full equipment. 4-piece examination room suites, consisting of table, cabinet, stool and recess. Other medical equipment used very little. Contact Village Clerk, Kimball, Minn. Phone 398-2725.

IMMEDIATE AND EXCELLENT opportunity to join well-established 3-man group practice in suburban Minneapolis. Salary open leading to partnership. Contact A. K. Schultz, Tyrol Clinic, 5250 Wayzata Blvd., Minneapolis, 55416, or call collect, 612—545-1661.

WANTED: General practitioner to join modern clinic in town of 2100 in southern Minnesota. New hospital being built. New municipal swimming pool, beautiful golf course and country club. Write R. S. Armstrong, M.D., or D. E. Halverson, M.D., Winnebago, Minnesota 56098.

Erratum

In the November, 1968, issue of Minnesota Medicine, Page 1618, "Coarctation of Aorta as Part of Shone Syndrome," there is an error in the stated Lanoxin dosage. In the sixth line from the top of the page, it should read 0.07 mg. Lanoxin per kilogram instead of 0.7.

Thirty-Second Annual Meeting The New Orleans Graduate Medical Assembly

The thirty-second annual meeting of The New Orleans Graduate Medical Assembly will be held March 10, 11, 12, 13, 1969, headquarters at The Roosevelt Hotel.

Nineteen outstanding guest speakers will participate and their presentations will be of interest to both specialists and general practitioners. The program will include fifty informative discussions on many topics of current medical interest, in addition to a clinicopathologic conference, medical motion pictures, round-table luncheons, and technical exhibits. This program is acceptable for three and one-half (3½) prescribed hours and twenty-eight (28) elective hours by the American Academy of General Practice.

An interesting and enjoyable program of entertainment for visiting ladies has been planned.

Electroencephalography Course

A Course in Current Problems in Electroencephalography: Advances toward their Solution; Date: March 13-15, 1969, Place: Houston, Texas. Sponsors: The American Electroencephalographic Society and Baylor University College of Medicine. For further information contact: Dr. Peter Kellaway, Baylor University College of Medicine, Texas Medical Center, Houston, Texas 77025.

the thousandth teaspoonful

Peptic ulcer patients find the thousandth dose of this antacid as effective and easy-to-take as the first!

Optimal neutralization[1] — provided by the combination of aluminum and magnesium hydroxides.
Unfailing good taste — confirmed by 87.5% of 104 patients in one study, after a total of 20,459 documented days on Mylanta Liquid or tablets.[2]
Concomitant relief of G. I. gas distress — provided by the proven antiflatulent action of simethicone[3].

Dosage: One or two tablets (well chewed or allowed to dissolve in the mouth); one or two teaspoonsful to be taken between meals and at bedtime, or as directed by physician.

DECLOSTATIN® 300 b.i.d.

Demethylchlortetracycline HCl 300 mg
and Nystatin 500,000 units
CAPSULE-SHAPED TABLETS Lederle

To guard susceptible patients against intestinal monilial overgrowth during broad-spectrum therapy—the protection of nystatin is combined with demethylchlortetracycline in DECLOSTATIN.

For your susceptible candidates, prescribe DECLOSTATIN—the broad-spectrum therapy that prevents monilial overgrowth.

Contraindication: History of hypersensitivity to demethylchlortetracycline or nystatin.

Warning: In renal impairment, usual doses may lead to excessive accumulation and liver toxicity. Under such conditions, lower than usual doses are indicated, and, if therapy is prolonged, serum level determinations may be advisable. A photodynamic reaction to natural or artificial sunlight has been observed. Small amounts of drug and short exposure may produce an exaggerated sunburn reaction which may range from erythema to severe skin manifestations. In a smaller proportion, photoallergic reactions have been reported. Patients should avoid direct exposure to sunlight and discontinue drug at the first evidence of skin discomfort. Necessary subsequent courses of treatment with tetracyclines should be carefully observed.

Precautions: Overgrowth of nonsusceptible organisms may occur. Constant observation is essential. If new infections appear, appropriat
measures should be taken.

In infants, increased intracranial pressure with bulging fontanels ha
been observed. All signs and symptoms have disappeared rapidly upo
cessation of treatment.

Side Effects: Gastrointestinal system—anorexia, nausea, vomiting, dia
rhea, stomatitis, glossitis, enterocolitis, pruritus ani. Skin—maculopa
ular and erythematous rashes; a rare case of exfoliative dermatitis h
been reported. Photosensitivity; onycholysis and discoloration of t
nails (rare). Kidney—rise in BUN, apparently dose related. Transie
increase in urinary output, sometimes accompanied by thirst (rare
Hypersensitivity reactions—urticaria, angioneurotic edema, anaphylaxi
Teeth—dental staining (yellow-brown) in children of mothers given th
drug during the latter half of pregnancy, and in children given the dr
during the neonatal period, infancy and early childhood. Enamel hyp
plasia has been seen in a few children. If adverse reaction or idios
crasy occurs, discontinue medication and institute appropriate therap

Average Adult Daily Dosage: 150 mg q.i.d. or 300 mg b.i.d. Should
given 1 hour before or 2 hours after meals, since absorption is impair
by the concomitant administration of high calcium content drugs, foo
and some dairy products. Treatment of streptococcal infections shou
continue for 10 days, even though symptoms have subsided.

One of the best things you can do for the cold sufferer

Ornade®

Prompt relief from nasal congestion and hypersecretion due to colds.

Before prescribing, see complete prescribing information in SK&F literature or *PDR*.
Contraindications: Glaucoma, prostatic hypertrophy, stenosing peptic ulcer, pyloroduodenal or bladder neck obstruction.
Precautions: Use cautiously in the presence of hypertension, hyperthyroidism, coronary artery disease; warn vehicle or machine operators of possible drowsiness.
Usage in Pregnancy: Use in pregnancy, nursing mothers and women who might bear children only when potential benefits have been weighed against possible hazards.
Note: The iodine in isopropamide iodide may alter PBI test results and will suppress I^{131} uptake; discontinue 'Ornade' one week before these tests.
Adverse Reactions: Drowsiness; excessive dryness of nose, throat or mouth; nervousness; insomnia. Other known possible adverse reactions of the individual ingredients: nausea, vomiting, diarrhea, rash, dizziness, fatigue, tightness of chest, abdominal pain, irritability, tachycardia, headache, incoordination, tremor, difficulty in urination. Thrombocytopenia, leukopenia and convulsions have been reported.
Supplied: Bottles of 50 capsules.

One capsule q12h for round-the-clock relief

Ornade® Trademark Each capsule contains 8 mg. of Teldrin® (brand of chlorpheniramine maleate); 50 mg. of phenylpropanolamine hydrochloride; 2.5 mg. of isopropamide, as the iodide.

Spansule® capsules

brand of sustained release capsules

Meet the President

Martin Van Herik, M.D.
President
Minnesota Radiological Society

See the President's Letter, Page 209.

Salt used to be an all or nothing proposition.
Now, there's a happy compromise.

HALF/SALT MIXTURE
MORTON®
HALF/SALT
MIXTURE™
NET WT. 3½

When you tell your patients to cut down on sodium, they have to settle for less than tasty meals. That takes a lot of will power. Now there's new Morton Half/Salt Mixture™. It contains half the sodium of regular salt so your patients can cut down on salt without cutting it out. But, they still get all the satisfaction of true salt flavor. You'll find that new Morton Half/Salt Mixture is far more dependable than will power. And, it makes low-sodium diets a lot easier for your patients to swallow.

President's Letter

Minnesota Radiological Society

On behalf of the Minnesota Radiological Society, I appreciate being invited to write this month's President's Letter. Last year marked the fortieth anniversary of the Minnesota Radiological Society. Dr. Leo G. Rigler, who for so many years was professor of radiology at the University of Minnesota, served as the first president of the society in 1928-1929; and he was followed in office by the late Dr. B. R. Kirklin of the Mayo Clinic. From a founding membership of about 20 radiologists, the society has grown to include more than 160 radiologists, physicists, and radiobiologists.

As the society has grown, so have its areas of interest. In the beginning the sharing and dissemination of scientific knowledge was the primary concern. More recently the society has become active in the area of socio-medical economics in addition to maintaining its scientific stature.

One cannot help but feel that radiology is presently in one of the most exciting eras of its existence. The past few years have seen the development of diagnostic radiologic procedures little short of phenomenal, particularly in its vascular, neurologic, and isotopic techniques. Therapeutic radiology has achieved parallel development, as evidenced by cobalt teletherapy, the linear accelerator, the betatron, and the therapeutic isotopes.

In the realm of medical economics the greatest breakthrough has been the advent of separate billing. This single mechanism has done more to make the radiologist a physician like other physicians than anything else that has happened since the inception of radiology as a specialty. Under this system the radiologist bills for the professional service he has rendered in the examination or treatment of a patient, and the hospital bills for the technical component of the examination or treatment. Thus the radiologist has a position analogous to that of other physicians such as surgeons who bill for the surgical operation while the hospital bills for the use of the operating room and equipment.

It is perhaps unfortunate that the radiologist has come to be thought of as a hospital-based physician, because actually in most cases he is not. According to a survey published in *Patterns,* a publication of Parke-Davis, radiologists spend about 19% of their work week in hospitals, which is considerably less time than is spent by many of their medical and surgical colleagues.

Like most physicians, radiologists are in short supply; and this pinch is evident in Minnesota as elsewhere. Organized radiology from the grass-roots radiologist up through the American College of Radiology is working actively to interest more young physicians in our specialty. We are also expanding the training of pararadiologic personnel. Within our ranks there is currently debate regarding just how much patient responsibility and even preliminary film interpretation should be relegated to the technologist. In my opinion the acute shortage of radiologists will soon make such debate merely academic. Undoubtedly we will find it more important to get on with the

It's almost as if you were there to give an injection of penicillin

V-Cillin K®, Pediatric dependable oral penicillin therapy

Potassium Phenoxymethyl Penicillin

Description: V-Cillin K, the potassium salt of V-Cillin® (phenoxymethyl penicillin, Lilly), combines acid stability with immediate solubility and rapid absorption. Higher, more rapid serum levels are obtained than with equal oral doses of penicillin G.

Indications: Streptococcus, pneumococcus, and gonococcus infections; infections caused by sensitive strains of staphylococci; prophylaxis of streptococcus infections in patients with a history of rheumatic fever; and prevention of bacterial endocarditis after tonsillectomy and tooth extraction in patients with a history of rheumatic fever or congenital heart disease.

Contraindication: Penicillin hypersensitivity.

Warnings: In rare instances, penicillin may cause acute anaphylaxis which may prove fatal unless promptly controlled. This type of reaction appears more frequently in patients with a history of sensitivity reactions to penicillin or with bronchial asthma or other allergies. Resuscitative drugs should be readily available. These include epinephrine and pressor drugs (as well as oxygen for inhalation) for immediate allergic manifestations and antihistamines and corticosteroids for delayed effects.

Precautions: Use cautiously, if at all, in a patient with a strongly positive history of allergy.

In prolonged therapy with penicillin, and particularly with high parenteral dosage schedules, frequent evaluation of the renal and hematopoietic systems is recommended.

In suspected staphylococcus infections, proper laboratory studies (including sensitivity tests) should be performed.

The use of penicillin may be associated with the overgrowth of penicillin-insensitive organisms. In such cases, discontinue administration and take appropriate measures.

Adverse Reactions: Although serious allergic reactions are much less common with oral penicillin than with intramuscular forms, manifestations of penicillin allergy may occur.

Penicillin is a substance of low toxicity, but it possesses a significant index of sensitization. The following hypersensitivity reactions have been reported: skin rashes ranging from maculopapular eruptions to exfoliative dermatitis; urticaria; and reactions resembling serum sickness, including chills, fever, edema, arthralgia, and prostration. Severe and often fatal anaphylaxis has occurred (*see* Warnings). Hemolytic anemia, leukopenia, thrombocytopenia, and nephropathy are rarely observed side-effects and are usually associated with high parenteral dosage.

Administration and Dosage: Usual dosage range, 125 mg. (200,000 units) three times a day to 500 mg. (800,000 units) every four hours. For infants, 50 mg. per Kg. per day divided into three doses.

See package literature for detailed dosage instructions for prophylaxis of streptococcus infections, surgery, gonorrhea, and severe infections.

How Supplied: Tablets V-Cillin K® (Potassium Phenoxymethyl Penicillin Tablets, U.S.P.), 125 mg. (200,000 units), 250 mg. (400,000 units), and 500 mg. (800,000 units).

V-Cillin K® (potassium phenoxymethyl penicillin, Lilly), Pediatric, for Oral Solution, 125 mg. (200,000 units) and 250 mg. (400,000 units) per 5 cc. of solution (approximately one teaspoonful). [042567A]

The Anatomy of the Facial Nerve

GEORGE L. KULLMANN, M.D.*
D. THANE R. CODY, M.D., Ph.D.†
Rochester, Minnesota

CONTROL OF THE FACIAL nerve originates in the motor cortex of the frontal lobe of the brain. From this region the supranuclear motor fibers converge via the pyramidal tracts onto the facial nuclei in the pons (Figure 1). Most of the fibers cross to reach the seventh nucleus of the opposite side, but some fibers proceed to the ipsilateral nucleus and eventually innervate the orbicularis oculi and frontalis muscles. Thus, a unilateral supranuclear lesion, which interrupts these fibers, will produce a spastic paralysis of only the lower half of the contralateral side of the face, whereas a lower-motor-neuron lesion results in a flaccid paralysis of the entire ipsilateral half of the face.

Motor Nucleus

The motor nucleus of the seventh cranial nerve is located in the pons, in close relationship to the abducens and salivary nucleus, as well as the spinal nucleus of the trigeminal nerve and the nucleus of the tractus solitarius (Figure 2). As the motor fibers leave the facial nucleus, they course around the nucleus of the abducens nerve and thus form the "genu of the facial nerve." The fibers then emerge from the caudal end of the pons, dorsal to the sixth cranial nerve and ventral to the eighth cranial nerve.

The Nervus Intermedius

These fibers are then joined by the nervus intermedius (of Wrisberg) to form the seventh cranial nerve. The nervus intermedius carries the parasympathetic visceromotor fibers from the salivary nuclei to the submandibular, sublingual, and lacrimal glands. The fibers to the lacrimal gland travel from the seventh nerve complex in the greater petrosal nerve and to the submandibular and sublingual glands in the chorda tympani nerve. The chorda tympani

†Mayo Clinic and Mayo Foundation: Section of Otolaryngology and Rhinology.

Read at the meeting of the Minnesota Academy of Ophthalmology and Otolaryngology, Rochester, Minnesota, May 13, 1968.

The terminology of the Nomina Anatomica 1965, 3rd Edition, is used, with naming of the intratemporal portions of the facial nerve according to House.

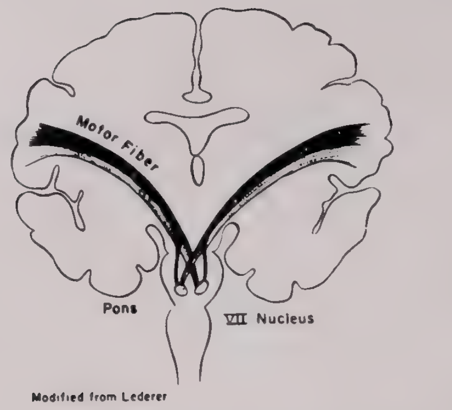

Fig. 1—Supranuclear motor fibers of facial nerves. (From: Kettel, K.: Peripheral Facial Palsy: Pathology and Surgery. Springfield, Ill., Charles C Thomas, Publisher and Copenhagen, Munksgaard, 1959, 341 pp. By permission of the publisher.)

nerve also carries special visceral afferent fibers, which supply the sensation of taste to the anterior two thirds of the tongue through the nervus intermedius and thence to the brain stem. In addition, it is believed that the nervus intermedius carries some general visceral afferents, which supply deep sensibility to the face and superficial tactile sensation to the posterior wall of the external auditory meatus.

Cerebellopontine Angle

This first part of the facial nerve is called the "cerebellopontine angle portion," and on its way to the internal acoustic meatus, it lies on the concave upper surface of the eighth cranial nerve. It enters the facial (fallopian) canal of the petrous portion of the temporal bone at the fundus of the internal acoustic meatus and is separated from the cochlear and inferior vestibular nerves by a transverse (falciform*) crest of bone and from the superior vestibular nerve by a vertical crest of bone (Figure 3). As the nerve enters the fallopian canal, it becomes the labyrinthine portion. This segment of the facial nerve takes a slightly curving course, the concavity of the flexure being an accommodation to the basal turn of the cochlea, to reach the geniculum.

The Geniculum

At this point, located in the medial wall of the epitympanic recess, the nerve turns suddenly posteriorly above the promontory. This sharp bend in the nerve is called the geniculum and is the area where the geniculate ganglion is located. Also here the greater petrosal nerve is given off, as well as a small branch to the lesser petrosal nerve. A third nerve may also branch off here, the external petrosal, which is an inconstant branch from the geniculate ganglion to the sympathetic plexus of the middle meningeal artery.

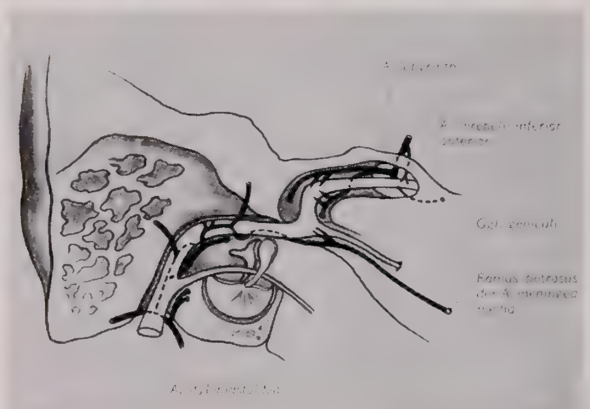

Fig. 7—Blood supply of facial nerve. (From Miehlke, A.: Die Chirurgie des Nervus facialis. München, Urban & Schwarzenberg, 1960, 208 pp. By permission of the publisher.)

Tympanic Portion

From the geniculum, the facial nerve arches downward on the medial wall of the aditus ad antrum between the stapes and the lateral semicircular canal. This is called the "tympanic portion" of the facial nerve. The facial nerve then curves slowly into the "mastoid portion" and descends vertically to reach the stylomastoid foramen. As the mastoid portion begins, the nerve to the stapedius muscle is given off, and at either the stylomastoid foramen or varying distances proximal to it, the chorda tympani nerve originates from the mastoid portion of the facial nerve and travels in its own bony canal toward the middle ear (Figures 4A and B).

The Three Branches

As the facial nerve leaves the temporal bone through the stylomastoid foramen, it gives off three branches: the digastric nerve to the posterior belly of the digastric muscle, the stylohyoid nerve to the stylohyoid muscle, and the postauricular nerve. The postauricular nerve is joined by the auricular branch of the vagus, as well as by branches from the greater auricular and lesser occipital nerves, and eventually innervates the occipitofrontalis and the auricular muscles.

The facial nerve then passes into the parotid gland anteriorly, where it forms the parotid plexus. Here the facial nerve divides into two major divisions, an upper zygomaticotemporal and a lower cervicofacial. These divide further into the five named terminal branches of the facial nerve. From above downward, these are the temporal, the zygomatic, the buccal (buccinator), the marginal mandibular, and the cervical. All the terminal branches anastomose with twigs of the fifth cranial nerve, except the cervical, which forms an anastomosis with branches of the second and third cervical nerves (Figure 5).

The facial nerve, of course, is responsible for the motor supply to all the muscles of expression, including the platysma. The exception is the levator palpebrae superioris muscle, which is supplied by the oculomotor nerve, explaining why the eye remains open in patients with complete paralysis of the peripheral facial nerve.

Histology

Similar to many other peripheral motor nerves, the facial is composed of bundles of fibers interspersed with connective tissue endoneurium and surrounded by the perineurium and epineurium. It is usual, however, to find the facial nerve consisting of only one large fiber bundle, with some very much smaller satellite bundles in the epineurium. Also, in the epineurium are found the vasa nervorum, which may be of considerable size. The perineurium and epineurium constitute the "nerve sheath," which fills about 50% of the fallopian canal (Figure 6). The nerve fibers occupy the remaining half of the canal. This nerve bundle is composed primarily of many myelinated fibers that range in size from about 1 to 14 μ. It is believed that the larger fibers are responsible for the transmission of motor impulses, whereas the smaller ones are the sensory and autonomic components. This belief is substantiated by the fact that the chorda tympani nerve and greater petrosal nerve are composed almost entirely of small myelinated fibers, which eventually form the nervus intermedius.

Blood Supply

The blood supply to the facial nerve (Figure 7) comes from the external and the internal carotid arteries, as well as from the vertebral system of arteries. The labyrinthine artery is a branch of either the basilar or, more usually, the anterior inferior cerebellar artery and supplies the preganglionic section of the nerve. This vessel does *not* anastomose with any of the other arteries. A branch of the external carotid artery, the posterior auricular artery gives off the stylomastoid artery, which enters the stylomastoid foramen and supplies the mastoid and some of the tympanic portion of the nerve. The petrosal artery, a branch of the middle meningeal artery, enters the middle ear space via the hiatus of the greater petrosal nerve and supplies the geniculum, the geniculate ganglion, and the remainder of the tympanic portion of the facial nerve.

There is a plexus of arteries, anastomosing on the promontory, that is primarily concerned with the blood supply to the middle ear, but occasionally may be involved in supplying the facial nerve. This plexus is composed of the posterior tympanic artery, a branch of the stylomastoid artery; the anterior tympanic artery, a branch of the maxillary artery; the caroticotympanic artery, a branch of the internal carotid artery; and the petrosal artery.

Summary

The anatomy of the seventh cranial nerve, as well as its histology and blood supply, has been reviewed.

The average man plays to the gallery of his own self-esteem.—Elbert Hubbard

Nobel Prize Winners in Medicine and Physiology

Wilhelm Einthoven 1924

For his discovery of the mechanism of the electrocardiogram

"The string galvanometer consists of a delicate thread, conducting electric current, stretched like a string in a magnetic field. As soon as the thread is electrified, it deviates from its equipoise in a direction at right angles to the direction of the magnetic lines of force. The magnitude of the deviation is proportional to the strength of the current flowing through the thread, so that this can be easily and exactly measured.

"Just as every muscle in its contraction generates an electric current, so also in the heart there is an evolution of electricity with every systole. . . . One needs only to lead the current from the hands and feet to the measuring instrument in order to see the variations in electric current, which show the same rhythm as the heart action.

"If one records the deviations of the measuring instrument one obtains a curve, which was called the electrocardiogram. But because of the imperfections of the capillary electrometer the curve directly recorded does not portray in an exact manner the actual variations in potential that have occurred. To get an exact picture one must construct a new curve based on the peculiarities of the instrument used and the data of the recorded curve, work requiring considerable time. This circumstance stood in the way of the practical application of electrocardiography to cardiac patients, and general interest in the ECG first developed later, after the string galvanometer made it possible to register the required pattern directly, easily, and quickly, and with satisfactory accuracy."

Einthoven first constructed a string galvanometer in 1903. From 1906 to 1921 he gradually improved it. By 1906 he had observed that different types of heart disease show different, and distinctive, tracings on the electrocardiogram. Between 1908 and 1913 he worked on the interpretation of the normal tracing, so as to provide a secure basis for the understanding of deviations from the normal result. His interpretation of each wave and complex in the recorded curve was worked out during this period, and the Prize was actually awarded not for the invention of the string galvanometer, but for the discovery of the mechanism of the electrocardiogram.*

What's Your Diagnosis?

A thirty-two-year-old white male, who was a heavy smoker, was employed in the taconite industry. For as long as he could remember, even prior to his smoking, he had had a rather noticeable cough, often productive of a small amount of yellowish sputum. This had not changed appreciably. Multiple chest roentgenograms had been taken because of his employment. Apparently these had all been considered "normal," although several times a second X ray was taken.

While attending a baseball game, he felt chilly and coughed up a small amount of bright red blood. Over the next few hours he coughed up approximately a cupful of bright red blood. He had no elevation of temperature and other than feeling rather weak and nauseated because of his constant coughing, he had no other particular symptoms.

What is your diagnosis? Turn to page 233.

Acute Suppurative Arthritis in Children

RAMON B. GUSTILO, M.D.*
DON P. AMREN, M.D.*
Minneapolis, Minnesota

THE GRATIFYING DECREASE in the mortality and morbidity of osteomyelitis and the mortality of joint infections as a result of sulfonamide, penicillin and broad-spectrum antibiotic treatment has not been followed by a comparable decrease in morbidity of joint infections. Wilkinson's[10] pessimistic view of 1952 is true today, "The story of infected hips has been written when the patient reaches us."

The reports of treatment of acute suppurative arthritis, particularly involving the hip joint, are very disappointing.[1]

Eyre-Brook[2] followed ten patients for five to 25 years and in 1960 reported uniformly bad results: capital epiphysis with persistent dislocation, one; loss of the capital epiphysis with residual neck in the acetabulum, one; loss of epiphyseal plate, two; coxa magna, four; gross osteomyelitis of the upper femur, one; no complications in only one patient.

In 1958 Samilson and co-workers[8] analyzed 35 cases of septic arthritis of the hip joint and reported the following complications: pathological dislocations in 10 out of 19 patients, coxa magna in three out of 19, osteomyelitis in nine out of 35 and spontaneous ankylosis in two patients. The few hips with good results had been treated by incision and drainage within four days of the onset of symptoms.

Obletz,[6] in 1960, reported suppurative arthritis of the hip in the neonatal period. The usual signs of fever, chills, swelling and prostration were not common. Typically the infant did poorly, refused to eat, was lethargic, had edema of the lower extremities and was febrile. Obletz advocated prompt surgical drainage.

In 1961, Ward, Cohen and Bauer[9] analyzed 21 cases of suppurative arthritis: 17 knees, two hips, one shoulder and one wrist. Four patients required surgical drainage; the rest were treated with aspiration and antibiotics.

---

*St. Louis Park Medical Center, Minneapolis, Minnesota.

This study was supported by a grant from the St. Louis Park Medical Center Research Foundation, Minneapolis, Minnesota.

The results were better in patients treated one week or less after onset of symptoms.

The largest reported group of patients with septic arthritis is Gilmour's[3] of 1962: 27 cases of pyogenic arthritis of the hip joint and 11 cases of septic arthritis of the knee joint. His early results were poor; 15 out of the 27 hips ended with disastrous results despite either repeated aspiration of the hip or drilling alone of the femur; however, seven of his last eight cases did well with posterior arthrotomy through a three-fourth square inch capsular incision and irrigation.

The purpose of this report of 32 patients with acute suppurative arthritis is to show that early diagnosis and prompt aggressive treatment are the key to decreasing the joint destruction and consequent morbidity.

Pathogenesis

Hematogenous septic arthritis starts with implantation of bacteria borne by the blood from a distant focus to the metaphysis, the articulating socket or (rarely) the synovium (Figure 1-A). For practical purposes a septic arthritis may be considered a metaphyseal osteomyelitis with spread to the joint by rupture through the cortex. Alternatively, the infection can extend to the cortex outside of the capsule and become extra-articular or extend throughout the medullary canal to become a massive osteomyelitis.

The anatomy of the hip joint makes it vulnerable to this process: the epiphysis and metaphysis are completely intracapsular; the main vascular supply is comprised of the posterior inferior and posterior superior arteries which branch off the medial and lateral femoral circumplex artery; the epiphysis stays open until 16 to 17 years of age and the joint is deeper in location and surrounded by thick muscular and neurovascular structures which limit accessibility for treatment.

In contrast, the anatomy of the shoulder, knee and ankle joints resists such spread of infection. In these joints the metaphyses are extra-capsular so that prior to closure of the epiphysis, a suppurative process usually spreads to the cortex outside of the capsule to become a subcutaneous abscess or extends into the medullary shaft to become a diaphyseal and metaphyseal osteomyelitis (Figure 1-B). Such

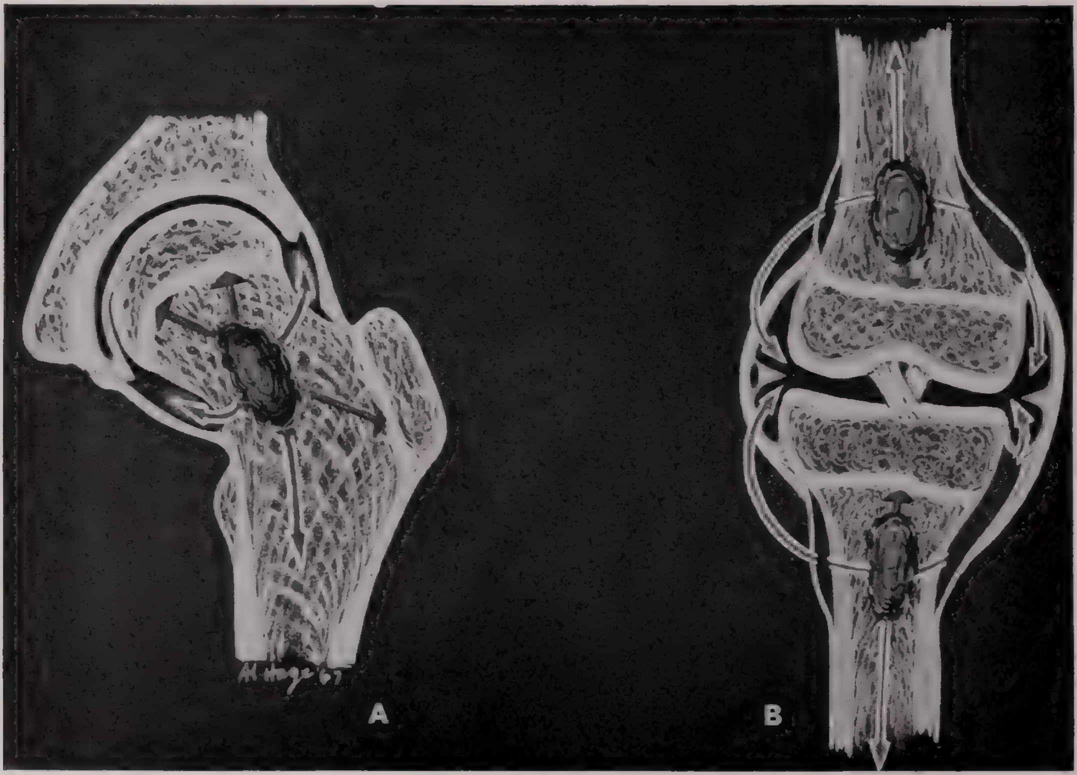

Fig. 1—Pathogenesis in septic arthritis.

infections rarely traverse the epiphyseal plate or epiphysis to break through the cortex and penetrate the capsule to gain access to the joint. However, when the epiphysis is closed, infection can spread directly into the joint. When infection has penetrated inside a joint, pus forms and the articular and subchondral cartilage is injured. Cartilage cell death is caused indirectly by a combination of nutritional failure and directly by injury from bacterial toxins.

Clinical Picture

The signs and symptoms vary with the severity of the infection, the etiologic agent and the patient's age. The typical clinical features observed in our 28 cases of septic arthritis were:

1. A very sick, toxic, miserable, irritable child who shouts, cries and resents any motion of the involved joint.
2. A temperature of 101 to 105° F.
3. A limp limb which the child will not use.
4. Localized bone tenderness.
5. Flexion deformity.
6. Leukocytosis and elevated sedimentation rate.

In constrast, the clinical picture in the neonatal infant is one of refusal to eat, lethargy, low hemoglobin and a gradually increasing temperature.

Regardless of age in the early stages (seven to 10 days), the x-ray is usually normal except for capsular distention. After two to three weeks, when the acute symptoms have subsided, bony x-ray changes such as mottling or periosteal elevation and layering are seen. Much later, sequestration develops.

Twenty-one patients were under 14 years of age, three under one year. Two out of five older patients had septic arthritis superimposed on rheumatoid arthritis.

The joints infected included 10 hips, nine knees, four ankles, two wrists and three elbows (Figure 2).

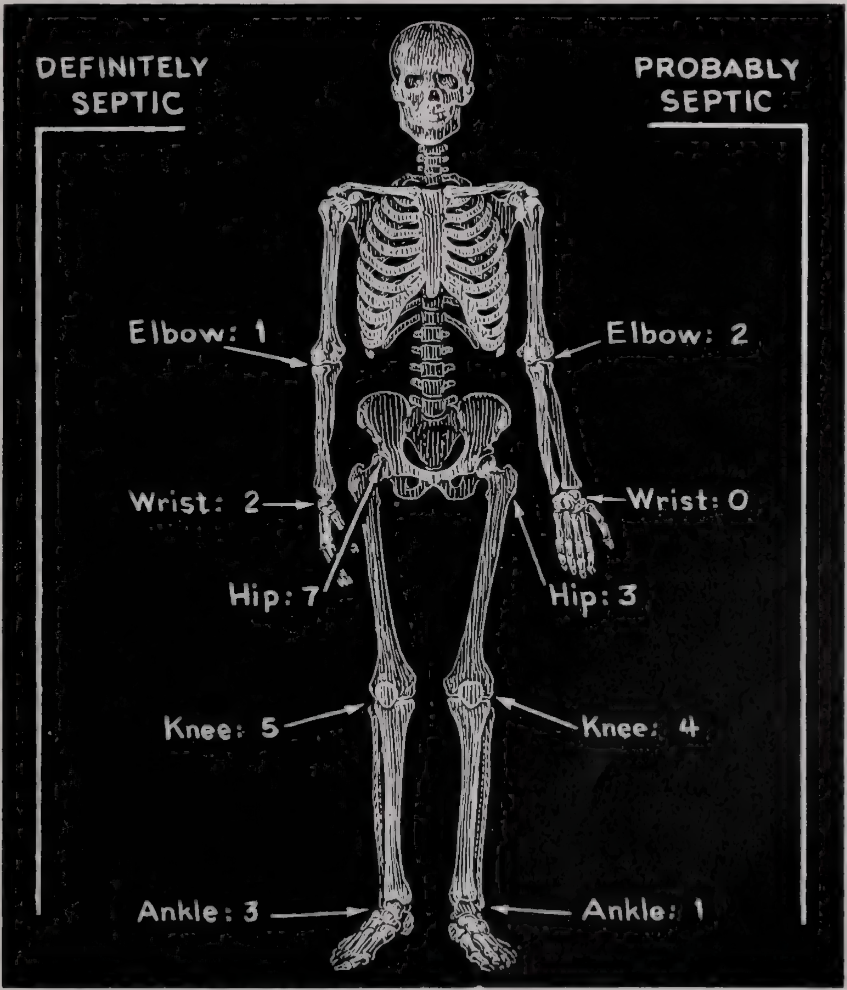

Fig. 2—Distribution of skeleton involvement in septic arthritis.

Twenty-seven patients (93%) had marked elevation of temperature and increased sedimentation rate. Leukocytosis (11,000-16,000) occurred in 20 patients (71%). Staphylococcus aureus was cultured from 13 patients. Six isolations were resistant to penicillin. Other bacteria found included Hemophilus influenza, Aerobacter, E-coli, Neisseria gonococcus and an unidentified gram-negative rod. Three patients with hip-joint involvement had positive blood cultures of Staphylococcus aureus coagulase positive.

Differential Diagnosis

Rheumatoid Arthritis

In acute juvenile rheumatoid arthritis more than one joint is usually involved. The synovium is inflamed and thickened with minimal effusion. Laboratory studies for rheumatoid factor and fluorescent antinuclear antibody are helpful if positive.

Toxic Synovitis

Toxic synovitis is quite common in the age group three to twelve years and is more common in boys. The common symptoms are pain in the hip with a limp. The temperature and white blood count may be slightly elevated. X-rays may show capsular distention. The acute symptoms may last three to five days. Suppurative arthritis can be excluded by aspiration and culture.

Rheumatic Fever

Rheumatic fever synovitis is part of a symptom complex which includes multiple joint involvement with erythema, carditis, abdominal pain, high sedimentation rate and positive C-reactive protein and a prior streptococcal infection.

Legg-Perthes Disease

Legg-Perthes disease synovitis presents as a limp with a vague onset followed later by typical x-ray findings in the head of the femur.

Hip-Joint Aspiration

The anterior approach is commonly used to aspirate the hip joint (Figure 3). Under sterile technique, the needle is inserted midway

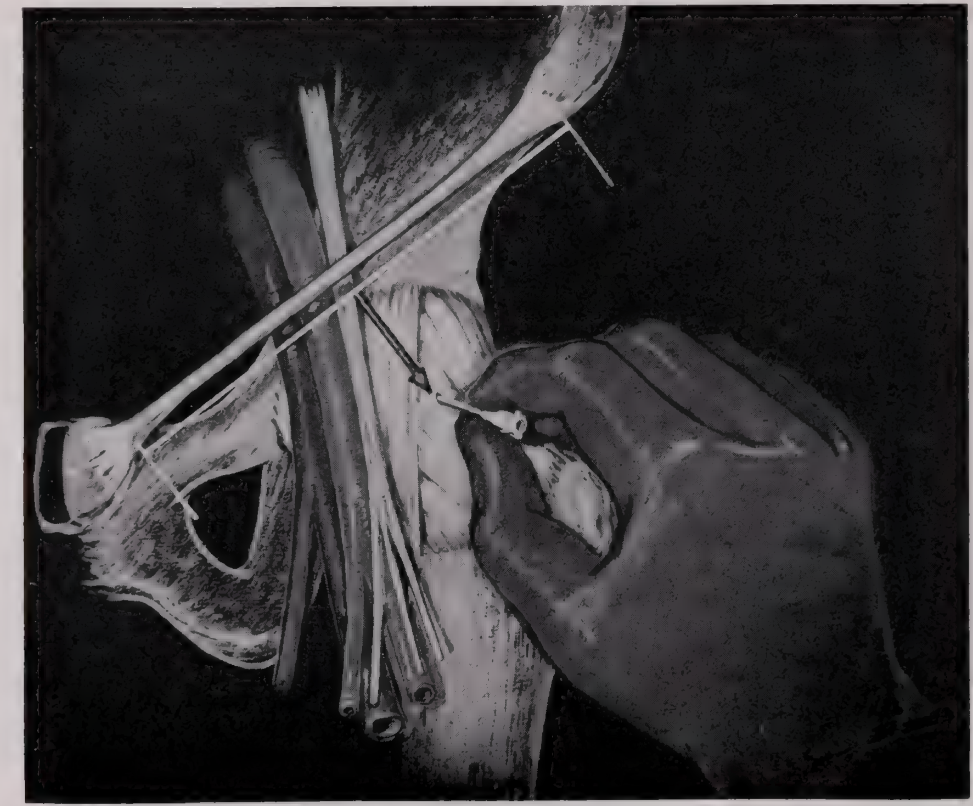

Fig. 3—Anterior approach of needle aspiration to the hip joint.

between the anterior-superior iliac spine and the symphysis pubis and directed 30 to 45° superiorly and medially. Procaine or xylocaine is infiltrated as the needle is directed with the index finger and thumb. The increased resistance felt as the needle reaches the joint capsule is followed by a giving-way sensation as the needle enters the joint. If no fluid is obtained by aspiration, entry into the joint can be checked by inserting the needle to touch bone. If the needle is touching the femoral head, it will move when the patient moves his leg. Alternately entry into the hip joint can be checked by injecting 3 to 5 cc of xylocaine and removing the syringe from the needle. If drops of xylocaine come out of the needle, the hip joint has been penetrated.

Analysis of 28 Cases

From 1960 to 1966, 34 patients were admitted to Methodist Hospital, Minneapolis, Minnesota, with monoarticular pain aggravated by motion and weight-bearing and the diagnosis of acute suppurative arthritis.

These patients were classified into three categories based on their entire clinical course and laboratory findings, including culture of the aspirated joint (Figure 2).

Definite Suppuration

In this group of definitely suppurative arthritis, there were 18 cases: patients who were sick on admission with severe pain and tenderness of the joint involved. They were highly febrile and had leukocytosis, increased sedimentation rate, and positive culture of the joint aspirate with or without positive blood culture.

Probable Suppuration

Probable suppuration was observed in ten patients. These patients had signs and symptoms identical with the first group except that culture of the joint aspirate was negative for any bacteria. The gross description of the aspirate was from very cloudy to sanguine-purulent.

Nonsuppurative

Nonsuppurative arthritis was obvious in six patients. These patients had a benign clinical course; two had nonspecific synovitis with no late sequelae, two had streptococcal arthralgia and two developed juvenile rheumatoid arthritis.

Our analysis will include only the first two groups of patients. The negative culture of the aspirate in Group 2 could be explained by treatment in about one half of the cases. Another probable reason for negative culture is that the fluid was aspirated early in the disease process when the reactive synovitis which precedes septic arthritis was present. Probably if the metaphysis had been drilled and cultured bacteriological identification might have been obtained. This was true in one patient whose joint fluid, although cloudy, was normal by culture, but in whom the aspirate from drilling the metaphysis revealed coagulase-positive Staphylococcus aureus.

Treatment

Twelve patients were treated by single or repeated aspiration and systemic antibiotics. Arthrotomy (open incision to the joint with Penrose drains or an irrigation-suction setup through the closed synovium) and antibiotics were used in 11 patients (seven hips, two knees, and two ankles), while drilling of the metaphysis was additionally used on three patients with hip disease.

Although all patients with septic arthritis of the hip were treated by arthrotomy, six were initially treated with large doses of intravenous antibiotics for two to five days without marked improvement.

Results of Treatment of Proven Septic Arthritis

Of the 18 patients with positive cultures, 16 were followed from six months to six and one-half years. Of the eight cases of septic arthritis of the hip joint, six were due to Staphylococcus aureus and two to Hemophilus influenzae. One was lost to followup. Five were normal clinically and had normal x-rays. One had fragmentation and avascular necrosis of the capital epiphysis; another had ankylosis of the hip joint with osteomyelitis and involucrum* of the proximal femoral shaft. These complicated cases followed infection by Staphylococcus aureus.

Other complications included asymptomatic narrowing of the wrist joint in one patient and of the ankle joint in another. A third patient had symptomatic marked narrowing of the subtalar joint. In two patients with rheumatoid arthritis, the residual of the infection was difficult to evaluate. To assess results of treatment of probable septic arthritis in the ten patients with a diagnosis of probable suppurative arthritis, seven were followed from one year to six years. Three were lost to followup. Seven were normal clinically and had normal x-rays.

---

*See Test Your Word Score Page 265.

Discussion

This study confirms past reports of the dire consequences of delayed diagnosis and treatment of septic arthritis and emphasizes that early diagnosis and aggressive antibiotic and surgical treatment can prevent most late sequelae. To wait for roentgenographic evidence of suppurative arthritis, i.e., narrowing of the joint, periostitis and lytic changes of the metaphysis of the long bones which may not appear until three weeks after onset of symptoms, is to wait too long; for severe complications are common if treatment is delayed even one week after onset of symptoms.

Diagnosis

Effective early diagnosis must be presumptive and based on clinical (history, physical examination and laboratory studies) judgment. Alternating two-finger palpation and pressure helps localize bone tenderness and soft tissue swelling and warmth. Leukocytosis and increased sedimentation rate are usually present. When septic arthritis is suspected, the joint should be aspirated under sterile technique. Examination of the aspirate should include gram smear, aerobic and anaerobic bacterial cultures and sensitivity studies. Blood cultures should also be made. As soon as the cultures are done the patient should be started on massive doses of antibiotics.

Surgical Approach

Suction Irrigation

Aspiration and antibiotics are usually not effective in controlling the infection of the hip joint. Immediate arthrotomy, placement of a suction-irrigation setup and drilling of the metaphysis should be done when clinical history of suppurative arthritis of the hip is accompanied by a grossly purulent aspirate and a positive gram stain of the aspirate. A 24-hour delay of surgery may be permitted when the diagnosis is doubtful and bacteriologic culture is needed to confirm the diagnosis. The patient who is toxic from bacteremia frequently improves rapidly when surgical decompression is done.

The suction-irrigation setup is used for five days. Each day three to 4,000 cubic centimeters of an antibiotic solution is introduced into and then sucked out of the wound. Neomycin was once popular but should not be used if other antibiotics will suffice; for toxic effects on the kidneys with death have been reported. Penicillin and methicillin are currently recommended. Where changes of metaphysis and proximal femoral shaft are observed, a single spica cast should be applied.

Other joints, i.e., the knees, ankles and elbows, can frequently be treated effectively by repeated aspiration and massive doses of antibiotics. However, if the local signs and symptoms persist two to three days or increase, surgical decompression should be done.

Antibiotic Therapy

The staphylococcus is the etiologic agent in 70-80% of the positive cultures obtained from patients with septic arthritis. Streptococci (group A beta hemolytic, viridans and faecalis), clostridia and pneumococcal organisms are frequently found. Gram-negative bacteria including Hemophilus, Salmonella, Pseudomonas, Klebsiella aerobacter and coli-form organisms are infrequently cultured.

Antibiotic treatment should be delayed until aspiration and blood cultures are taken. Initial antistaphylococcal therapy should include penicillin and a penicillinase-resistant penicillin (Methicillin, oxacillin, nafcillin, cloxacillin or dicloxacillin). Methicillin is the preferred parenteral penicillinase-resistant penicillin because of serum-binding considerations, and cloxacillin and dicloxacillin are the best oral agents because of gastrointestinal absorption patterns. Parenteral administration is always preferred initially. Because of the increased incidence of Hemophilus influenzae infections in young children[11], ampicillin should be substituted for penicillin for children under age four years. If the patient is allergic to the penicillins, cephalothin, erythromycin or tri-acetyl-oleandro-mycin can be used. The initial antibiotic choices are necessarily subject to modification as the results of in-vitro antibiotic sensitivity testing become available.

After several days to two weeks of initial parenteral therapy, oral therapy is substituted. Antibiotic therapy should be continued until evidence of inflammation is gone and healing is manifested by x-ray examination, a period of one to 12 months.

Summary

An analysis of 32 cases of suppurative arthritis is presented, emphasizing the diagnostic signs, method of hip-joint aspiration, laboratory findings, x-ray findings early and late, and therapeutic regime. Suppurative arthritis of the hips offers special problems because of enclosure of the epiphysis and metaphysis in its capsule. In hip infection better results may be obtained by earlier diagnosis and arthrotomy. Infection of other joints may be managed by systemic antibiotics and repeated aspiration unless toxicity of the patient dictates surgical decompression of the joint. Antibiotic therapy should be directed initially against the staphylococcus and modified according to culture or gram stain of the aspirate results. Antibiotic therapy should continue until evidence of inflammation is gone and healing is manifested by x-ray examination.

Shakespeare's Doctors

Dr. Caius

From the zenith of sublime tragedy and superb character delineation Shakespeare's versatile genius could descend facilely to the nadir of caricature and horseplay. In The Merry Wives of Windsor, Dr. Caius, the French doctor, contributes hilarity by his coarse accent and his rash impetuosity.

In love with Ann Page and learning that he has a rival in the person of Parson Hugh Evans, Caius challenges the parson to a duel, announcing in high dudgeon: "I vill cut his troat in de Park. I vill cut all his two stones; by gar, he shall not have a stone to trow at his dog."* (The vulgar among the audience must have howled at this pun.)

The duel never comes off, however. But Evans has the last word when he says of Caius: "He has no more knowledge in Hibbocrates and Galen,—and he is a knave besides."†

It's the Law

Permitting Office Girl to Treat Patient Is Evidence of Doctor's Negligence

Evidence that a doctor permitted his office girl, a high school graduate with two years' experience as a nurses' aide, to treat a patient's lacerated hand on at least twelve occasions was held sufficient to send to the jury the question of the doctor's negligence, even in the absence of expert testimony. Accordingly, the Massachusetts Supreme Court overturned a lower court's directed verdict for the doctor.

The patient had consulted the doctor after injuring his hand at work. The doctor bathed the hand, gave pencillin and antitetanus injections, and prescribed medication for relief of pain.

When the patient returned to the doctor's office two days later, he was treated by the doctor's office assistant, who removed the bandage, soaked and bathed the hand, and rebandaged it. She instructed the patient to return to the office two days later. He did so and was treated by the doctor, who found that the thumb was swollen and that the flesh around the stitches was swollen and infected.

For more than a month the patient continued treatment, visiting the doctor's office a total of seventeen times. On no more than four of the visits was he seen by the doctor, being treated on the other occasions by the office assistant. She removed stitches, squeezed pus out of the thumb, prescribed pills, injected penicillin, removed and reapplied bandages, even advised the patient as to the treatment to be followed.

In the patient's suit against the doctor for malpractice, there was no expert testimony that the doctor was negligent in his treatment of the patient. However, the court said that there was sufficient evidence from which the jury could have found that the doctor did not use his best judgment in order to produce a good result. One basis for such a finding was the patient's testimony that the doctor failed to prescribe hospitalization, even after it was clear that the patient's thumb was infected. Another basis was the action of the doctor in permitting the patient to be treated by his office assistant to the extent described. The court concluded that the jury would be warranted in finding, without the aid of expert opinion, that the doctor's treatment of the patient was not consistent with standard medical practice.

Abdominal Aortic Aneurysm Eroding into Duodenum

Pain at Unusual Site and Death from Gastrointestinal Hemorrhage

EARL E. GAMBILL, M.D.*
Rochester, Minnesota

THIS CASE IS reported because of its unusual interest. First, the slowly progressive pain and loss of weight and strength, suggestive of malignancy, raised the question predominantly of either carcinoma of the pancreas or retroperitoneal lymphoma. Second, the intermittent and progressive nature of the pain confined to the lower part of the abdomen and lower part of the back as represented in this case seems a bit unusual for aneurysm of the upper part of the abdominal aorta. Finally, the case illustrates the importance of early exploration since, if this patient had undergone abdominal exploration prior to the fatal hemorrhage, the chances are fairly good that resection of the aneurysm and substitution of a graft might have saved his life.

Report of Case

A 64-year-old unemployed man came to the Mayo Clinic on March 4, 1963, because of intermittent but increasingly frequent pain that he had had in the lower part of the abdomen, scrotum, and lower part of the back since December 1962. The pain had begun in the lower right abdomen, over the right iliac crest, and across the lower lumbar region, initially on the right and subsequently also on the left. At first it occurred about every three to four hours. It was not, he said, a bowel cramp, and there was no history of peptic ulcer features. The pain was not affected by defecation or urination or by coughing, sneezing, or bending. It was worsened by sleeping on the right side. It interfered with sleep, causing the patient to sit up in a chair at night, as he felt somewhat better sitting up than lying down. When he was admitted some three months after the beginning of the illness, the pain was awakening him one to three times each night and was occurring during more of the day and the night than at the beginning. He obtained some relief while lying prone on his suitcase cushioned by a pillow. Associated symptoms were anorexia, loss of strength, despondency, increased flatus, and loss of more than 26 lbs in six to eight months. In 1960 he had had a myocardial infarction; since then he had been taking 5 mg of warfarin (Coumadin) daily.

Physical Examination

On physical examination the patient weighed 179 lbs

---

*Mayo Clinic and Mayo Foundation: Section of Medicine.

His blood pressure was 140/80 mm Hg, pulse rate 108/min, and temperature 98.2 F. There was a grade 2 systolic murmur over the apex of the heart and over the second interspace near the right sternal border, but no audible bruit over the abdomen and no palpable masses. There was tenderness to pressure in and just above the right groin and over the region of the inguinal canal, but there were no masses or hernias. The prostate was enlarged (grade 1) and benign. There was tenderness to percussion over the third lumbar vertebra.

Neurologic Findings

Neurologic findings were essentially normal except for some decrease in vibratory perception about the knees and ankles and over the iliac crests.

Laboratory Analysis

Analysis of the urine showed red and white blood cells and hyaline casts (grade 1) with occasional granular and leukocytic casts. The specific gravity was 1.019. There was 10 ml of residual urine. The hemoglobin concentration was 12.5 gm/100 ml of blood, the leukocyte count 11,800/cu mm, and the sedimentation rate 77 mm in one hour (Westergren method). Values for serum bilirubin, acid and alkaline phosphatase, and blood urea, and the serologic reaction for syphilis were normal. The concentration of fasting blood sugar was 108 mg/100 ml (normal 65 to 90 mg). The prothrombin time (Quick) was 21 seconds. The sulfobromophthalein test of hepatic function showed that 8% of the dye was retained at the end of one hour. X-ray examination of the chest and excretory urography revealed no abnormalities. Proctoscopic examination for a disstance of 24 cm showed only hemorrhoids. X-ray examination of the lumbar spine disclosed hypertrophic changes with calcification confined to the lower abdominal aorta without widening. Subsequent review of the films provided no evidence of aneurysm. X-ray studies of the colon with the aid of barium showed diverticulosis in the region of the sigmoid. The terminal ileum was normal. An electrocardiogram showed the scar of an old infarct, the Q waves in leads 2 and 3 being lengthened with the S wave in lead 1.

Diagnostic Possibilities

It was felt that this could be a case of carcinoma of the pancreas in which pain had begun in the lower part of the abdomen and had not progressed far enough to be felt in the upper part. Besides, he had hyperglycemia with a negative family history of diabetes. A test of pancreatic function was performed with secretin (Vitrum), 1 unit/kg of body weight, given as a stimulus after the patient had fasted all night. The tip of the drainage tube was at the junction of the second and third parts of the duodenum as evidenced by a simple roentgenogram of the abdomen prior to starting the test. Constant suction of gastric and duodenal contents was carried out for one hour after stimulation with secretin. The test indicated an abnormally low volume (less than 1 ml/min) of secretion with essentially normal bicarbonate content, findings quite compatible with those noted in patients with pancreatic carcinoma.

It was felt that the abdomen should be explored, the most likely lesions being, in order, retroperitoneal lymphosarcoma or carcinoma of the pancreas. The surgeon who saw the patient concurred in this view. The patient did not wish to have the operation then, decided that he might return later, and was dismissed on March 14, 1963.

The home physician wrote that on March 20 (six days after dismissal from the Mayo Clinic) the patient had been hospitalized because of acute upper gastrointestinal hemorrhage with shock. The blood pressure was unobtainable and the pulse was weak and thready. The prothrombin time (Quick) on March 21 was 16 seconds.

The patient passed large quantities of bright red blood by rectum as well as vomiting copious amounts. The blood pressure gradually rose to 80/68 mm Hg, where it remained stable until March 23 when it again fell to 0 and he was given 500 ml of blood. Following transfusion the blood pressure rose to 110 to 150 systolic and remained stable until March 25, when it began to fall. He was given another 500 ml of blood, after which the pressure rose to 90/58 and he said he felt well. Twenty-four hours later he had had no further rectal bleeding. He was given a routine back rub and was then placed on his back, following which his color suddenly changed markedly, he had severe dyspnea and muscular twitching, and died quickly.

Autopsy

According to the local pathologist, autopsy revealed the white scar of an old myocardial infarct near the base of the heart posteriorly, the left coronary artery being narrowed by atheromatous plaques. The abdominal aorta had become a fusiform aneurysm from just below the renal arteries to the bifurcation, being dilated to about 5 to 8 cm on cross section, with the anterior upper part of the aneurysm lying against and firmly adherent to the transverse duodenum. At the site of the adhesion the duodenum contained an ulcer measuring 4 by 4 cm, and in the base of the ulcer an opening measuring 6 by 2 mm communicated with the lumen of the aortic aneurysm. The aneurysm contained a layered thrombus through which had developed a channel leading to the ulcer. The stomach contained a large blood clot. The duodenum, jejunum, ileum, cecum, colon, and appendix contained blood and clots. The pancreas was normal in size and contour and the cut surface was not remarkable. Microscopically the pancreas was normal. The liver also appeared to be normal, as did the gallbladder. The spleen, adrenals, and kidneys were normal. The pathologist summarized the findings as (1) abdominal aortic aneurysm ulcerating into the transverse part of the duodenum and producing massive hemorrhage into the duodenum, (2) arteriosclerotic heart disease with old healed infarcts on the left, and (3) amyloid kidneys.

Comment

Just why this aneurysm was not palpable by the many physicians who had examined the patient, both at home and at the Mayo Clinic, is obscure. Perhaps the most logical answer would be that an aneurysm was not suspected. The aneurysm must have become larger and more extensive than that which presumably was present on March 14, since the calcification that was visible on roentgenograms of the lumbar spine some three weeks prior to death was in the lower half of the abdominal aorta and indicated no abnormal widening of the aorta at this level. The progressive, relentless pain extending to the back and being worse in recumbency, the weight loss, the anorexia, and the loss of strength suggested malignancy involving the retroperitoneal region. The limitation of pain to the lower part of the abdomen and to the lower lumbar and sacral region rather than the upper lumbar and lower thoracic region suggested that the lesion was most likely located at a level lower than the pancreas. Therefore, a possible retroperitoneal lymphosarcoma loomed high among the likely possibilities. Yet the newness of the hyperglycemia and the results of the secretin test compatible with pancreatic carcinoma could not be overlooked. The lowness of the site of pain is interpreted as being likely due to stimulation of nerve fibers at the root of the mesentery. The low secretory volume of the pancreas is unexplained but could have been related to interference with pancreatic outflow caused by pressure against the pancreas and duodenum by the aneurysm. Although the secretin test was done in the Gastrointestinal Research Unit by an experienced technician, the possibility that the results were due to laboratory error cannot be dismissed.

Acknowledgment

I am indebted to Dr. Robert Lanning, Hannibal, Mo., who referred this patient and provided information on subsequent developments, including the autopsy report.

Disease as Reprisal V

Why was Job afflicted with boils?

God doubted his faith and wanted attestation of his physical endurance and moral stamina, after Satan's taunt.

So went Satan forth from the presence of the Lord, and smote Job with sore boils from the sole of his foot unto his crown. (Job 2:7)

And Job's ordeal by boils continued unremittingly until God was finally mollified by Job's admission of God's transcendent power and authority and by his humble self-abasement.

I know that thou canst do every thing, and that no thought can be withholden from thee.

Wherefore I abhor myself, and repent in dust and ashes. (Job 42:2, 6)

He must have had a magnificient build before his stomach went in for a career of its own.—Margaret Halsey

Quackery

Fundamentally, quackery is what quackery does. Kenneth L. Milstead, a Food and Drug official, employed this concept in seeking to mark the border beyond which quackery lay.

"When," said Dr. Milstead, "an untrue or misleading health claim is deliberately, fraudulently or pretentiously made for a food, drug, device or cosmetic, this is quackery. . . .

"It matters not whether the quackery is practiced by the witch doctor or the licensed medical practitioner; the Indian medicine man or the pharmacist; the proprietary drug manufacturer or the clerk in the health food store; the health lecturer, the self-styled nutritionist, the doorstep diagnostician, the fly-by-night operator or some of our most respected food, drug, device and cosmetic manufacturers—it is still quackery.

"It matters not which mask it wears—ignorance, superstition, fear, gullibility, folklore, myth, half-truth, or falsehood—it is still quackery.

"And it matters not whether the article is harmless or whether it gives some psychosomatic relief; whether it is cheap or whether it has value for other purposes; whether it is produced by an obscure firm or whether it is produced by a 'reputable' firm—the promotion of it is still quackery."*

Of the Epidemics — Case I

Philiscus, who lived by the Wall, took to bed on the first day of acute fever; he sweated; towards night was uneasy. On the second day all the symptoms were exacerbated; late in the evening had a proper stool from a small clyster; the night quiet. On the third day, early in the morning and until noon, he appeared to be free from fever; towards evening acute fever, with sweating, thirst, tongue parched; passed black urine; night uncomfortable, no sleep; he was delirious on all subjects. On the fourth, all the symptoms exacerbated, urine black; night more comfortable; urine of a better color. On the fifth, about mid-day, had a slight trickling of pure blood from the nose; urine varied in character, having floating in it round bodies, resembling semen, and scattered, but which did not fall to the bottom; a suppository having been applied, some scanty flatulent matters were passed; night uncomfortable, little sleep, talking incoherently; extremities altogether cold, and could not be warmed; urine black; slept a little towards day; loss of speech, cold sweats, extremities livid; about the middle of the sixth day he died. The respiration throughout, like that of a person recollecting himself, was rare, and large, and spleen was swelled upon in a round tumor, the sweats cold throughout, the paroxysms on the even days.*

Physical ills are the taxes laid upon this wretched life; some are taxed higher, and some lower, but all pay something.—Lord Chesterfield

Some people think that doctors and nurses can put scrambled eggs back into the shell.—Dorothy Canfield Fisher

Open Heart Surgery in Elderly Patients*

J. C. KISER, M.D.
T. A. PETERSON, M.D.
F. E. JOHNSON, M.D.
Minneapolis, Minnesota

OPEN HEART SURGERY can be performed safely in elderly patients. With careful selection, application of current refinement in bypass technique, and assiduous attention to technical detail, patients even in the eighth decade can receive substantial functional improvement from these procedures. We have operated upon four patients whose ages ranged from 71 to 79 years for both valvular and congenital cardiac lesions. All survived and are currently living and improved.

Case Reports

Case 1

A 75-year-old male with severe calcific aortic stenosis. Functional class III, atrial fibrillation and repeated bouts of congestive heart failure, grade II aortic systolic murmur.

Chest X-Ray and Cardiac Fluoroscopy: Cardiomegaly with left ventricular contour, heavily calcified aortic valve.

Electrocardiogram: Atrial fibrillation, left ventricular hypertrophy.

Cardiac Catheterization: 50 mm. gradient across the aortic valve with a cardiac output = 2.4 L/min (index).

Surgery: Heavily calcified aortic valve replaced with a Cutter prosthesis.

Postoperative Course: Uncomplicated. Dismissed on the 11th postoperative day.

Case 2

A 71-year-old female, functional class IV. Severe mitral incompetence, pulmonary hypertension, marked tricuspid incompetence, grade IV holosystolic apical murmur and grade III systolic murmur along the lower right sternal border. Marked neck vein distention. Liver enlarged and pulsatile.

Chest X-Ray and Cardiac Fluoroscopy: Cardiomegaly with marked right and left atrial enlargement, no valvular calcification.

Electrocardiogram: Atrial fibrillation.

Cardiac Catheterization: Aortic valve normal, confirmed severe mitral incompetence, pulmonary hypertension (pulmonary artery pressure—110/38), marked tricuspid incompetence.

Surgery: Mitral valve repair, tricuspid annuloplasty.

Postoperative Course: Slow convalescence, no specific complications. Dismissed on the 22nd postoperative day.

Case 3

A 79-year-old female with acute onset of severe mitral insufficiency four months prior to admission. Functional class IV, atrial fibrillation, dyspnea, orthopnea, hepatomegaly and peripheral edema. Grade IV apical holosystolic murmur.

---

*See editorial page 261.

Chest X-Ray and Cardiac Fluorescopy: Cardiomegaly, left atrial enlargement, no valvular calcification.

Electrocardiogram: Atrial fibrillation.

Cardiac Catheterization: Confirmed clinical findings of severe mitral incompetence. Aortic valve normal.

Surgery: Ruptured chordae, anterior leaflet of mitral valve. Valve replaced with a Cutter prosthesis.

Postoperative Course: Complicated by recurrent bouts of fluid retention. Dismissed on 47th postoperative day.

Case 4

A 76-year-old female. Secundum atrial septal defect, functional class IV, grade III systolic ejection murmur in the left third interspace.

Chest X-Ray and Cardiac Fluoroscopy: Enlarged pulmonary artery, right ventricular enlargement.

Electrocardiogram: Incomplete right bundle branch block.

Cardiac Catheterization: 60% left to right shunt at atrial level. Cardiac output = 1.75 L/min (index). Pulmonary artery pressure 54/18.

Surgery: Repair of large secundum atrial septal defect.

Postoperative Course: Developed rapid atrial fibrillation, attempt at cardioversion unsuccessful. Rate controlled with digitalis. Slow but steady improvement. Dismissed on 48th postoperative day.

Discussion

When hemodynamically correctable heart disease is present in the elderly patient and is the major factor limiting activity, then age should not be considered a contraindication to cardiac surgery.

The diagnosis of the lesion in question can be ascertained with a high degree of accuracy using the standard techniques of palpation and auscultation, cardiac fluoroscopy and electrocardiography. When necessary, cardiac catheterization can be accomplished safely.

While the conduct of extracorporeal circulation is essentially the same regardless of age, errors in technique, resulting in inadequate coronary perfusion, excessive hemolysis, inadequate systemic flow, and air embolism may be particularly devastating when they occur in the elderly.

Severe, acquired multiple valve disease does occur in the elderly patient; however, calcific aortic stenosis and mitral valve disease as isolated lesions are more common. Complex forms of congenital heart disease are rarely encountered. Age adds a peculiar feature affecting the risk of surgery in each of these more common lesions and merits separate attention.

Calcific Aortic Stenosis

This diagnosis is generally suspected in the patient who has symptoms of angina, syncope, or dyspnea, and who is found to have an aortic systolic murmur. Confirmation rests on the electrocardiographic evidence of left ventricular hypertrophy (in the absence of significant hypertension) and the finding of a heavily calcified aortic valve by fluoroscopy. In the typical case, further laboratory study is unnecessary. In the elderly patient, however, trivial aortic stenosis or valvular sclerosis may give rise to aortic ejection murmurs. Voltage criteria for ventricular hypertrophy may be absent, due to the decline with age of the voltage of the QRS complex. ST and T wave abnormalities also become less specific. The symptoms of syncope must be distinguished from Stokes-Adams attacks and extracranial vascular occlusive disease. Confusing findings indicate the need for appropriate laboratory study.

The risk of aortic valve replacement in the elderly is altered by the technical difficulty which may be encountered in suturing an aortic wall which is thin and damaged by arteriosclerosis. Re-bleeding in the early postoperative period from the aortotomy continues to be the most worrisome feature in this operation. It is doubtful that coronary artery disease significantly contributes to the risk of aortic valve replacement when associated with severe aortic stenosis.

Mitral Valve Disease

Surgery for acute mitral insufficiency resulting from ruptured chordae can be expected to produce good hemodynamic results. Often valve replacement is not required. The lungs have not been damaged by chronic pulmonary venous hypertension and can be expected to have near normal compliance. Age is clearly not a deterring factor toward surgical repair.

When the lungs have been exposed to chronic pulmonary venous hypertension for many years, and severe pulmonary artery hypertension is associated with right ventricular dilatation and tricuspid incompetence, the risk of surgery may be high regardless of age. Chronic right ventricular failure (with pulsating neck veins and hepatomegaly) is a late and needless complication. Pulmonary vascular obstruction and atrial fibrillation, repeated pulmonary emboli and, rarely, associated organic tricuspid disease may be factors in its development. All of these may be present simultaneously, and the relative importance of each may be difficult to assess. The extent to which these factors are reversible or lend themselves to repair largely determines the outcome of the surgical procedure. There may be some patients with long-standing right ventricular failure who do poorly after surgery because of a *dominant "myocardial factor."* More often, however, this diagnosis conceals diagnostic or technical error and is used as an excuse for failure to improve following surgery. Certainly in the preoperative evaluation, this diagnosis should never be made except by the most rigid process of exclusion.

Recognizing that the greatest risk of mortality in this group of patients is "low cardiac output" in the early postoperative period, we favor a plastic repair of the valve when possible. The elderly patient does not require a perfect hemodynamic result in order to be improved sufficiently to allow sleep in the recumbent position and to avoid dyspnea with the level of activity consistent with his age.

Although the postoperative recovery period was prolonged in each of these mitral valve patients (22 and 47 days respectively), the final result was gratifying. Fluid retention in the late postoperative period, which often accompanies mitral valve surgery in functional class III and IV patients, was a problem in only one case.

Atrial Septal Defect

Atrial septal defect repair in the elderly can be expected to provide good results if there is still a large left-to-right shunt present. If, with many years of volume overload, the right ventricle has lost much of its distensibility so that the end diastolic pressure is elevated, preventing left-to-right shunting, then closure of the defect cannot be expected to be beneficial. The development of severe pulmonary hypertension with high pulmonary resistance may likewise mitigate against a favorable result. Short-term anticoagulation in the early postoperative period may be a worthwhile safeguard, since pulmonary embolism seems to be more common after atrial septal defect repair in adults.

Summary

Although the risk of surgery in potentially correctable cardiac lesions may be altered by age, proper selection and attention to technical detail can yield satisfying results. In this group of patients undergoing open heart surgery, whose ages ranged from 71 to 79 years, all are living and improved.

Answer to What's Your Diagnosis

(From page 218)

Bronchiectasis is one of the most common causes of hemoptysis. Although there are multiple other possibilities, this would be considered first with this history.

The aim of medicine is to prevent disease and prolong life; the ideal of medicine is to eliminate the need of a physician.—Wm. Mayo

Shakespeare and Medicine

The Hallucination of Lady Macbeth

Shakespeare's insight into the dark and secret depths of the guilty human mind was so phenomenal for his time as to make his grasp appear an intuitive endowment: an innate power derived from within rather than acquired from without.

His arresting portrait of Lady Macbeth in her sleep-walking scene is a masterpiece of dramatic impact and psychological penetration. Her usual poise and reserve shattered by morbid hallucinations generated by guilt and remorse, she walks about in nocturnal somnambulism, agonizing over imaginary and accusatory blood stains on her hands.

"Out, damned spot! out, I say!—Hell is murky!—Fie, my lord, fie! a soldier, and afeard?—Yet who would have thought the old man to have had so much blood in him?"

That the doctor shrewdly assesses her condition is evident from his somewhat cryptic comments:

> "The heart is sorely charged."*
> "This disease is beyond my practice."*
> "Unnatural deeds do breed unnatural troubles; infected minds will to their deaf pillows discharge their secrets. *More needs she the divine than the physician.*"*

When Macbeth confronts the doctor later with the question: "How does your patient, doctor?" he answers:

> "Not so sick, my lord, as she is troubled with thick-coming fancies, that keep her from her rest."*

Whereupon Macbeath charges him:

> "Cure her of that. Canst thou not minister to a mind diseased, pluck from the memory a rooted sorrow, raze out the written troubles of the brain, and with some sweet oblivious antidote cleanse the stuffed bosom of that perilous grief which weighs upon the heart?"*

To which the doctor replies in seven words of apocalyptic dimensions that echo down the corridors of time:

> *"Therein the patient must minister unto himself."**

Three Basic Brain Models

of the Last Three Centuries

ROBERT E. BUCKLEY, M.D.
Castro Valley, California

THE CONCLUSIONS which Galileo and Newton applied to mathematics and physics three to four centuries ago had direct and dramatic influence on the model of the universe which was accepted at that time. The result was a refutation of the Ptolemaic theory of astronomy. The secularization of science was vigorously opposed because it appeared to refute the basic assumption of theology: namely, that the existence of the universe and the development of man were the direct result of an act of intention by a divine person. The increased sophistication regarding energy forces and cause-effect mechanisms appeared to diminish the probability that the intention of an anthropomorphic god could account for the existence of man in the universe. The response in the 19th century to Darwin's theory of evolution revealed quite clearly that secular science was seen as being in opposition to the theory of divine intention.

Application of these concepts of a non-intentional or "mechanical" cause-effect relationship in biology has been a gradual one until the 20th century. These changes can be illustrated by the consideration of three brain models, representing each century's biologic and secular answers to questions regarding motion, emotion, and intention behavior.

The first model is based on a simple hydraulic theory; the second represents a much more sophisticated understanding of anatomy. The phylogenetic brain model of the 20th century is both descriptive and useful, since it has led to more questions than it "answers."

The Brain Model of the Middle Ages

The first brain model appears to have answered questions and satisfied curiosity for about 1400 years. This can be called the "Vital Fluid" model. The energy theory which it used was probably developed when the Roman Empire mastered the techniques of building and using aqueducts. These concepts were employed by Galen in the 2nd century A.D. In this brain model, the nerves were believed to be hollow and filled with fluid. Disturbance of a nerve altered the dynamics of fluid in the ventricles of the brain, releasing some vital "animal spirits," which would flow to muscles and cause activity. This was basically the brain model of Descartes when he published "Traite de l'Homme" in 1664. The analogy he used was drawn from hydraulically activated dolls which were popular among the aristocracy of the time. The value of Descartes' proposals lies not in his answers but in the fact that he dared to approach the questions at all. His conclusion expressed the dissatisfaction of the era with the mythology of devils, evil, and witchcraft which had been dominant for so many centuries. The model he proposed was an ancient one; yet the implicit rejection of supernatural forces in biology left his successors free to search for more sophisticated answers.

The Brain Model of the 19th Century

The succeeding 150 years brought a high degree of sophistication about the central nervous system, although primarily in anatomy rather than physiology. In 1800, Xavier Bichat published an extensive review regarding brain anatomy and behavior: a work which revolutionized the teaching of gross anatomy and was accepted as dogma for over a century. With regard to the nervous system he identified two great complexes: one arising from the autonomic ganglia and the other from the brain and spinal cord. He clarified the anatomic separation of the autonomic and somatic nervous systems. His conception of the origin of emotions was his point of continuity with the past; he believed that emotional experience began in the organs of the body, rather than being projected to them. This was demonstrated in the association of heart activity with anger, sobbing and respiration with grief, and stomach distress with resentment.[1]

While Bichat's conclusions were both brilliant and revolutionary, their acceptance as medical dogma in the 19th century served to dampen curiosity and inhibit the understanding of emotional responses and behavior. Curiosity, which is stimulated by incomplete answers, is often stifled by dogmatic conclusions. It is paradoxical that Sigmund Freud, whose theories based on clinical observations were to revolutionize psychology in the 20th century, accepted this idea that visceral symptoms were not psychological in origin. He concluded that hysterical symptoms involving the cerebrospinal nervous system could be used as symbolic resolutions of psychic distress. However,

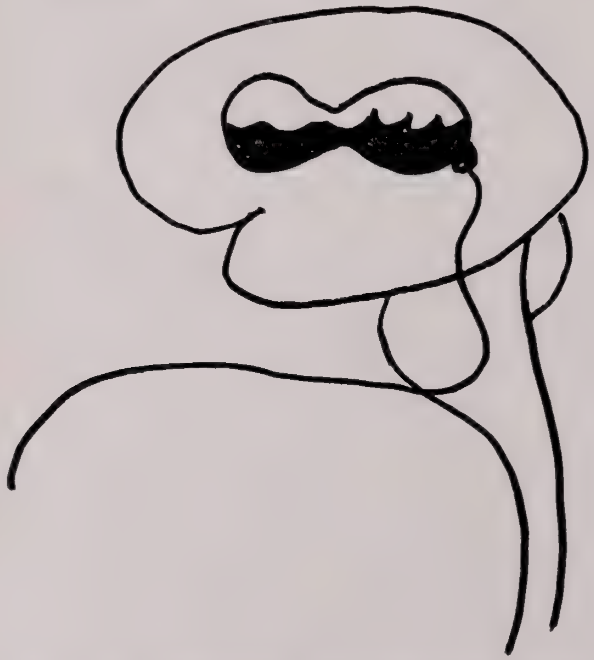

Fig. 1—The "Vital Fluid" Brain Model of the Middle Ages from Galen to Descartes.

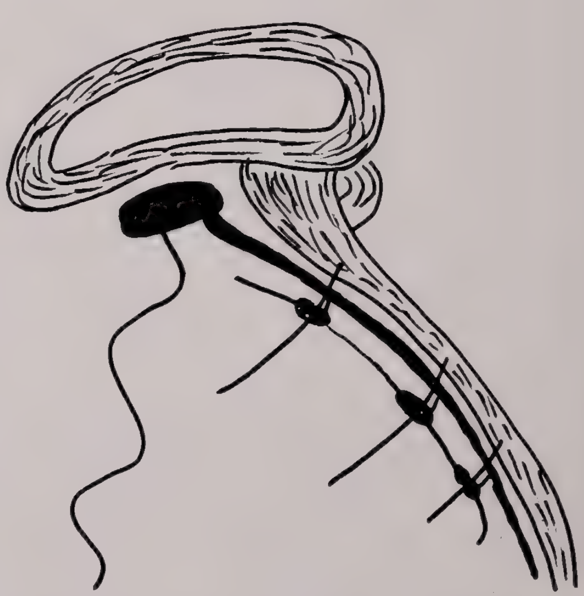

Fig. 2—The 19th Century Brain Model of Bichat, Composed of Two Independent Systems.

he saw the ganglia or "little brains." of the automatic system as being independent. This illustrates that he was a 19th century genius who increased the freedom of 20th century thought, and that, like Bichat's, his propositions should not be projected into dogma.

The Brain Model of the 20th Century

At the end of the 19th century studies in comparative anatomy presented biology with a new conception of the brain as an organ which showed progressive development and enlargement during the course of evolution. While the spinal cord and brain stem were seen to be structurally consistent among vertebrates, mammalian development proceeded by adding new structures to the basic, primitive brain. Hughlings Jackson expressed this when he proposed that the highest brain centers which developed last in the course of evolution impose discrimination and control over the primitive behavior of the lower centers.[2] Drive behavior involving feeding, fighting, flight, and sexual arousal are certainly pre-mammalian in development. The higher centers influence activation, direction, and inhibition of these primitive drives which will have focal centers in the structures directly associated with the brain stem.

Visceral Brain or Limbic System

An important elaboration of this concept was proposed by C. Judson Herrick in 1933. The structures of the rhinencephalon or "nose brain" had been found to be anatomically related to the olfactory nerve and behaviorally related to the sense of smell involving feeding, searching, avoidance, and sexual behavior. On the basis of extensive comparative studies Herrick found that this system included the ancient cortex of early evolution and was integrated with the hypothalamus at the top of the brain stem.[3] He therefore concluded that this system served as a non-specific activator for all cortical activities, either exciting or inhibiting such functions as memory, learning and affect. Papez in 1937 proposed a reverberating circuit for emotional experience within this system which has subsequently become the basis for a large amount of productive research.[3]

Paul MacLean has reviewed the studies of this system and, in calling it the "visceral brain," has emphasized its important influence upon the automatic nervous system and psychosomatic disease. He later pointed out that these structures had been called the "limbic lobe" by Broca in 1878, since the rhinencephalic structures became a "limbus" or border for the cerebral peduncles as evolution proceeded with the development of the neocortex.[1] When MacLean summarized the conclusions of Herrick regarding the integration of the olfactory apparatus of fishes and reptiles, with the developing hypothalamus, he concluded that the brain stem and spinal cord constituted a "neural chassis" for behavior. With the addition of this system and its hypothalamus to direct choices and select behavior, evolution had added a "driver at the wheel of the neural chassis." This articulate description illustrates that the brain model of the 20th century is one which emphasizes both activation and inhibitory mechanisms, both of which are essential for selecting behavior.[4]

Phylogenetic Brain Model

In 1962 Paul MacLean proposed an apt and simple description of these brain systems which can provide the basis for the brain model of the 20th century. He observed that nature has endowed man with essentially three superimposed and integrated brains.[5] The most primitive is the "reptile brain" comprised of the spinal cord and brain stem with its motor nuclei of the autonomic nerves and the nonspecific neurones of the reticular system. This is essentially the "neural chassis" he had mentioned previously. The next to develop was the "early mammalian brain" which consists of the visceral brain or limbic system and contains the hypothalamus and its circuits which became the "wheel" for the neural chassis below. The medial forebrain bundle of this brain can be said to separate into two circuits, one dealing with self-preservation and the other with species preservation. These brain systems are basically "non-literate" and must be integrated with the last system to develop, the "primate brain" of the neocortex, which contains the extensive tracts of the association areas of the cortex which Hughlings Jackson referred to almost a century ago as the "highest brain centers," which regulate behavior. This phylogenetic brain model is a capsule summary of the work of many investigators and provides a generalization within which many findings can be placed in psychobiologic perspective.

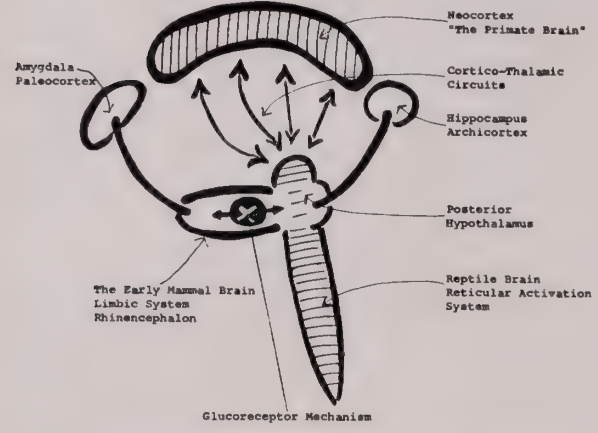

Fig. 3—The Phylogenetic Brain Model of MacLean and the 20th Century.

A Psychobiologic Summary

The study of man and his behavior during the past century has primarily been by two disciplines, physiology and psychology, which were principally concerned with objective phenomena and subjective experience. Physiology and psychology represent two viewpoints—two different levels of logical abstraction—which are concerned with the *same* biologic life process. Herrick has summarized this quite explicitly: "Psychology is a biologic discipline, but it should be a psychobiology and not merely a subdivision of physiology. What we must do now is to bring together these artificially separated domains of experience, the subjective and the objective, and build a coherently integrated psychobiology."[6]

Metabolic Requirements

The phylogenetic brain model provides a useful generalization which helps to organize data. Studies of the metabolic activity of the reptile and early mammalian brain systems have shown them to have less need for glucose in their functioning than the primate brain. On the other hand, their metabolic activity is greater at birth than the neocortex which has not yet matured to its normal adult physiologic capacity,[7] although the adult neocortex uses much more glucose.

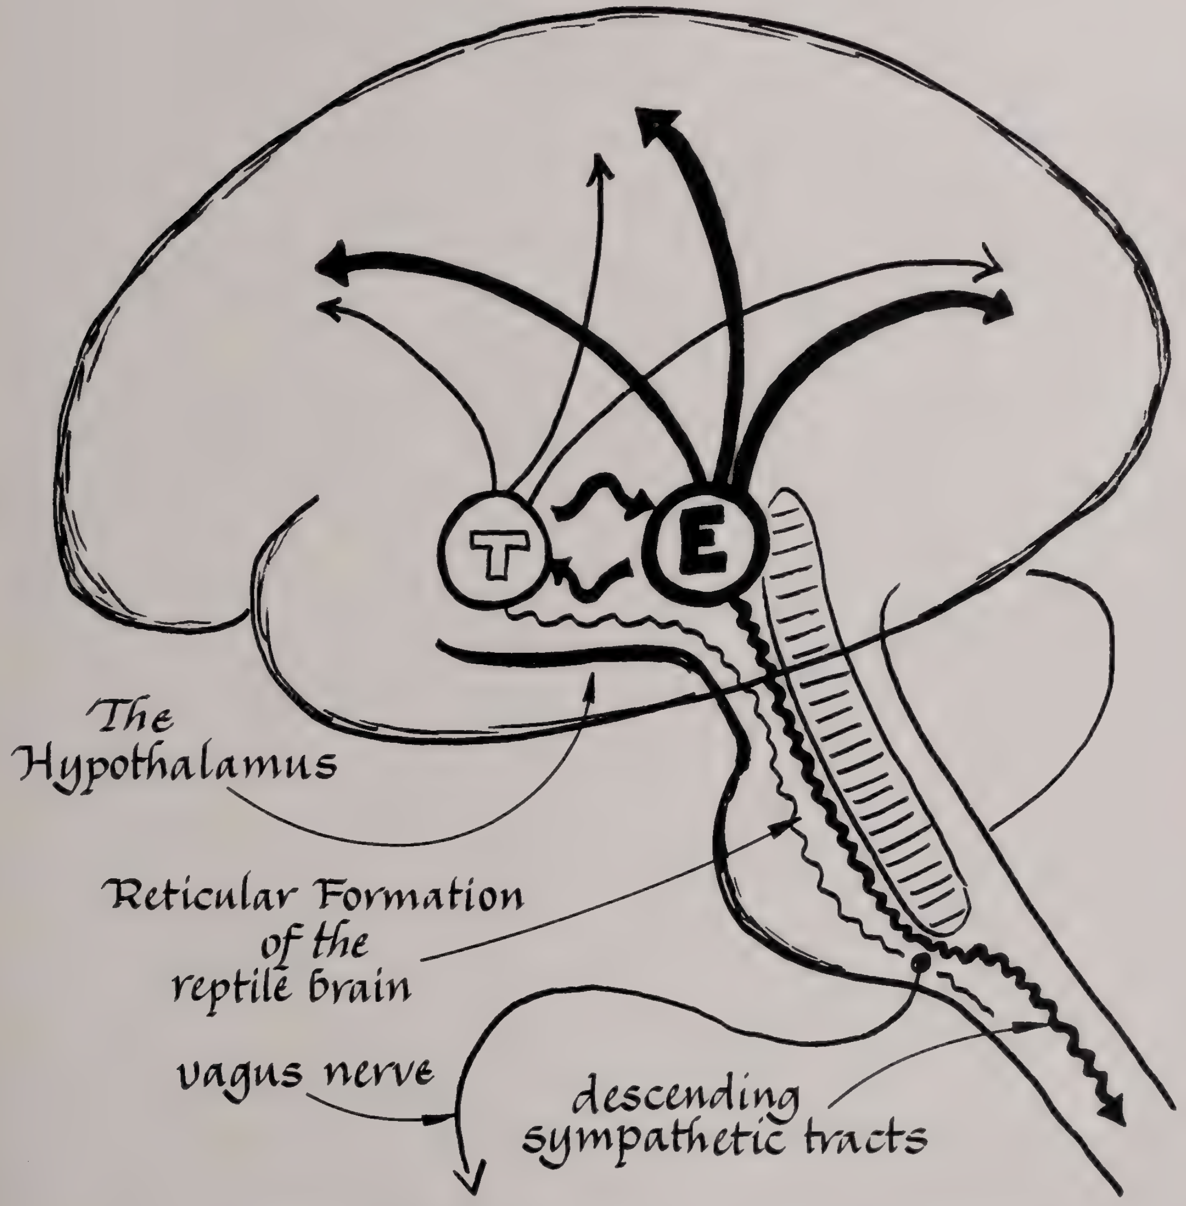
Comparative Enzyme Systems

We would naturally expect that the enzyme systems of the reptile brain would be "primitive" compared with the neocortex of the primate brain, since the reptile brain will still function at temperatures which are much below those that the mammalian brain requires. This is confirmed in man by current work on hypothermia, since the brainstem structures maintain their functioning long after the structures above have been inhibited. The same findings were observed during the insulin hypoglycemic coma therapy treatment of schizophrenia. Brain stem nuclei maintain respiration and cardiac function during hepatic and renal coma when the activity of the primate brain has been inhibited.

Response to Drugs

These brain systems respond differently to barbiturate and to tranquilizing drugs. The principal neurophysiologic distinction between these drugs is that barbiturates depress activity in the primate brain, while the tranquilizers, in moderate doses, do not.[8] Moreover, when the barbiturates depress neocortical activity they allow an increased activity in the posterior sympathetic hypothalamus[9] where activation is associated with aggressive behavior. This can help to account for the disorientation and "temper tantrums" which senile patients so frequently have when given barbiturates. Since the neocortex of the primate brain is the first system to degenerate under the stress of aging, the addition of barbiturates which depress activity here has an additive effect and can increase the symptoms of senility.

Tranquilizing drugs do not inhibit the neocortex so readily. Also various tranquilizers differ markedly in their effects on key brain areas and thus vary in their therapeutic effect on human behavior.[8] In particular, chlorpromazine (Thorazine) depresses activity in the posterior hypothalamus of the early mammalian brain[9] and tends to diminish the impulsive aggressive behavior of the senile.



T
E
The Hypothalamus
Reticular Formation of the reptile brain
vagus nerve
descending sympathetic tracts

Fig. 4—The Gellhorn-Hess Physiologic Brain Model. Two action systems are represented here. The E-system is the ergotropic system and its pathways are represented with the heavy lines. Its descending "motor" tracts activate the sympathetic division. The T-system is the trophotropic system represented with lighter arrows. Its descending motor tracts activate the parasympathetic division of the autonomic nervous system. The major relay area for these systems is in the hypothalamus. One arrow between the T and the E nuclei here represents the process of "reciprocal inhibition" which functions during physiologically normal behavior. The other arrow represents "spill-over" of activation, since intense activation of one system can paradoxically activate rather than inhibit the other system. The "E"-system is dominant during the waking state.

Basis of Emotions

This phylogenetic brain model is obviously not intended as a blueprint for the complicated maze of positive and negative feed-back circuits of the brain. It provides a useful framework in which the development, location and function of circuits and systems can be described. The rhinencephalic circuits activated by the sense of smell were developed during the course of evolution to direct behavior related to feeding, fighting, flight, and sexual arousal. The integration of these circuits of the limbic system with the primate brain which eventually evolved provides the biologic basis for the experience which we now label "emotion."[10] The extensive studies of the neurophysiologic circuits involved in emotions and emotional disorders[11] now provide the basis for the psychobiologic study which Herrick saw as our next area of understanding: the integration of the objective and subjective domains of experience.

The Psychobiologic Conclusion

"Mind is not something acting on the body to make it go. It is the body in action. My mind is not something I have. It is something that I am. For I am a minding body."—C. Judson Herrick.[6]

Addendum

The phylogenetic brain model which has been proposed by Paul MacLean can also be called an "anatomic" model. The fact that these three systems are integrated in their function is accepted as an implicit fact. A physiologic brain model which begins to describe this anatomic model can currently be proposed. This physiologic brain model represents conclusions which correct the assumption of the Bichat model of the 19th century, that the somatic and autonomic nervous systems were independent of each other in their action. There are operant systems of entering sensory impulses which have connections with the reticular system in the "reptile" brain stem, as they proceed to sensory areas of the neocortex. There are ascending tracts to the hypothalamus which is an important relay center for circuits within the limbic system of the "early mammal brain," and which extensively influence the "primate brain" of the neocortex.

The hypothalamus which MacLean had called "the driver at the wheel of the neural chassis"[12] has been called "the hub of the limbic system" by Gellhorn.[13] It was called the "head ganglion" of the autonomic nervous system by Fulton in 1940, and its descending tracts regulate the motor cells of the autonomic nervous system in the brain stem and spinal cord. Activation of the ascending tracts from the posterior hypothalamus are associated with arousal of the cortex, and apparently uncomfortable, anxious or rageful behavior.[13] The downward tracts activate the sympathetic division, with increased blood pressure, pulse, and release of epinephrine. Activation of the anterior hypothalamic area is associated with cortical activity seen with sleep, and the downward tracts activate the parasympathetic division of the autonomic nervous system.

The balance and equilibrium of these divisions of the autonomic nervous system was the primary focus of Ernst Gellhorn for about thirty years. He concluded that the principle of "reciprocal inhibition" which Charles Sherington had proposed to account for smoothly integrated muscle activity was also functioning in the hypothalamus. Sherington proposed that in order for the extensor muscles of the extremities to function smoothly, the flexor muscles were "reciprocally inhibited." Gellhorn's conclusion was that in order for the sympathetic division to function in its normal physiologic state it had an inhibitory effect upon the parasympathetic division. This is the basis for his concept of hypothalamic "tuning."[13]

These studies can be integrated with the extensive studies of W. R. Hess which emphasize the ascending tracts to the cortex.[14] He called the responses associated with activation of the sympathetic division the "ergotropic"* responses. Those associated with the parasympathetic division he labeled the "trophotropic"* responses. Activation of the "ergotropic system" is associated with increased activity of the motor apparatus (skeletal and respiratory muscles). When the trophotropic system is "tuned up" and dominates activity, the parasympathetic discharges are quite apparent, along with a lessened activity and responsiveness of the somatic nervous system. Dr. Gellhorn's latest book, "Principles of Autonomic-Somatic Integrations"[14] provides a basis for the proposal of a "physiologic" brain model, which operates within the phylogenetic or "anatomic" model of MacLean. The "ergotropic" and "trophotropic" response systems quite obviously link the "three superimposed brains in the mind of man." Their influence on activating, inhibiting and coordinating activity in these three brains can provide the basis for reverberating circuits which will probably be the focus of study for neurophysiology in the last half of the 20th century.[15]

It's the Law

Hospital Liable for Unauthorized Autopsy

A man in a hospital expired because of lung cancer. A hospital resident requested the widow to sign a form authorizing autopsy. The form had already been signed by two witnesses. The widow refused permission for autopsy.

Through several mistaken impressions, an autopsy was performed. Ten days after death, the widow read the death certificate and discovered that an autopsy had been performed. A hospital official testified that the body had not been mutilated, nor the burial interfered with.

The widow testified that during his lifetime her husband had expressed objections to an autopsy. She stated that she had worried, lost sleep and weight, and had difficulty remaining at her work as the result of the autopsy.

Even though the body was not mutilated, or the burial interfered with, the widow's mental suffering was compensable, the Louisiana intermediary appellate court ruled. The award was $1500.*

A Nawadir Anecdote

A very popular branch of literature, both in Arabic and Persian, was constituted by collections of strange and quaint anecdotes, called Nawadir. . . In such books a special section is often devoted to Medicine and Physicians.

One of the older Arabic books of this sort is a work entitled al-Faraj bada 'sh-Shidda ("Joy after Sorrow," or "Relief after Distress").

The case of a dropsical patient forms the subject of the fifth of these anecdotes. He was, after being dosed with various drugs, pronounced incurable by the physicians of Baghdad, and thereupon begged that he might be allowed to eat and drink what he pleased, and not, as he expressed it, be "destroyed by dieting." One day he saw a man selling cooked locusts, of which he bought and ate a large quantity. Violent purging followed this repast and lasted three days, at the end of which he was so weak that his life was despaired of, but he gradually recovered and was entirely cured of his dropsy. On the fifth day, being able to walk abroad, he met one of the physicians who had seen him before, and who was amazed at his recovery, about which he questioned him. "These were no ordinary locusts," said the physician, when he heard the story; "I should like you to point out to me the man who sold them to you." The seller being found and questioned, said that he collected the locusts in a village some miles from Baghdad, whither, for a small reward, he accompanied the physician, who found the locusts in a field in which grew quantities of the herb called Madharyun (Laurel-spurge or Spurge-flax), known to be beneficial in small doses for dropsy, but too dangerous to be commonly prescribed. The double coction which it had undergone in the locusts' bodies had, however, so mitigated its violence that its results had in this case proved wholly beneficial.

Other anecdotes in this book include a cure for apoplexy by flagellation, of pleurisy by a scorpion-bite, and of paralysis by a decoction of colocynth in milk.*

On Sweats

Those sweats are the best in all acute diseases which occur on the critical days, and completely carry off the fever. Those are favorable, too, which taking place over the whole body, show that the man is bearing the disease better. But those that do not produce this effect are not beneficial. The worst are cold sweats, confined to the head, face, and neck; these in an acute fever pronosticate death, or in a milder one, a prolongation of the disease; and sweats which occur over the whole body, with the characters of those confined to the neck, are in like manner bad. Sweats attended with a miliary eruption, and taking place about the neck, are bad; sweats in the form of drops and of vapour are good. One ought to know the entire character of sweats, for some are connected with prostration of strength in the body, and some with intensity of the inflammation.*

Some people are always grumbling because roses have thorns. I am thankful that thorns have roses.—Alphonse Karr

Pernicious Anemia in North American Indians

RONALD OLIN, M.D.[*]
RYAN B. HARRINGTON, M.D.[†]
Fargo, North Dakota

RACE AND HEREDITY are major determining factors in acquiring Addisonian pernicious anemia. This disease occurs primarily in Caucasians residing in the temperate zone of North America and Europe or their offspring anywhere in the world. The predisposition or susceptibility is inherited probably as the effect of a single, dominant, autosomal‡ gene[1], and auto-immune phenomena have been implicated in the causation[2]. Familial incidence varies from 8 to 30%[3].

Pernicious anemia has been reported in most racial groups living in North America. It is more common in persons of Scandinavian, English, Irish and Canadian descent; relatively uncommon in those of Jewish, Russian, Greek, Italian, Scotch and German; and rare in pure-blooded Negroes and Orientals.[4] We have been unable to find any reported cases of pernicious anemia in persons of North American Indian descent. Two such cases in American Indians are reported in this paper.

Case Reports

Case 1

A 55-year-old male Indian from Ponsford, Minnesota, was referred to the Fargo Clinic on March 15, 1968, for evaluation of anemia. In November 1967, he noted the onset of burning of the tongue and loss of taste. He was hospitalized elsewhere from January 14 to 23, 1968, because of weakness. An upper G.I. series was done and he was transfused four units of whole blood. He was then dismissed from the hospital on a multivitamin preparation which he took daily until one week before being seen. In February 1968, he noted the gradual onset of numbness of the hands, legs and feet, rapidly progressing to unsteadiness of gait. He had lost 30 pounds in five months, despite a good appetite. He denied the use of alcohol, toxic exposure, diarrhea, icterus or melena. Chronic stasis and eczematoid dermatitis of the legs had been present for the preceding eight years. His hair had begun to turn grey at age 45 years.

He was a member of the Chippewa (Ojibway) tribe and resided on the White Earth Indian Reservation in West-Central Minnesota. Both his mother and his father were Chippewas from the same reservation. His father who had "Irish blood" died in 1930 at age 56 from anemia; his legs were previously "crippled." His mother who had "French-Canadian" blood had come originally from the Fort Francis, Ontario, area and had died at age 56 from heart trouble; she had no known anemia. A brother, 54, had anemia. No definite diagnosis was made.

[‡] See Test Your Word Score Page 265.

Physical Examination

Physical examination revealed a well-developed, grey-haired, stoic individual 69 inches tall, weighing 186 pounds (Figure 1). Blood pressure was 90/60 Hg.; pulse, temperature and respirations were normal. The tongue was red, smooth and deeply grooved. The legs showed chronic eczematoid dermatitis. Other positive findings were confined to the nervous system. Taste sensation was absent. Vibration sense was absent at the ankles and knees and slightly diminished at the wrists. Touch, pin-prick and two-point discrimination were symmetrically diminished in the upper and lower extremities distally in a stocking-glove distribution. All deep-tendon reflexes were absent. Babinski sign was absent. Moderate distal weakness was present in all extremities. His gait was ataxic and his Rhomberg's sign positive.

Laboratory Findings

Laboratory investigation revealed a hemoglobin of 10.6 gm. %, hematocrit of 32%, leukocyte count of 8050 per cmm. with a differential of 17% lymphocytes, 75% segmented neutrophils, 4% basophils and 4% eosinophils, and a sedimentation rate of 80 mm. per hour (Westergren). The platelet count was 164,000 per cmm. A peripheral blood smear showed occasional macrocytes and hypersegmented neutrophils, slight poikilocytosis and moderate anisocytosis. Gastric analysis showed a histamine-fast achlorhydria. A Schilling test using 0.5 microcuries of Racobalamin 57 revealed 1% urinary excretion in 24 hours before and 4.5% excretion after intrinsic factor. A stool examination was guaiac negative and also negative for ova and parasites, fat and meat fibers. Serum protein electrophoresis revealed a slight elevation of gamma globulin at 1.96 gm. %. The following tests were normal or negative: V.D.R.L. flocculation test, routine urinalysis, serum iron, fasting blood sugar, blood urea nitrogen, serum cholesterol, bromsulfthalein dye excretion, urine for porphobilinogen and serum carotene. Chest x-ray revealed a prominent vascular shadow at the left hilus and minimal pleural thickening at the left apex. X-ray of the esophagus, stomach and duodenum was negative. A 12-lead electrocardiogram was normal. His blood type was Group A, Rh positive (D).

Because of the severe peripheral neuritis, he was hospitalized for two weeks and received vitamin B-12, 1000 micrograms, intramuscularly, daily. After one week of treatment, his taste returned. However, the numbness of the extremities, the absent reflexes, and the broad-based gait persisted. On March 29, 1968, the hemoglobin was 12 gm. %, sedimentation rate 54 mm. per hour (Westergren) and the reticulocyte count 3.3%.

He was dismissed from the hospital and advised to receive vitamin B-12, 1000 micrograms, intramuscularly twice weekly during the month of April.

When seen on May 7, 1968, his gait had improved considerably, but the numbness in the hands and feet persisted. He had gained eight pounds. He was still areflexic and had sensory deficits in the extremities. The hemoglobin was now 13.8 gm. % and he was advised to receive vitamin B-12, 1000 mcg., intramuscularly every three weeks.

Case 2

A 65-year-old male Indian from Mandaree, North Dakota, was referred to the Neuropsychiatric Institute Hospital in Fargo on March 7, 1967, for evaluation of numbness and burning dysesthesias of the upper and lower extremities of three months' duration. The dysesthesias originated in the fingers and then the toes. He had also noticed a shock-like sensation radiating from the neck to the shoulders, arms and down the back with neck flexion (Lhermitte's sign). Cervical spine traction had been attempted elsewhere one month prior to admission without benefit. The numbness and burning subsequently progressed, ascending to the wrists and knees. His voice had been raspy for one month and he had lost eight pounds in the preceding three months. He denied alcohol abuse, toxic exposures, previous anemia or diabetes and was taking no medications.

He was a member of the Hidatsa (Gros Ventre) tribe and resided on the Fort Berthold Indian Reservation in West-Central North Dakota. There was no family history of anemia. He thought that he was pure-blooded although he recalled that his maternal grandmother had light skin and brown hair.

Physical Examination

Physical examination revealed a well-developed, well-nourished, healthy-appearing individual. His height was 69 inches and weight 174 pounds. Blood pressure was 142 systolic and 90 diastolic; pulse, temperature and respirations were normal. The tongue appeared normal. Neck flexion produced a shock-like sensation radiating down both arms. Foraminal compression signs were absent. Muscle strength was normal in the upper and lower extremities. The deep tendon reflexes were active, equal and normal in the upper extremities. The knee and ankle jerks were slightly hyperactive. Babinski sign was absent and there was no clonus. Sensory examination including touch, pinprick, two-point discrimination, vibratory and position senses were normal. The gait was normal and Rhomberg's sign was negative. Indirect laryngoscopy revealed normally functioning vocal cords. The remainder of the physical examination was not remarkable.

Laboratory Findings

Laboratory investigation revealed a hemoglobin of 11.2 gm. %, hematocrit of 33%, leukocyte count of 7500 per cmm. with a differential of 25% lymphocytes, 66% segmented neutrophils, 3% monocytes and 6% eosinophils and a sedimentation rate of 50 mm. per hour (Westergren). The reticulocyte count was 2.7%. A peripheral blood smear showed many macrocytes, marked anisocytosis and poikilocytosis, occasional nucleated red blood cells and some hypersegmented polymorphonuclear cells with up to seven lobes. First-strength purified protein derivative and histoplasmin skin tests were both positive (2+). Blastomycin and coccidioidin skin tests were negative. A Schilling test using 0.5 microcuries of Racobalamin 57 revealed 2.3% urinary excretion in 24 hours before and 12.5% excretion after intrinsic factor. The following laboratory tests were normal or negative: V.D.R.L. flocculation test, routine urinalysis, fasting blood sugar, blood urea nitrogen, serum calcium, serum acid and alkaline phosphatase, and serum transaminase. Chest x-ray revealed a 3-cm. density in the postero-inferior aspect of the right hilus and a few calcific foci at the left hilus and left base. Tomograms revealed that the right hilar mass was sharply outlined and contained calcium. Skull x-ray was negative. X-ray of the cervical spine revealed narrowed disc spaces throughout and lipping of the anterior and posterior aspects of C-3 through to C-7. X-ray of the esophagus, stomach and duodenum revealed large, irregular calcific densities in the left mid-abdomen representing calcification in lymph nodes; there was also a small, self-reducing hiatal hernia and a normal small bowel pattern.

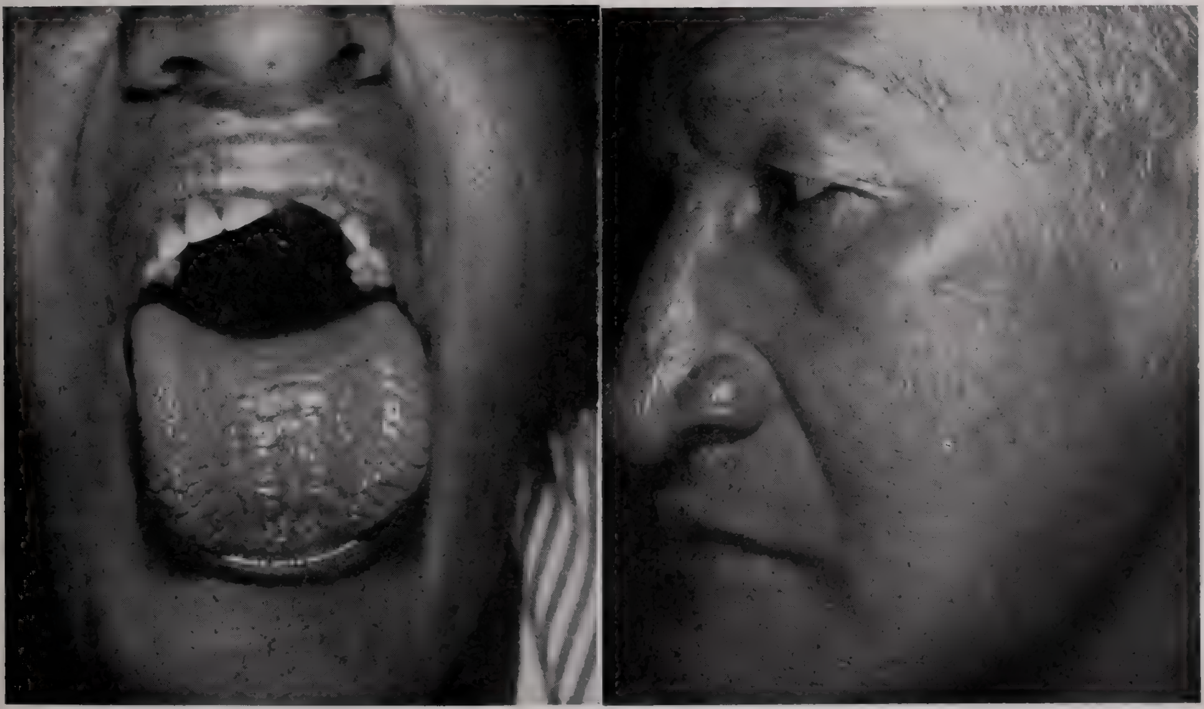
The patient was given vitamin B-12, 1000 micrograms intramuscularly daily, for one week. He was dismissed from the hospital on March 16, 1967, to be followed by his local physician who was advised to give him vitamin B-12 1000 micrograms intramuscularly every other day for two weeks, then weekly for three weeks and then once monthly.

Follow-up with his local physician on March 26, 1968, revealed that the hemoglobin was normal; but the numbness and burning dysesthesias of the hands and feet had persisted.

Comments

The North American Indian probably originated from Northeastern Asia, having crossed the Bering Strait to the Western Hemisphere approximately 15,000 years ago.[5] The earliest groups of hunters settled in Alaska, the Yukon and the Northwest Territories as ancestors of the present day Eskimos. Some migrated further south to inhabit Canada, the United States, Mexico, Central and South America as Indians. Radiocarbon dates indicate that men had reached the tip of South America some 8,000 years ago. The term Indian was first used by Columbus to describe the natives of the New World that he believed to be Indios (natives of India). There is some question whether more Indians exist now than when Columbus discovered America. At present, about 500,000 Indians live in the United States and are confined largely to 150 to 200 usually squalid reservations. Full-blooded Indians are rare.

The main health problems of the Indian population are infant mortality, malnutrition, mental retardation, cirrhosis of the liver, violent injuries and infections. Contact with Caucasians has subjected the Indians to tuberculosis and venereal diseases; also through intermarriage they have become subjected to diseases with a genetic predisposition, such as pernicious anemia. This has been true also



Figure—Case 1 showing smooth, shiny tongue of pernicious anemia.

of the American Negro; for pernicious anemia, although rare, does occur, probably as a result of intermarriage. Of 329 cases of pernicious anemia seen at Johns Hopkins University between 1925 and 1940 where the white:colored ratio was 3:1, there were 33 cases in Negroes.[6] At Cook County General Hospital, pernicious anemia occurred in 36 Negroes and 170 Caucasians per 100,000 hospital admissions.[7] Pernicious anemia is rare in full-blooded Orientals,[8] of whom the North American Indian is likely a descendant.

Of 85,300 discharges from Public Health Service Indian and community hospitals in 1967, there were 29 cases with a primary diagnosis of pernicious anemia and other macrocytic anemias; their data does not separate the two varieties. The number of cases may be smaller than 29 since some patients may have been admitted more than once during the year.[9]

The Director of Indian and Northern Health Services of Canada has informed us that pernicious anemia is not one of the diseases cross-indexed in Ottawa from the hospital records of Indians and Eskimos. The Charles Camsell Hospital, Edmonton, Alberta, the main referral center for Alberta Indians and the Eskimos and Indians of the Northwest and the Yukon Territories, a population of 35,000 Indians and 5,000 West Arctic Eskimos, had no Eskimos with a diagnosis of pernicious anemia in the past 15 years. However, five male and two female Indians had the diagnosis recorded. All but one were Alberta Indians and most were of mixed blood with White French-Canadian, or *métis** admixture. The diagnosis was not proven in approximately half of the patients. All five males were 57 years of age or older; one female was 38 and the other 81 years old. One laboratory-proven case of pernicious anemia occurred in a 75-year-old Prairie-Cree Indian who considered himself pure-blooded and looked so.

Summary

Two cases of Addisonian pernicious anemia in North American Indians of mixed-blood are presented. Both patients were afflicted more neurologically than hematologically. Pernicious anemia is uncommon in full-blooded Indians and the genetic predisposition has probably come through intermarriage with Caucasians. It is recommended that pernicious anemia be considered in Indians with neurological manifestations or anemia.

Your Chances Are Good

You have two chances—one of getting the germ and one of not. And if you get the germ you have two chances—one of getting the disease and one of not. And if you get the disease you have two chances—one of dying and one of not. And if you die—well, you still have two chances.—Author unidentified

When man is no longer anxious to do better than well, he is done for.—Haydon

Acute Neurological Deterioration Following Lumbar Puncture

DON M. LONG, M.D.*
E. L. SELJESKOG, M. D.*
SHELLEY N. CHOU, M.D.*
LYLE A. FRENCH, M.D.*
Minneapolis, Minnesota

In 1934 WALTER DANDY began a discussion on the use of lumbar spinal puncture by stating: "Lumbar puncture is one of the most used and abused procedures employed for neurological diagnosis and therapy." Later in the same discussion he said: "I have seen at least twenty deaths resulting from lumbar puncture." In this same report he modified this statement by saying he had reference only to cases in which increased intracranial pressure was suspected or found to be present.[1] The dangers inherent in this procedure done under these circumstances have subsequently been abundantly documented by other neurosurgeons. Frankel and German reported a two-per-cent mortality in patients with brain tumors, and others have had a similar experience.[3] In spite of these formidable figures there has been an increasing tendency to minimize the dangers of lumbar puncture, especially by those not so intimately responsible for patients with elevated intracranial pressure.[2]

Because neurosurgeons do have this intimate responsibility, besides almost daily experience with this problem, they have become concerned over these trends. In order to emphasize this concern the following report of six cases which came to the attention of the Neurosurgical Service at the University of Minnesota in a single six-month period from August 1, 1967, through February 1, 1968, are presented. In all the patients the neurological deterioration seemed unequivocally related to the lumbar puncture. Additional cases in which less catastrophic changes occurred have been omitted, and patients with spinal cord tumors with increased neurological deficit after myelography or spinal puncture are also not included.

Case Reports

Case 1

A 46-year-old lady with a two-week history of occasional headaches, increased fatigue and some mental deter-

---

*Division of Neurosurgery, Department of Surgery, University of Minnesota Hospitals.

Supported in part by the Morris T. Baker Fund and Clinical Cancer Training Grant CA #08101.

ioration was admitted to a hospital and a diagnosis made of psychological depression. Psychiatric consultation suggested the depression was on an organic basis. Skull roentgenograms and an electroencephalogram revealed no abnormality. The lumbar spinal fluid pressure was measured at 280 mm. of water. The morning following the lumbar puncture the patient was found to be comatose, but the exact duration of this state could not be definitely determined.

Examination after transfer to the University Hospitals on August 1, 1967, revealed the patient to be comatose and unresponsive to pain. There was severe bilateral papilledema and a left abducens nerve paresis. The deep tendon reflexes were hyperactive in the lower extremities, and the Babinski response was positive bilaterally with bilateral ankle clonus. The clinical impression was that the patient had a right frontal lobe neoplasm with herniation of the temporal lobe into the incisura of the tentorium secondary to increased intracranial pressure. A right carotid angiogram substantiated the diagnosis. Emergency craniotomy and right frontal lobectomy were performed with removal of a glioblastoma multiforme.

Postoperatively the patient made a dramatic recovery and 11 days later the patient's family considered her quite normal except for a mild change in her mental status. She was transferred to a convalescent hospital for a combination of radiation therapy and chemotherapy.

Case 2

A two-and-one-half-year-old boy was well until August 1967, when there was the onset of episodic vomiting and a minor personality change. Gradually he became progressively more withdrawn and more dependent and began to sleep for longer periods of time. On October 14, 1967, the patient fell down a flight of stairs and thereafter limped, favoring his right leg. On October 19, 1967, the vomiting became projectile and he staggered when he tried to walk. Because of increasing lethargy he was hospitalized that night. About 2:00 a.m. the patient had an episode described as a seizure. He then had a lumbar puncture which revealed grossly bloody fluid. This procedure was followed by a steadily increasing number of extensor spasms. When the patient arrived in the emergency room of the University Hospitals he was opisthotonic and responded to stimulation by decerebrate posturing. Neurological examination revealed the child to be comatose with a decerebrate response to pain. He had very hyperactive deep tendon reflexes, bilaterally positive Babinski signs and severe bilateral papilledema. A tentative diagnosis of posterior fossa neoplasm was made. An emergency ventriculogram showed obstruction of the aqueduct, and immediately thereafter a craniotomy revealed a medulloblastoma involving the vermis. Within the neoplasm was a large hematoma. All the grossly visible neoplasm was removed. Postoperatively the patient recovered from his decerebrate state, and his subsequent course was one of gradual improvement. He was given deep roentgen therapy to the posterior fossa and spinal axis. At the time of discharge he was alert but had a residual right hemiparesis and diminished visual acuity.

Case 3

A 73-year-old man, partially crippled with rheumatoid arthritis, had a three-week history of dizziness, suboccipital headaches, staggering gait and double vision. The day before admission he vomited four times and that evening became mentally confused. Examination revealed an obtunded patient who responded only with grunts. Funduscopic examination showed optic discs with sharp margins. Carotid pulses were equal and there were no bruits. The patient had a right hyperreflexia and a positive left Babinski sign. He could not look to the left nor upward. The initial diagnostic impressions were stroke syndrome or intracranial tumor. Immediately after admission a lumbar puncture was performed. The fluid was clear, questionably yellow-tinged, and the pressure was 230 mm. of water. The following morning the patient was comatose. An electroencephalogram was performed which revealed a focal delta area in the right frontal region. At this point neurosurgical consultation was obtained and a tentative diagnosis of posterior fossa tumor was made. Shortly thereafter ventriculography showed evidence of a mass in the cerebellum. A posterior fossa exploration revealed a large metastatic tumor in the left cerebellar hemisphere. The neoplasm was removed without difficulty but the patient did not recover and expired two days after operation.

Case 4

A 26-year-old man developed severe bifrontal headache about two weeks prior to admission. He was treated for sinusitis for a week without relief. He then developed a temperature elevation, was found to have a bacterial tonsillitis, and was treated with intramuscular penicillin. Twelve hours later he suddenly developed left leg numbness and weakness. The following day he had a severe hemiparesis and nuchal rigidity. Penicillin therapy was continued for two more days. Then a lumbar puncture was performed. Four hours later he developed generalized seizures and became unresponsive with fixed, dilated pupils.

He was transferred to the University Hospitals as an emergency case. Examination at the time of admission revealed a very lethargic, unresponsive patient whose pupils were equal and reacted slowly to light. There was a severe left hemiparesis. There was no papilledema. Skull films revealed the presence of a frontal sinusitis. Brain scan and carotid angiogram were within normal limits. A diagnosis of cortical thrombophlebitis was made and the patient successfully treated with intravenous antibiotics and anticonvulsants after the right frontal sinus was drained surgically. He was discharged from the hospital on the eleventh postoperative day without a neurological deficit.

Case 5

An 11-month-old girl had developed focal seizures one month prior to admission. These involved the left side of the face and had followed a bout of left otitis media. She had been treated with penicillin and sulfadiazine. An electroencephalogram revealed no abnormality. The seizures were controlled with phenobarbital, mebaral, and mysoline. Three days prior to admission the child had begun to vomit and was found to be very lethargic. On the morning of admission a lumbar spinal puncture was performed. The pressure was not measured but was "believed to be elevated." There were no cells; the protein content was 28 mgm. per cent. Shortly after the lumbar puncture the patient became comatose with fixed, dilated pupils. She was immediately transferred to the University Hospitals.

At the time of admission the patient was totally unresponsive with a left-sided flaccid paralysis. The pupils were dilated and fixed and there was evidence of bilateral papilledema. Ventricular needles were placed into both frontal horns in the emergency room and purulent material obtained bilaterally. An emergency brain scan demonstrated a large right posterior-frontal mass. It was believed that a large brain abscess had ruptured into the ventricular system or that the patient had a purulent encephalitis. Treatment with intravenous antibiotics was instituted but the patient continued to deteriorate and died on the third day after admission. Postmortem examination revealed a diffuse encephalitis. The etiology was not proven.

Case 6

A 21-year-old male gave a history of headaches, nausea, and personality change of one year's duration. Examination upon admission revealed ataxia, right-sided cerebellar signs, nystagmus, but no papilledema. A diagnosis of posterior fossa tumor was made, but later revised when a right parietal focus was found on brain scan. Carotid angiography was normal. A combined pantopaque-air ventriculogram was performed via the frontal approach, but visualization of the right lateral ventricle and posterior fossa was inadequate. Without papilledema and with access to the ventricle above, a pneumoencephalogram was deemed safe. An 18-spinal needle was introduced at the fourth lumbar level; no fluid was removed; 7 cc. of air were slowly injected. The patient immediately became decerebrate. He was returned to the supine position and recovered spontaneously in a few seconds. No further air was injected. Because of the positive brain scan and failure to fill the lateral ventricle with air, a presumptive diagnosis of a deep right parietal tumor was made. An emergency craniotomy revealed a large thalamic glioblastoma nearly filling the lateral ventricle as well as obliterating the posterior part of the third ventricle and upper aqueduct. The intraventricular portion of the tumor was removed and a ventriculo-cisterna magna shunt performed. The patient recovered well initially but deteriorated after several months and expired with brain stem infiltration by the tumor.

Discussion

The mechanisms by which catastrophic events associated with lumbar puncture occur have been debated at length. It is now generally agreed that a shift of intracranial contents with internal herniation of brain substance is the primary pathogenetic mechanism. These herniations may take several forms, the most important of which are herniation of the medial aspect of the temporal lobe (hippocampal gyrus or uncus) through the tentorial opening on one or both sides, and thrusting of the cerebellar tonsils through the foramen magnum.[1]

Uncal Herniation

Herniation of a temporal lobe is usually accompanied by ipsilateral compression of the third cranial nerve with resultant pupillary dilatation and contralateral body paralysis due to compression of the cerebral peduncle. Occasionally the opposite peduncle may be compressed against the tentorial edge, resulting in a "falsely" localizing ipsilateral hemiparesis. In this type of herniation death usually results from mid-brain hemorrhages secondary to vascular damage.

Tonsillar Herniation

The pressure cone formed by herniation of the cerebellar tonsils through the foramen magnum is also well known. Symptoms arise by compression of the medulla and upper cervical cord. Early cases may present bilateral spasticity, hyperreflexia, positive Babinski signs, intermittent decerebration and hiccoughing. Death occurs as a result of medullary failure, usually cessation of respiration.

Other Incisural Herniations

Less well known internal herniations also occur. The supracallosal gyrus may herniate laterally beneath the falx of the cerebrum. The cerebellum may herniate upwards to occlude the posterior cerebral arteries, producing "cortical" blindness due to infarction of the occipital lobes, either uni- or bilaterally. This upward displacement of the cerebellum may compress the upper midbrain, mimicking a pineal neoplasm. Rarely the brain may herniate into the pituitary fossa creating an acute hypopituitarism.

Indications

This presentation should not be construed as condemning the judicious use of lumbar puncture. Certainly the procedure is an invaluable diagnostic and therapeutic aid in many situations. Even increased intracranial pressure alone is not a contraindication, for pressure elevations are commonly found in meningitis, subarachnoid hemorrhage, and pseudotumor cerebri where spinal tap is rarely attended by any difficulty. It is primarily in the presence of an *intracranial mass lesion,* especially one located in the posterior fossa, that lumbar puncture becomes a dangerous procedure. When there is a strong clinical suspicion that a space-occupying lesion exists, lumbar puncture is usually ill-advised. Only in very special situations, e.g., a suspected acoustic nerve tumor, do a lumbar puncture and spinal fluid examination serve any useful purpose in the diagnosis of brain tumors. When clinical suspicion is high, there is nothing that can be learned from lumbar puncture which will change the course of the evaluation.

By competent neurological evaluation and funduscopic examination, the presence of increased intracranial pressure can be adequately assessed without the risk of herniation that exists if this elevation is determined by spinal tap. When signs and symptoms strongly suggest a tumor, certainly no cytologic or chemical finding in the spinal fluid will alter the necessity of studying the patient with roentgenograms, radioactive isotope brain scan, angiography, or air encephalography as indicated. It is true that examination of the spinal fluid would eliminate the possibility of meningitis, encephalitis or subarachnoid hemorrhage, but the clinical differentiation of these from brain tumor should rarely be a problem; so this is not really a practical consideration.

Necessity

It is believed that before a lumbar puncture is performed, it is well to consider carefully what combination of data may be obtained. These data refer, of course, to cerebrospinal fluid dynamics, chemical analysis, and cytological examinations. If this information, whatever it may be, will not influence the subsequent management of the patient, it is safe to say that the contemplated spinal puncture is unnecessary. Furthermore, in addition to the mortality and morbidity that may arise as a result of the puncture, an untimely spinal tap may render subsequent diagnostic procedures, such as a pneumoencephalogram or myelogram with cerebrospinal fluid analysis, much more difficult to execute and evaluate. This frequently will mean an unnecessarily prolonged hospitalization for the patient.

Hazards

It has often been said that an atraumatic tap with a small needle and removal of a small amount of fluid is a safe procedure. While it certainly is desirable to perform the puncture as atraumatically as possible, it is not likely that either of these precautions adds great safety in the presence of a brain tumor. With increased pressure the initial amount of fluid removed is not nearly so important as that which leaks through the dural hole afterwards. It has been our experience that patients having a laminectomy 24 hours following myelography often have extradural cerebrospinal fluid and a visible hole in the dura through which cerebrospinal fluid can be seen to flow.

Summary

We have reported six cases in which profound neurological deterioration occurred in direct consequence of lumbar puncture or air encephalography. These were collected at random in a single six-month period from patients seen by the neurosurgical service of the University of Minnesota Hospitals and are reported to emphasize the dangers of lumbar tap when a space-occupying intracranial mass is present. It is our general contention that lumbar puncture is superfluous in the diagnosis of brain tumor and that *safe* punctures cannot be performed with certainty. All patients to undergo diagnostic or therapeutic spinal tap should be carefully evaluated for signs and symptoms of increased intracranial pressure, and should have a funduscopic examination to determine the presence or absence of papilledema. If such signs and symptoms exist we believe lumbar puncture presents an appreciable danger and should be avoided.

Take Time to Laugh—It is the music of the soul.

now she can cope...

thanks to

Butisol SODIUM®

(SODIUM BUTABARBITAL)

the "daytime sedative" for everyday situational stress

When stress is situational—environmental pressure, worry over illness—the treatment often calls for an anxiety-allaying agent which has a prompt and predictable calming action and is remarkably well tolerated. Butisol Sodium (sodium butabarbital) meets this therapeutic need.

After 30 years of clinical use . . . still a first choice among many physicians for dependability, safety and economy in mild to moderate anxiety.

Contraindications: Porphyria or sensitivity to barbiturates.

Precautions: Exercise caution in moderate to severe hepatic disease. Elderly or debilitated patients may react with marked excitement or depression.

Adverse Reactions: Drowsiness at daytime sedative dose levels, skin rashes, "hangover" and systemic disturbances are seldom seen.

Warning: May be habit forming.

Usual Adult Dosage: As a daytime sedative, 15 mg. (¼ gr.) to 30 mg. (½ gr.) t.i.d. or q.i.d.

Available for daytime sedation: Tablets, 15 mg. (¼ gr.), 30 mg. (½ gr.); Elixir, 30 mg. per 5 cc. (alcohol 7%).

BUTICAPS® [Capsules Butisol Sodium (sodium butabarbital)] 15 mg. (¼ gr.), 30 mg. (½ gr.).

McNEIL

McNeil Laboratories, Inc., Fort Washington, Pa.

In childhood

Warnings: Lomotil should be used with caution in patients taking barbiturates and with caution, if not contraindicated, in patients with cirrhosis, advanced liver disease or impaired liver function.

Precautions: Lomotil is a Federally exempt narcotic with theoretically possible addictive potential at high dosage; this is not ordinarily a clinical problem. Use Lomotil with considerable caution in patients receiving addicting drugs. Recommended dosages should not be exceeded, and medication should be kept out of reach of children. Should accidental overdosage occur, signs may include severe respiratory depression, flushing, lethargy or coma, hypotonic reflexes, nystagmus, pinpoint pupils, tachycardia; continuous observation is necessary.

Adverse Reactions: Side effects reported with Lomotil therapy include nausea, sedation, dizziness, vomiting, pruritus, restlessness, abdominal discomfort, headache, angioneurotic edema, giant urticaria, lethargy, anorexia, numbness of the extremities, atropine effects, swelling of the gums, euphoria, depression and malaise. Respiratory depression and coma may occur with overdosage.

Dosage: The recommended initial daily dosages, given in divided doses until diarrhea is controlled, are as follows:

diarrheas...

- careful supervision
- electrolyte replacement
- specific anti-infective therapy

and...

LOMOTIL®

TABLETS/LIQUID

Each tablet and each 5 cc. of liquid contains:

diphenoxylate hydrochloride (Warning: May be habit forming)	2.5 mg.
atropine sulfate	0.025 mg.

LOMOTIL, in conjunction with specifically indicated medical management, may be lifesaving in children with severe diarrhea.

Lomotil lowers the excessive intestinal propulsion characteristic of diarrhea. This reduction of precipitate intestinal flow allows a normal or more nearly normal reabsorption of fluid and electrolytes and counteracts the dehydration so hazardous to children.

Moreover, eight years' experience has demonstrated that Lomotil controls diarrhea with a minimum of unwanted secondary actions.

Senra del Valle and his associates[1] conducted a study of 477 children with diarrhea, most of whom were hospitalized with the disorder. Lomotil, used in 407 of the children, shortened the duration of the diarrhea.

Grinszpan, Goldstein and Divito[2] used Lomotil in 20 children with diarrhea and also reported a prompt disappearance of diarrhea. Harris and Beveridge[3] in a double-blind study of 50 children with diarrhea, however, found no clear pattern to suggest that Lomotil influenced the course of the condition.

Michener, Brown and Turnbull[4] added evidence supporting the beneficial effects of Lomotil in 80 children, concluding that Lomotil was highly useful in controlling abdominal cramping, diarrhea and hypermotility.

Children: Total Daily Dosage

3-6 mo.	½ tsp.* t.i.d. (3 mg.)
6-12 mo.	½ tsp. q.i.d. (4 mg.)
1-2 yr.	½ tsp. 5 times daily (5 mg.)
2-5 yr.	1 tsp. t.i.d. (6 mg.)
5-8 yr.	1 tsp. q.i.d. (8 mg.)
8-12 yr.	1 tsp. 5 times daily (10 mg.)
Adults:	2 tsp. 5 times daily (20 mg.) or 2 tablets q.i.d.

Based on 4 cc. per teaspoonful.

Maintenance dosage may be as low as one-fourth the initial daily dosage.

THE BETTMAN ARCHIVE

Just one tablet at bedtime • Prevents painful night leg cramps • Permits restful sleep

How many of your patients stamp their feet at night and lose sleep because of painful leg cramps? Unless prompted, they usually fail to report this distressing condition and suffer needlessly.

One tablet of QUINAMM at bedtime usually controls distressing night cramps and permits restful sleep with the initial dose.

Prescribing information—Composition: Each white, beveled, compressed tablet contains: Quinine sulfate, 260 mg., Aminophylline, 195 mg. **Indications:** For the prevention and treatment of nocturnal and recumbency leg muscle cramps, including those associated with arthritis, diabetes, varicose veins, thrombophlebitis, arteriosclerosis and static foot deformities. **Contraindications:** QUINAMM is contraindicated in pregnancy because of its quinine content. **Side Effects/Precautions:** Aminophylline may produce intestinal cramps in some instances, and quinine may produce symptoms of cinchonism, such as tinnitus, dizziness, and gastrointestinal disturbance. Discontinue use if ringing in the ears, deafness, skin rash, or visual disturbances occur. **Dosage:** One tablet upon retiring. Where necessary, dosage may be increased to one tablet following the evening meal and one tablet upon retiring. **Supplied:** Bottles of 100 and 500 tablets.

Adenomammectomy*

ADENOMAMMECTOMY as a more complete type of procedure for obtaining breast biopsy specimens would seem to be more radical than would be necessary in most circumstances. It is true that even with our more sophisticated methods of supplementing physical examination in the evaluation of breast lesions, there continue to be a number of patients who require operative approaches for the final and complete reassurance of both the physician and the patient. Limited biopsy specimens from indeterminate nodules through minimal incisions have sometimes led to overlooking an adjacent more significant nodule than the one that seemed apparent to the surgeon through this limited approach. This, however, is uncommon and related directly to the responsibility of the individual surgeon. It would not appear to be justification for a radical type of local excision of the breast for every indeterminate lesion.

The surgeon should have a strong responsibility to obtain an excellent cosmetic result whenever possible with breast surgery. Usually he can accomplish this by judiciously limiting the excision of breast tissue. The use of a circumareolar incision to obtain biopsy specimens in all quadrants of the breast is usually possible and permits a satisfactory cosmetic result with respect to the resulting scar. For that rather uncommon group of patients who have sufficient fibrous or cystic mastitis, with or without pain, in whom excision of extensive portions of the breast would seem indicated and who may have had multiple biopsy specimens taken previously, it would seem more reasonable at this time to be thinking of a complete subcutaneous mastectomy, with replacement by a suitable prosthesis. Adenomammectomy and attempted reconstruction of the breast obviously leave considerable breast tissue behind as a threat for neoplasia in the future.

The final word on breast prostheses is a long way from being written, but it would seem reasonable to use those techniques that are available at the present time when one is dealing with benign disease and contemplating the sacrifice of a major amount or all of the breast to gain reassurance and relief of pain. Even with certain malignant lesions, the survival of patients may be such that the use of subcutaneous prostheses will have an increasing role.

Embolism

Clinicians are all familiar with thromboembolic diseases, but the less common varieties of embolic phenomena are not as well known. Evarts'[1] discussion of fat embolism should stimulate interest in this syndrome, particularly in those who deal with traumatic injuries.

A multitude of substances, both endogenous and exogenous, have gained access to the circulation, sometimes by iatrogenic means.

Recent studies have emphasized the importance of atheromatous embolism. Fragments of atheromatous material, chiefly cholersterol crystals derived from plaques in large arteries, may occlude smaller vessels. This disease may imitate a variety of conditions, including polyarteritis nodosa, peripheral vascular disease, and subacute bacterial endocarditis[2]. Muscle biopsy has been useful in establishing the diagnosis, also direct visualization of retinal emboli.

Some examples of exogenous emboli are: (1) fragments of indwelling venous catheters sheared off by the needle tip[3]; (2) the ball from an intracardiac ball valve prosthesis[4] (decrease in size over a period of time may allow the ball to escape from its cage with predictably catastrophic results); and (3) the tip of a varicose vein "stripper[5]."

Improvements in design and use of these materials should decrease the incidence of exogenous embolism, but those familiar with Murphy's Law* will realize that episodes of this nature will continue to occur.

Food Allergy and Gastrointestinal Allergy*

Many patients with obvious allergy to food do not consult a physician because it is apparent to them that if they avoid the easily identified offending food, they will not have allergic symptoms. Strawberries, seafood, fish, and nuts commonly cause acute and often transient symptoms. The importance of foods causing persistent allergic symptoms is, however, a controversial matter. Some allergists find that foods frequently cause chronic nasal symptoms and asthma. Many other allergists are unable to confirm these observations. The importance of making this diagnosis is apparent, since removal of the offending foods should cause a disappearance of symptoms. Diagnostic tests, in general, are on a shaky scientific foundation. Skin testing for offending foods has been found to be generally unreliable. Elimination diets are sometimes helpful. A carefully taken clinical history is certainly important, but patients often are uncertain as to the importance of various foods. A provocative diet containing the suspected food given on several separate occasions may be a valuable technique. Another type of testing involves the leukopenic index, which is based on the unproved idea that leukopenia occurs after the ingestion of a food to which a patient is allergic.

The provocative intradermal food test has been proposed as another diagnostic procedure. This involves attempting to induce al-

Smiles speak louder than words

for the good taste of Soyalac

Milk-free, hypo-allergenic Soyalac has a pleasing taste that is eagerly accepted by most infants. It's similar to mother's milk in composition and assimilation, much like cow's milk in consistency and completely free of fibre. Extensive clinical data support Soyalac's value in promoting growth and development. Soyalac is also excellent for growing children and adults.

lergic symptoms by intradermal injection of relatively concentrated food extracts. If a reaction occurs, a further intradermal injection of the same extract in higher dilution is given to relieve the provoked symptoms. The mechanism involved in relieving symptoms by further injection of the same material in a diluted form is not clear, and the validity of this type of testing awaits double-blind studies.

Gastrointestinal allergy is a term describing symptoms involving the gastrointestinal tract caused by allergic (antigen-antibody) reactions. Usually foods are implicated, but drugs, injectants, and inhalants also are believed to produce gastrointestinal allergy. Possible symptoms cover a wide spectrum of gastrointestinal complaints and none are specific. Ingelfinger and co-workers[1] have proposed three criteria for diagnosis. 1. The symptoms should be caused by substances that are innocuous when given to the bulk of the population. 2. Lesions or functional changes in the gut should be demonstrated. 3. Emotional and mechanical factors should be excluded and the role of subjective attitudes minimized by testing various substances under carefully controlled conditions. The offending food, which is given in a double-blind fashion, should cause reproducible symptoms, signs, or x-ray findings at a rather constant interval; and other foods should not do this.

Many disorders are associated with excessive loss of proteins from the gastrointestinal tract. Waldmann and associates[2] studied six children who had a syndrome consisting of edema, anemia, hypoalbuminemia, hypogammaglobulinemia, eosinophilia, and growth retardation. There was a significant amelioration of the clinical symptoms and disorders of protein metabolism in three of these patients when a milk-free diet was given. When milk was re-introduced into the diet, there was diarrhea and vomiting, increased eosinophilia, an increase in the number of Charcot-Leyden crystals in the stools, and a worsening of the protein-losing gastroenteropathy. They called this syndrome "allergic gastroenteropathy."

Greenberger and colleagues[3] have reported protein-losing enteropathy associated with gastrointestinal allergy in an adult. A specific food intolerance was correlated with the symptoms of gastrointestinal involvement and changes in the intestinal mucosa, including an increased infiltration of eosinophils. An exhaustive work-up failed to reveal any other cause for the patients' protein-losing enteropathy, and it was proposed that the excessive enteric loss of protein was due to injury to the gastrointestinal mucosa by specific food allergens. The mechanism of this loss in patients with gastrointestinal allergy has not been defined. It may be due to a localized hypersensitivity reaction in the intestinal mucosa with development of mucosal edema and passive diffusion of plasma proteins into the intestinal lumen. Such a process could conceivably subside rapidly when the offending agent is removed from the intestinal tract.

Gastrointestinal allergy must be differentiated from almost all other organic diseases of the gastrointestinal tract. This diagnosis can be made only when other pathologic conditions have been carefully excluded.

Open Heart Surgery in Elderly Patients

THE PRACTICING PHYSICIAN in the community hospital has to be a realist. New procedures, often glamorized both in medical publications and by the lay press, must be given a hard look; for, if results and mortality rates do not measure up to expectations, then the local medical doctor must bear much of the burden of the poor result and, unlike the relatively sequestered specialist, must live with the family.

Open heart surgery a decade ago was a high-risk procedure and failures were not uncommon; hence a skeptical attitude by the general physician to this innovation was not without justification. Yet when the procedure was successful, the result was often startling, for the correction of a defective valve or the closure of a septal defect can turn a pitiful cardiac cripple into a robust human. While techniques were being refined, open cardiac surgery was limited largely to correction of congenital defects, for only in the very young did the great potential benefit warrant the high risk of the operation.

Times have changed and open heart surgery is no longer an innovation; it has withstood the test of time and is an accepted procedure. The adult with acquired valvular disease that limits his capabilities and restricts his activities should be considered for corrective surgery. Accurate preoperative assessment, technical operative finesse, proficiency in the bypass, and diligent postoperative care have lowered the risk sufficiently so that the realistic clinician must now reassess his attitude toward surgery for his patient.

It seems to this viewer that now instead of asking: why should the patient be subjected to the risk of surgery, one should ask: why shouldn't the patient be offered the benefits of surgical correction. The four remarkable patients with an average age of 75, who successfully underwent open heart surgery, as reported here by Doctors Kiser, Peterson, and Johnson*, amply demonstrate the rewards of this change of attitude.

Vertebral Basilar Artery Insufficiency

THE EXCELLENT ARTICLE by Dr. Klassen in the September issue* comprehensively covers this subject in its various aspects. A pure hemiplegia may be either cerebral or pontine. A lesion of the pons may produce a complete hemiplegia similar to that of a lesion in the motor cortex or the internal capsule of the cerebrum. To localize such a brain stem or posterior fossa involvement, one must rely on a Horner's syndrome, vestibular manifestations, cerebellar symptoms, cranial nerve findings, and various visual manifestations. The latter occur because the posterior cerebral arteries supply the visual area and originate from the basilar artery. In hemi-sensory involvement of deep sensation, such as position sense, vibration sense, and stereognosis, the lesion is usually cortical or supratentorial; whereas, when pain and temperature are involved alone, the brain stem is more apt to be involved.

Generally, most cases are in the arteriosclerotic age group, and arterial insufficiency of the vertebral basilar circulation is readily suspected. A man in his early forties complained of shifting hemi-sensory symptoms. Neurological evaluation was repeatedly negative; therefore conversion hysteria or psychoneurosis was suspected. He had been demoted several times in his job and was the

*Klassen, A. C.: Vertebral-Basilar Insufficiency. Minnesota Med 51:1183, 1968.

Dear Doctor,
You made me
what I am today
a whole lot
slimmer!

TEPANIL —the right start in support of the weight-control program *you* recommend. It reduces the appetite. Doesn't kill it. Weight loss is significant—gradual—yet there is a relatively low incidence of CNS stimulation. Because TEPANIL works on the appetite, not on the "nerves."

Contraindications: Contraindicated concurrently with MAO inhibitors, in patients hypersensitive to diethylpropion hydrochloride, and in emotionally unstable patients known to be susceptible to drug abuse.

Warning: Although generally safer than the amphetamines, use great caution when prescribing for patients with severe hypertension or severe cardiovascular disease. Should not be used during the first trimester of pregnancy unless potential benefits outweigh potential risks.

Side Effects: While rarely causing therapy to be withdrawn, side effects may occur occasionally; CNS effects (such as insomnia, nervousness, jitteriness), dryness of mouth, thirst, nausea, abdominal distress, constipation, headache, allergic response including urticaria or other dermatitis; rarely associated with tachycardia, cardiac arrhythmia or ECG changes.

Convenience of two dosage forms: TEPANIL Ten-tab tablets: One 75 mg. tablet daily, swallowed whole, in midmorning (10 a.m.); TEPANIL: One 25 mg. tablet three times daily, one hour before meals. If desired, an additional tablet may be given in midevening to overcome night hunger.

Use in children under 12 years of age is not recommended.

THE NATIONAL DRUG COMPANY
DIVISION OF RICHARDSON-MERRELL INC.

only unsuccessful sibling in his family. He finally developed a quadriplegia and definite bulbar symptoms. Autopsy showed a marked stenosis of the basilar artery (without thrombosis) resulting in demyelinization of both pyramidal tracts in the pons.

Difficulty in the differential diagnosis is demonstrated by the following care and conditions. An older patient with some evidence of arteriosclerosis had two episodes of transitory squint and diplopia with some vague cerebellar findings. At autopsy this proved to be two aneurysms of one vertebral artery and calcification of the dentate nuclei of the cerebellum. Vertebral basilar disease occasionally may mimic multiple sclerosis with fluctuating cerebellar findings, cranial nerve findings, and pyramidal tract and sensory findings. The age of onset generally makes the differential not too difficult. The so-called hemiplegic variety of migraine will produce transitory hemisensory and hemiplegic symptoms. Occasionally these may remain permanent. The posterior circulation, though rare, may be involved in migraine, producing various combinations of a cerebellar and brain stem involvement. The age of onset and a positive family history generally point to a correct diagnosis.

A man in his early sixties with some evidence of arteriosclerosis and elevated blood pressure, in whom the diagnosis of vertebral basilar artery insufficiency seemed apparent, proved to have an angioblastoma. Its removal resulted in complete cure of the patient.

Another patient had episodes of diplopia and also separate episodes of vertigo. He was first treated for Meniere's disease. When the transitory episodes of diplopia occurred, the patient was referred for neurological study. He was negative neurologically, but vertebral angiography showed a complete occlusion of one vertebral artery in the vertebral canal in the cervical region. The other artery was small. At operation an osteophyte was found obstructing the artery. This was removed and the patient has remained free of symptoms now for a number of years.

Dr. Klassen suggests that angiography should be reserved mainly for cases showing a suspected subclavian steal. A significant difference in blood pressure in the arms and symptoms following exercise of the arms leads one to suspect this condition. Unfortunately some cases of subclavian steal do not show such a difference in blood pressure.

In our experience vertebral angiography by catheterization of the brachial artery is free of serious complication. As far as I know, no extensive autopsy study of the extracranial vertebral arteries has been performed. Perhaps more angiography followed by more autopsy studies would help improve our diagnostic and therapeutic skill. As yet no one knows precisely which cases should have contrast studies.

In a number of studies anticoagulation therapy has seemed to be of definite value, but in a few the outlook seems little different with or without such treatment. A fair percentage of cases of infarction of the brain stem have been preceded by intermittent insufficiency. Actual infarction of the brain stem is frequently fatal or leaves the patient with serious residuals. Until we are able to predict which cases of intermittent insufficiency will go to infarction, there remains a strong argument in favor of anticoagulation therapy.

Bad Temper

As a youngster I once happened to see a man opening a door in a hurry, and when things did not go as he wished, he bit the lock, kicked the door, and reviled the gods; his eyes became wild like those of a madman, and he almost foamed at the mouth like a boar. At this I took such a hatred against temper as to wish never to be seen disgracing myself in one.

Restrain and hide your anger within yourself. For though one cannot become void of anger by the mere wish, one can control the unseemly manifesations of this passion.—Galen

DIARRHEA

TROCINATE
BRAND THIPHENAMIL HCl

The first 400 mg. Trocinate tablet usually relieves discomfort so promptly that Diarrhea ceases to be a bother

Trocinate has no known therapeutic value other than relaxing smooth muscle by direct action when coming in contact with the spastic muscle cell. Trocinate has none of the troublesome side-effects of anticholinergic drugs. Trocinate relieves the discomfort of diarrhea by decreasing both peristalsis and muscle tone. Trocinate is metabolized by the body and eliminated in the urine as harmless degradation products. Normal intestinal function is resumed.

The action of Trocinate is prompt, making the spacing of dosage easy. Often one or two 400 mg. tablets are sufficient to control diarrhea. The recommended dosage in spasm of the G. I. and G. U. tract is 400 mg. q. 4 h. A prescription of twelve (12) 400 mg. tablets will, in most cases, allow the patient to have a few to keep in reserve.

Placental Localization

LOCALIZATION OF THE PLACENTA by radioisotopic technique constitutes an important advancement in obstetrical practice. It can be localized because it is a highly vascular organ. It can be seen if the patient's plasma or red cells are made radioactive. Current practice favors labeling the plasma.

As pointed out in the paper by Loken and co-workers, labeling the plasma is of use in diagnosing the cause of vaginal bleeding in the third trimester. We also have found such techniques particularly important in localizing the placenta prior to amniocentesis for transuterine fetal blood transfusion.

Technically, the test is fairly simple to perform, particularly insofar as the patient is concerned. A simple injection into the antecubital vein is virtually all that is needed. Then she has but to lie under a scintigraphic apparatus. For the physician it is somewhat more difficult in that human serum albumin must be labeled with pertechnetate ion in the laboratory. Owing to its short half-life, the labeled material must be used immediately. Sterility and pyrogenicity tests are of value only in retrospect.

While of unquestioned value, it is not necessary to employ a scintillation camera to perform such tests. Higher resolution scans may be obtained with more conventional rectilinear scanners. The chief potential advantage offered by the camera is that one might possibly avoid the necessity to retard the disappearance from the plasma of the radioactive medium by attaching it to a protein.

High degrees of accuracy have been reported by several workers in the field. Even so, it is not a static procedure. The use of many other compounds with even shorter half-lives than that of 99m-technetium is being explored. Were the test to remain at its current stage of development, however, it has already an important niche in the obstetrician's diagnostic armamentarium.

You May Be Right

Treatment of Leg Cramps of Pregnancy with Vitamin B6

On the basis of the hypothesis that there may be a disturbance in the vitamin B6 metabolism in pregnancy, and that isoniazid-induced peripheral neuropathy[1,2,3,4] can be prevented by the administration of pyridoxine hydrochloride, one hundred milligrams of pyridoxine hydrochloride was administered intramuscularly to 23 pregnant women complaining of cramps, and this gave relief of cramp symptoms within 48 hours in all 23 patients.

In the past year .1 to .2 units of lidocaine 2% was added to the pyridoxine hydrochloride in order to relieve the pain of injection.

I therefore suggest that this method of treatment for leg cramps be carried out empirically by other physicians in order that larger clinical experience can be gained.

R. J. Thurn, M.D.
Duluth, Minnesota

Editor's Note: The above is an excerpt from Dr. R. J. Thurn's original, scientific manuscript. The paper was sufficiently documented with reference to its title, and all twenty-three patients with leg cramps who were treated by pyridoxine injection had resolution of their cramps. Ideally a tryptophane load test before and after treatment and also on a control non-cramp group would be included. It must be pointed out that Dr. Thurn is in general practice and does not have a clinical laboratory at his disposal. There is no better proof than his success.

Letter to the Editor

General Practice in Rural Ireland

Ireland is comprised of the Irish Republic (26 counties), an independent state, and of Northern Ireland (6 counties) which is part of the United Kingdom. The Health Service in Northern Ireland is part of the British National Health Service; medical services are provided by the State for persons of all income levels. These services are provided free of direct charge to the patient. Doctors in General Practice are paid on a capitation basis.

In the Irish Republic, General Practitioner services are provided free to the lower income group by the State. This group is composed of those who are medically indigent. These services are provided through a Dispensary System. The type of life which a General Practitioner leads depends on whether he is in Dispensary or private practice or both, and, whether he is in a predominantly rural or urban area. For example, the small town where I work has a population of about one thousand and a hinterland con-

methamphetamine HCl 15 mg.,
phenobarbital 64.8 mg. (1 gr.)
(Warning: may be habit forming).

One Ambar Extentab before breakfast can help control most patients' appetite for up to 12 hours. Methamphetamine, the appetite suppressant, gently elevates mood and helps overcome dieting frustrations. Phenobarbital, the sedative in Ambar, controls irritability and anxiety... helps maintain a state of mental calm and equanimity. Both work together to ease the tensions that erode the willpower during periods of dieting.

Also available: Ambar #1 Extentabs®—methamphetamine hydrochloride 10 mg., phenobarbital 64.8 mg. (1 gr.) (Warning: may be habit forming).

BRIEF SUMMARY/**Indications:** Ambar suppresses appetite and helps offset emotional reactions to dieting. **Contraindications:** Hypersensitivity to barbiturates or sympathomimetics; patients with advanced renal or hepatic disease. **Precautions:** Administer with caution in the presence of cardiovascular disease or hypertension. **Side Effects:** Nervousness or excitement occasionally noted, but usually infrequent at recommended dosages. Slight drowsiness has been reported rarely. See package insert for further details.

A. H. ROBINS COMPANY,
RICHMOND, VA. 23220

A·H·ROBINS

taining two villages and many small farms, adding a further two thousand persons. I am in private general practice and also provide service to the lower income group as the District Medical Officer.

There is one Dispensary in my own town, Athboy, and one at Ballivor seven miles away. These small clinics consist of a consulting-cum-dispensing room and a waiting room. They are staffed by myself and a nurse. Four Dispensary sessions are held each week. Patients are seen, treated and the required drugs dispensed. Domiciliary calls are made to patients if necessary.

There is no local hospital and all cases, both medical and surgical requiring investigation or in-patient treatment, are referred to the appropriate consultant at our County hospital which is ten miles away, or to a Dublin hospital thirty miles away. There is a Maternity unit in a neighbouring town seven miles away and most patients are delivered there or in one of the Dublin Maternity hospitals. Nowadays domiciliary delivery is rare; 95% of all deliveries are in hospitals.

In Ireland medical services are midway between the free enterprise system obtaining in the U.S. prior to Medicare and total government control as in the British National Health Service. General Practitioners in their private practices are paid directly by the patient, though some patients recoup part of their fees from the Voluntary Health Insurance Agency. This is a State, non-profit, voluntary insurance scheme (like Blue Cross). For his Dispensary work the Practitioner is paid a salary by the local Health Authority. This is a fixed annual salary which bears no relation to his work load or to the number of services he is called upon to provide. The office of District Medical Officer is called a "part-time appointment" though he is bound by contract to provide twenty-four hour care. In the time not actually taken up by his Dispensary patients he must, of necessity, supplement his income by seeing private patients. These are seen at the doctor's office, usually in the afternoon and provided with domiciliary visits when required. My private office is situated in my home. Many patients are attended in their homes and at least one third of every working day is spent doing house calls!

The spending of so much time doing house calls will doubtless seem very strange to our American colleagues. It should be pointed out that until recently only a relatively small proportion of the population had motor cars, and public transportation in many rural areas is unsuitable and frequently inconvenient for patients. The pattern of practice is gradually changing with the realisation by the public that the doctor can give superior service at his office. In spite of this change, doctors are often called twenty-five miles or more, at odd hours on the most frivolous calls—"Mrs. Murphy has a sore leg, Doctor." This might be a deep vein thrombosis, but is more likely to be a varicose ulcer which she has had for several months!

The present system is in its dying stages and the Government has published a White Paper giving details of a proposed new service. The basic policy of the Government is to substitute for the Dispensary system a service with the greatest practicable choice of doctor and least practicable distinction between private and public patients. It is still proposed to confine State General Practitioner services to about 40% of the population. The Department of Health favours payment in this new service on a capitation basis, while the Profession are unanimously seeking payment on a fee per item of service basis. It is felt that experience in the United Kingdom and elsewhere has shown that the capitation method of payment does not foster a good

advertising contributed for the public good

doctor-patient relationship. Also, under capitation the doctor contracts to give unlimited service for a limited fee and is without redress if the calls made upon him are excessive.

The Profession believes in the concept of the patient's individual responsibility to provide health service for himself and his family, and fears an extension of the present State service from the 40% already covered to cover for the whole population. Two of the three major political parties are committed to such an extention.

It is noted in other European countries that the Health Service usually started on a limited scale and has been gradually extended to large sectors of the public. If this is to be the case in Ireland a system whereby the more affluent patient would pay at least part of his fee would seem to be most desirable. In some other countries it is apparent that it has become increasingly difficult for the family doctor to establish a personal relationship with each patient. In Ireland this has never been a problem and it would be a tragedy for Irish medicine if increasing State intervention were to upset the delicate balance between doctor and patient.

D. Waldron-Lynch, M.D.
Athboy, Ireland

President's Letter (Continued from page 209).

task of furnishing the superior quality of training for increased numbers of technologists that will unequivocally qualify them to relieve the harried radiologist of some of his more routine functions.

My musings must be brought to a close, and perhaps this can be most effectively accomplished by voicing the impression that radiology has passed from childhood to youthful maturity as a medical specialty. Certainly it has become one of the axes upon which medical practice not only rests but revolves. Nevertheless, I believe one can predict that the applications and techniques of radiology in the next decade will advance so dramatically as to defy comprehension by most of us today.

The Editor's Soliloquy

"Watching" A Breast Tumor?

CONTRARY TO THE time-honored legal dictum that declares a man innocent until proven guilty, a breast tumor can never be considered innocent per se until it is unequivocally diagnosed and out. The diagnosing physician may justifiably regard himself as having a high degree of clinical acumen, based on observation and experience; but his judgment—as well as the new-in-vogue mammogram, echogram and thermogram— can never be infallible, because medical science, though progressively more precise and accurate, is not a mathematically exact science, but always involves the indeterminate and elusive doctor-patient equation. Hence a mistake in a clinical diagnosis can be justified as human error, and though it may not exceed two or three percent, that small deviation can still account for the unpredictable difference between life and death for some individuals.

Nothing is more distressing than to encounter a patient who says that her physician is "watching a breast tumor!" Periodic breast examinations are commendable; but to "watch" a breast tumor is a dangerous medical practice—all the more so because the patient has probably been "watching" her own breast tumor for a month or two before consulting her physician. One wonders: Does she finally seek professional advice merely for assurance that her "watching" tactics are defensible? Or, in her understandable apprehension, does she want someone to "watch" with her—in the hope that two persons "watching" will be more effective than just one person? Unfortunately no amount of "watching" can dematerialize a tumor!

A physician can almost always identify the physiologic breast lobulation that varies from the normal and differentiate between a slight deviation on the one hand and a tumor on the other. If he cannot distinguish with certainty he will seek consultation; he surely will not "watch" the suspected aberration—no matter how inconsequential it may seem.

Cystic disease of the breast may vary in its palpability from time to time and needle aspiration of the cystic fluid does not guarantee the absence of covert malignancy. The physiologic variation in the breast's degree of induration, which may be cyclic, should be evident within 14 days; therefore to "watch" a breast tumor for more than two weeks appears tantamount to waiting for an unequivocally positive diagnosis.

Numerous studies have indicated that radical removal of breast cancers, without demonstrable metastases, carries an infinitely better prognosis than when the lymph-nodes are involved. The patient or the doctor who is doing nothing more than "watching" a breast tumor may thereby be guilty of changing the prognosis irreversibly from favorable to unfavorable.

Either a breast tumor is obvious or it is suspicious. Only when no tumor can be palpated is the physician justified in recommending periodic examination alone. He cannot "watch" a breast tumor!—

OLD DOC HESS SAYS: Untruth dies hard—C.O.R.

New drugs take exams, too.

Today, virtually every medical school in the United States cooperates with pharmaceutical manufacturers in the clinical evaluation of new and promising drugs. Just as you might find it significantly more difficult to practice medicine without the useful new compounds made available through original pharmaceutical research in the past twenty years—prescription-drug manufacturers would find it equally difficult to obtain extensive, long-term, dependable evaluations of new therapeutic agents without the close cooperation of medical staffs and clinical facilities of medical schools and teaching hospitals. Such cooperation leads toward more effective care of more patients—the common goal of medical and pharmaceutical research—toward reduction in the cost of disease, toward increase in useful longevity.

This message is brought to you as a courtesy of this publication on behalf of the producers of prescription drugs.

DECLOMYCIN
DEMETHYLCHLORTETRACYCLINE

You've made it one of your specific in acute otitis medi

DECLOMYCIN acts against many strains of H. influenzae, pneumococci and streptococci, t
most common invaders. In otitis media, where it
is difficult to isolate the causative organism, thi
coverage may be important. However, some strai
may be resistant and other pathogens can be involved.

You've found the high serum levels of DECLOMYCIN important, too. Its prolonged acti
permits convenient 300 mg b.i.d. or 150 mg q.i.d. administration.

When specimens are obtainable, your culture studies will indicate the usefulness of DECLOMYCIN.

Effectiveness: DECLOMYCIN Demethylchlortetracycline should be equally or more effective therapeutically than other tetracyclines in infections caused by organisms sensitive to the tetracyclines.

Contraindication: History of hypersensitivity to demethylchlortetracycline.

Warning: In renal impairment, usual doses may lead to excessive accumulation and liver toxicity. Under such conditions, lower than usual doses are indicated, and, if therapy is prolonged, serum level determinations may be advisable. A photodynamic reaction to natural or artificial sunlight has been observed. Small amounts of drug and short exposure may produce an exaggerated sunburn reaction which may range from erythema to severe skin manifestations. In a smaller proportion, photoallergic reactions have been reported. Patients should avoid direct exposure to sunlight and discontinue drug at the first evidence of skin discomfort. Necessary subsequent courses of treatment with tetracyclines should be carefully observed.

Precautions: Overgrowth of nonsusceptible organisms may occur. Constant observation is essential. If new infections appear, appropriate measures should be taken. In infants, increased intracranial pressure with bulging fontanels has been observed. All signs and symptoms have disappeared rapidly upon cessation of treatment.

Side Effects: Gastrointestinal system—anorexia, nausea, vomiting, diarrhea, stomatitis, glossitis, enterocol
pruritus ani. Skin—maculopapular and erythematous rashes; a r
case of exfoliative dermatitis has been reported. Photosensitiv
onycholysis and discoloration of the nails (rare). Kidney—rise in B
apparently dose-related. Transient increase in urinary output, so
times accompanied by thirst (rare). Hypersensitivity reactions—u
caria, angioneurotic edema, anaphylaxis. Teeth—dental staining (
low-brown) in children of mothers given this drug during the latter
of pregnancy, and in children given the drug during the neonatal p
od, infancy and early childhood. Enamel hypoplasia has been see
a few children. If adverse reaction or idiosyncrasy occurs, disconti
medication and institute appropriate therapy. Demethylchlorte
cycline may form a stable calcium complex in any bone-forming tis
with no serious harmful effects reported thus far in humans.

Average Adult Daily Dosage: 150 mg q.i.d. or 300 mg b.i.d. Sho
be given 1 hour before or 2 hours after meals, since absorptio
impaired by the concomitant administration of high calcium cont
drugs, foods and some dairy products. Treatment of streptococ
infections should continue for 10 days, even though symptoms h
subsided.

DECLOMYCIN®
DEMETHYLCHLORTETRACYCLINE

Capsules: 150 mg; **Tablets:** film coated,
mg, 150 mg and 75 mg of demethylchlorte
cycline HCl.

heavenly relief
for unearthly cough

Benylin®
EXPECTORANT

Each fluidounce contains: 80 mg. Benadryl® (diphenhydramine hydrochloride, Parke-Davis); 12 grains ammonium chloride; 5 grains sodium citrate; 2 grains chloroform; 1/10 grain menthol; and 5% alcohol. An antitussive and expectorant for control of coughs due to colds or of allergic origin, BENYLIN EXPECTORANT is the leading cough preparation of its kind. BENYLIN EXPECTORANT tends to inhibit cough reflex... soothes irritated throat membranes. And its not-too-sweet, pleasant raspberry flavor makes BENYLIN EXPECTORANT easy to take. PRECAUTIONS: Persons who have become drowsy on this or other antihistamine-containing drugs, or whose tolerance is not known, should not drive vehicles or engage in other activities requiring keen response while using this preparation. Hypnotics, sedatives, or tranquilizers if used with BENYLIN EXPECTORANT should be prescribed with caution because of possible additive effect. Diphenhydramine has an atropine-like action which should be considered when prescribing BENYLIN EXPECTORANT. ADVERSE REACTIONS: Side reactions may affect the nervous, gastrointestinal, and cardiovascular systems. Drowsiness, dizziness, dryness of the mouth, nausea, nervousness, palpitation, and blurring of vision have been reported. Allergic reactions may occur. PACKAGING: Bottles of 4 oz., 16 oz., and 1 gal.

Curbstone Consultation

INTRATHORACIC TUMOR

QUESTION: I referred a three-and-a-half-year-old child for removal of an intrathoracic tumor. Surgery was abandoned because of bleeding after only partial removal of the tumor. Repeated histologic sections showed the tumor to be benign ganglioneuroma. Although the child continues to do well I am concerned as to what the future course of management should be. What potential exists that this tumor may degenerate, for example, into a malignant neuroblastoma if left alone?

ANSWER: Although malignant neuroblastomas may mature into benign ganglioneuromas (or even eventually progress to scar tissue) there is no evidence that the reverse occurs. Partially removed ganglioneuromas ordinarily cause no further symptoms, and watchful waiting is all that is indicated in such cases.

Harold D. Kletschka, M.D.
Houston, Texas

LANGER'S ARCH

QUESTION: What is Langer's arch and is it of any clinical significance?

ANSWER: Langer's arch results from an anomalous muscle which traverses the axillary cavity extending from the lateral border of the latissimus dorsi to the undersurface of the insertion of the pectoralis major. It probably occurs in about five percent of individuals, but in only a relatively small percentage is it developed to such an extent as to be of clinical importance. The chief clinical significance of this structure is that when presenting as a mass in the axilla, this anatomic variation must be differentiated from pathologic conditions in that region. This structure may lead to confusion in such operations as radical mastectomy if the surgeon is unaware of its existence.

He who laughs frequently is kind and genial in all things and is not worried over trifles. He who laughs rarely is contrary and critical.

Laboratory Letter

The Pill and Protein Bound Iodine and T-3 Results

Occasionally a physician has asked me why protein bound iodine and T-3 results don't jibe in women on oral contraceptives. What brands, he wanted to know, were responsible? How high did drugs push the protein bound iodine? How much could they depress the T-3? How should he approach thyroid function in women on hormones?

All good questions. Here is a go at the answers. First, though, a few scraps of important information: (1) Most thyroxine binds to globulin in serum; less than 0.1% goes unbound, or "free," (2) Protein bound iodine measures mostly the iodine attached to this globulin. (3) The amount of globulin inversely affects the T-3 value (the more globulin circulating, the less radioactive tri-iodo-thyronine "taken up"). When a woman takes birth control pills, estrogen in the pills increases that portion of protein to which thyroxine clings, thereby forcing the protein bound iodine up and the T-3 down.

To get at the other answers, I recently went over the drug histories of 50 women on contraceptive pills who had high protein bound iodines and low T-3s. Types of pills included C-Quens, Enovid and Enovid-E, Norinyl and Norinyl-1, Ortho-Novum, Ovulen, and Provest. Thus, all the commonly used agents exerted a thyroid effect. And a significant one, too. Values for protein bound iodine ranged from 8.1 mcg.% to 21.0 mcg.% (mean 10.1 mcg.%) and for T-3 from 24% to 8% (mean 19%).

Yet when I multiplied protein bound iodine by T-3 to get a Free Thyroid Index:

$$\underset{(4\text{-}8\ \text{mcg.}\%)}{\text{Protein Bound Iodine}} \times \underset{(25\text{-}35\%)}{\text{T-3}} = \underset{(100\text{-}280)}{\text{FTI,}}$$

48 patients fell into the euthyroid range. From this and other studies, I am convinced the Index reliably measures thyroid status when patients have drug or disease-induced protein charges.

Up to this point, I have not mentioned two other serum tests: T-4 by column chromatography and "free" T-4 by a mixed isotope dilution method. In our laboratory, the T-4 column test, though accurate and precise enough, has not solved the pill problem. Like protein bound iodine, estrogen sends it up. And like protein bound iodine, drugs containing organic or inorganic iodine, will cause high results. Theoretically, "free" T-4 ought to be the answer since globulin changes do not influence it. But it is more expensive than a protein bound iodine and T-3 together, gives about the same information[1] and, at least in the Mayo Clinic experience, "distinguished poorly between different levels of thyroid function."[2]

The Viewing Box

Mass Behind the Heart

THIS 53-YEAR-OLD MAN was hospitalized with a chief complaint of hematemesis and melena. The patient's history included recurring, intermittent jaundice and bouts of cholangitis for 30 years. Cholecystectomy was performed in October 1967, at which time a liver biopsy revealed biliary cirrhosis.

Presently, the patient has cholangitis, edema of the lower extremities, and ascites. Physical examination revealed deep jaundice and a spleen enlarged to three fingerbreadths below the left costal margin; the liver was not enlarged.

What is your diagnosis? (See next page.)

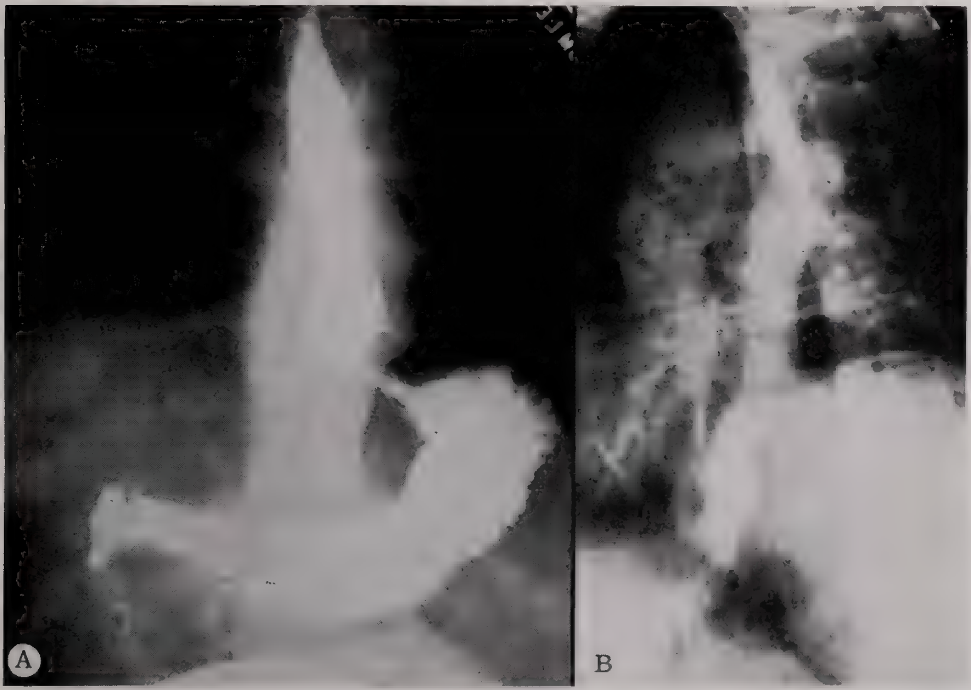

Fig. 1—(*A*) and (*B*), Barium examination of esophagus October 26, 1967, revealed a mass closely associated with the lower esophagus, deviating it anteriorly just above diaphragm. In addition, evidence of calcification in right upper quadrant was noted.

Diagnosis: Massive esophageal varices. Extrahepatic portal vein obstruction.

Comment

Most esophageal varices are associated with portal venous hypertension secondary to intrahepatic obstruction. The most common cause of intrahepatic obstruction is long-standing hepatic cirrhosis. Extrahepatic obstruction produced by thrombosis of the portal vein, pancreatitis, or extrinsic compression is rare by comparison.

Esophageal varices may be present with either intrahepatic or extrahepatic obstruction, as flow in the portal system away from the liver into the systemic veins ("hepatofugal" flow) occurs with both. In extrahepatic block, the blood flow through collateral channels bridging the obstruction in the portal vein is inadequate to decompress the proximal portal venous systems.

The first examples of the radiographic diagnosis of esophageal varices were published by Wolf[1] in 1928 in a case of syphilitic involvement of the liver and spleen. He noted circumscribed, translucent areas on the posterior wall of the esophagus. The patient later died of hemorrhage. Kirklin and Moersch[2] found similar filling defects in the lower esophagus that were associated with portal hypertension and hepatic cirrhosis.

The diagnostic accuracy of the barium examination of the esophagus in the detection of esophageal varices is limited. Reports indicate an accuracy of this procedure in the range of 25 to 50%.[3,4] Percutaneous splenoportography with serial filming during a period of at least 12 seconds is the most reliable radiologic examination for the detection of esophageal varices. During this procedure, measurements of splenic pulp pressure can be made easily. Usually, splenoportography reveals the anatomy of the portal vein system and the changes thereof in enough detail for the surgeon to decide on the operability of the patient and to choose the type of operative procedure.

The unusual aspects of this case include: (1) the enormous size of the collateral channels; (2) the sparseness of the collateral channels at the lower esophagus, instead of the many vessels usually present with portal obstruction; (3) the absence of the characteristic submucosal filling defects in the lower esophagus on the esophagogram; (4) the extramural position of the varices, as seen on the splenoportogram; and (5) the simulation of a mass

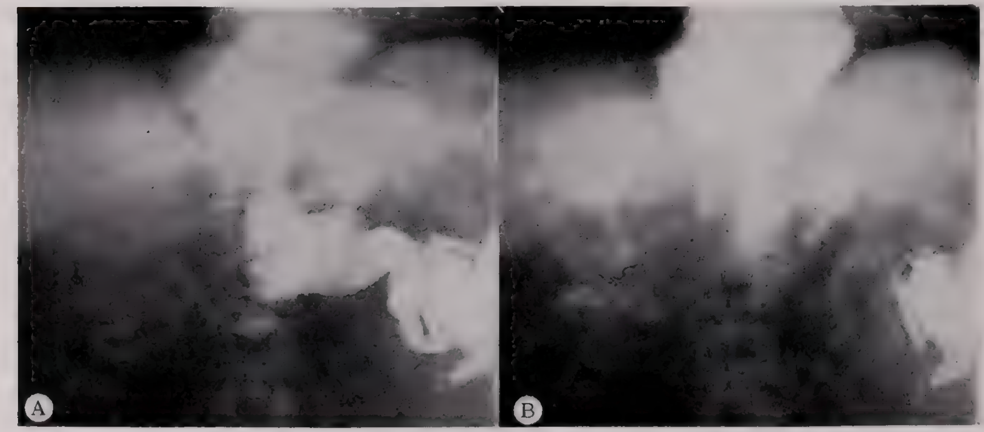

Fig. 2—Percutaneous splenoportogram on February 2, 1968, revealed a dilated splenic vein. (*A*), Bulk of contrast medium subsequently filled huge tortuous cardiac veins in lower esophageal region. (*B*) Film reveals hepatic radicals filled with medium from collateral network, indicating extrahepatic portal vein obstruction. Splenic pulp pressure was elevated to 38 cm. of water.

in the mediastinum, with deviation of the esophagus anteriorly.

Differential diagnosis of the esophagogram includes aneurysm of the lower thoracic aorta and paraspinal abscess or mass.

Bizarre submucosal defects caused by esophageal varices have been reported, including some defects that have been mistaken for malignant lesions of the lower esophagus or stomach.[5] However, we could not find any reports of extramural varices that have produced detectable changes on the esophagogram.

Complications of portal hypertension are well known; the most serious include hematemesis, pancytopenia, and death. Prompt diagnosis and treatment can be life-saving. Various surgical procedures have been performed, but the creation of a shunt between portal and systemic venous circulation has proved to be the most helpful.

For Diseases of the Fundament

For diseases of the fundament, a sovereign remedy is bear's gall, mixed with the grease; to which some persons are in the habit of adding litharge and frankincense. Butter, too, is very good, employed with goose-grease and oil of roses. Bull's gall upon lint is a remarkably useful remedy, and has the effect of making chaps of the fundament cicatrize with great rapidity. Bear's blood is curative of inflamed tumours and apostemes upon these parts in general; as also bull's blood, dried and powdered. The best remedy, however, is considered to be the stone which the wild ass voids with his urine, it is said, at the moment he is killed. This stone, which is in a somewhat liquefied state at first, becomes solid when it reaches the ground: attached to the thigh, it disperses all collections of humours and all kinds of suppurations: it is but rarely found, however, and it is not every wild ass that produces it, but as a remedy it is held in high esteem.—Pliny

Fracture Conference

Posttraumatic Affections of the Metacarpal Joints of the Thumb

Dr. Paul R. Lipscomb:*

Injuries to the thumb are not rare, and usually our attention is directed to this area after an acute injury, though it is possible to see the patient for the first time after repeated exposure to minor trauma, which may result in early degenerative changes at the base of the thumb, with crippling hand symptoms.

Case 1

Dr. Rogers C. Southall:†

This 43-year-old meat-packer had been seen at our institution in 1953 because of fatiguing of her thumb and prominence of the base of the thumb for the preceding three years. Some atrophy was also noted. In 1962 she returned with weakness and numbness in the median distribution of her hand, thenar atrophy, and an adduction contracture of the first metacarpal (Figure 1 *A*).

Dr. Lipscomb:

I think you can see on the roentgenogram the subluxation of the first metacarpal on the trapezium. We could not get a history of a specific injury; yet this is true of many patients that have the localized type of degenerative change. We proceeded with an arthrodesis, because this woman needed to use her thumb in her work. She was 43 years old, with many years of work still ahead of her.

Dr. Southall:

The postoperative films (Figure 1 *B*) show the thumb after surgery to the first metacarpo-carpal joint. She also had section of the transverse carpal ligament to decompress the median nerve in the carpal tunnel. This was done bilaterally.

Fracture conference held April 24, 1968.

*Professor of Orthopedic Surgery, Mayo Graduate School of Medicine (University of Minnesota), Rochester and Consultant, Section of Orthopedic Surgery, Mayo Clinic, Rochester.

†Resident in Orthopedic Surgery, Mayo Graduate School of Medicine, (University of Minnesota), Rochester, Minnesota.

Dr. Lipscomb:

Three months after surgery she returned to work. Her work in the meat-packing plant required a strong pinch and grasp; hence the arthrodesis. In older women I think that excision of the trapezium is probably just as good a procedure as arthrodesis, provided the cartilage is still present over the distal end of the navicular.

Dr. Southall:

Five years later when she returned to our clinic (Figure 1 *C*) she still had thenar atrophy, but she was relieved of pain and numbness in her hands.

Dr. Lipscomb:

Many of these symptoms, of course, are due to traumatic arthritis as a consequence of injuries to the metacarpal trapezial (metacarpal greater multangular joint).

Dr. Mark B. Coventry:*

This seems to be almost exclusively a female disease, and I wonder if it might be due to the relaxed connective tissues that women have, as opposed to men. I don't think I have ever seen symptomatic degenerative arthritis of this joint in a male.

Dr. Lipscomb:

This is true of the type that we have shown here; the males we have seen with these degenerative changes do give a history of injury, usually a fracture. However, I have seen a man, who was also a packing-house worker, with essentially the same condition as has just been described. Perhaps it

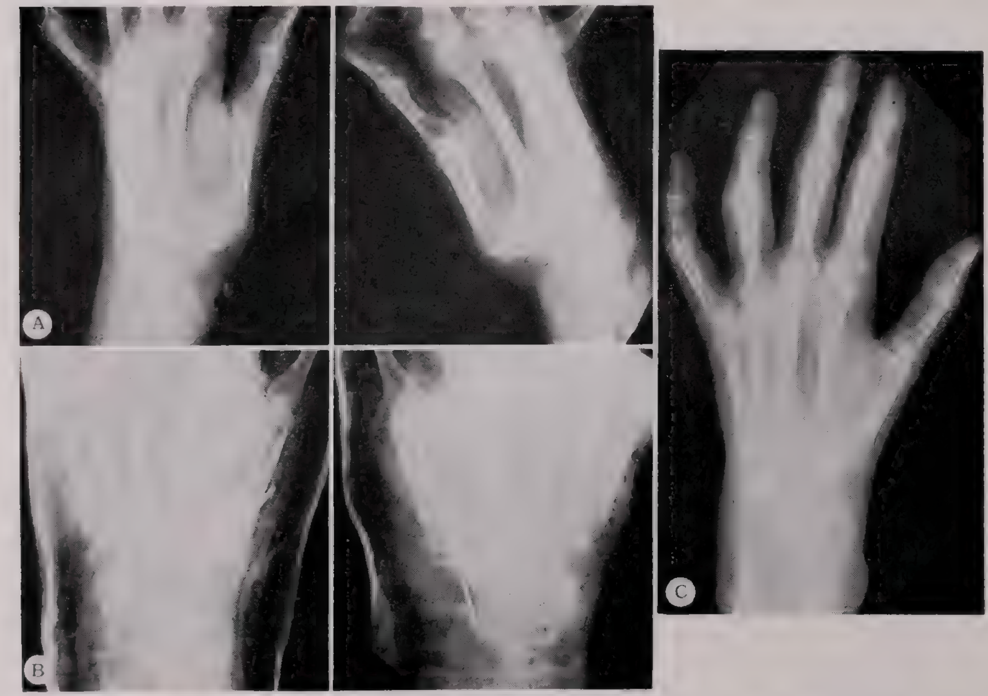

Fig. 1 (Case 1)—(A) Preoperative, showing degenerative arthritis of metacarpo-carpal joints. (B) Postoperative, showing arthrodesis of first metacarpo-carpal joint, with crossed Kirschner wires for fixation. (C) Five years later, showing fusion of metacarpo-carpal joint of left hand. In the interval, destructive changes developed in the fourth proximal interphalangeal joint, suggestive of rheumatoid arthritis.

is like rheumatoid arthritis, which is more common in women, five to one. There are so many of these conditions that are associated with metabolism of collagen tissues. It is not a true degenerative phenomenon, but trauma does contribute.

Case 2

Dr. Southall:

The next patient is a 50-year-old clinic consultant who was Indian wrestling with his son when his thumb was forced into radial abduction and he felt a sudden "pop." He noticed swelling and instability of the metacarpophalangeal joint. A diagnosis of rupture of the ulnar collateral ligament of the metacarpophalangeal joint of the thumb was made.

Dr. Lipscomb:

He had too much pain to place stress on the site of injury when I was examining him in the office, but I could demonstrate definite instability. These injuries usually produce a rupture of the collateral ligament on the ulnar side of the thumb. Occasionally an injury will rupture the radial collateral ligament rather than the ulnar collateral ligament. Rupture of the latter is a common injury; sometimes, the adductor tendon gets caught in the joint and then surgery is necessary.

Dr. Southall:

The discussion was whether to treat him with a gauntlet cast or by a method that would allow him to have his thumb free. It was elected to use two pins across the joint to immobilize it (Figure 2). These Kirschner wires were removed a month later, and the patient started mobilizing his thumb.

Dr. Lipscomb:

He continued to practice in a way that he said he couldn't have done if a cast had been applied. He had tenderness where the ends of the Kirschner wires had been buried beneath the skin and said that if he had to go through it again, he would prefer the cast; but if he had elected the cast originally, I suspect he would have wanted it this way. I did not repair the ligaments

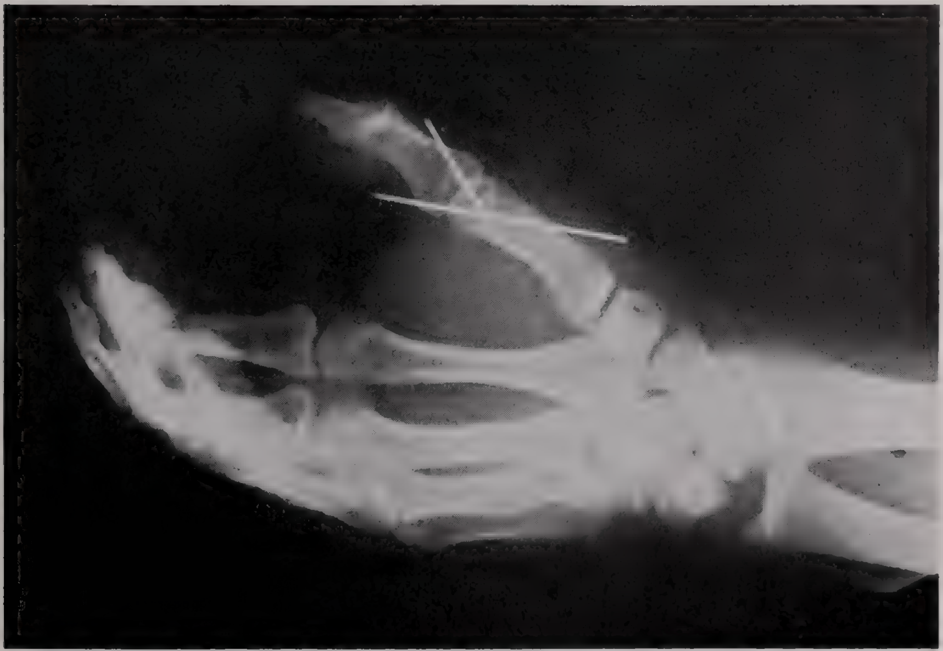

Fig. 2 (Case 2)—Kirschner wires immobilizing metacarpophalangeal joint of thumb.

on the ulnar side of the first metacarpo-carpal joint, because this was an acute injury, and I thought that with approximation of the ends of the torn ligament and firm fixation it would heal without actual surgical repair.

Case 3

Dr. Southall:

The next patient is a 27-year-old bricklayer who fell from a scaffold in April 1967 and injured his left thumb. Thereafter he complained of "looseness" (as opposed to his other thumb) and instability. He had normal flexion and extension. At his work he found that he was unable to pick up bricks or cement blocks. In September 1967, a roentgenogram showed how wide the thumb could be abducted (Figure 3). These, you will note, are stress films.

In September 1967, the ulnar collateral ligament was exposed surgically and was found to be avulsed from the proximal phalanx and curled upon itself. It was resutured to the proximal phalanx after two Kirschner wires had been inserted to ensure immobilization. Approximately one month later the wires were removed, and the patient was noted to have good stability at the site of injury. Three months later he returned to work. About six months after surgery, when he returned for reexamination, he complained of some stiffness in this joint and moderate pain when lifting heavy cement blocks. However, there was no instability.

Dr. Lipscomb:

The point we would like to make here is that we did not repair the ligaments and then insert the Kirschner wires. We put the wires in to hold the joint in normal position and then repaired the ligament. This was a very unstable situation, and it would have been impossible to tack and hold the

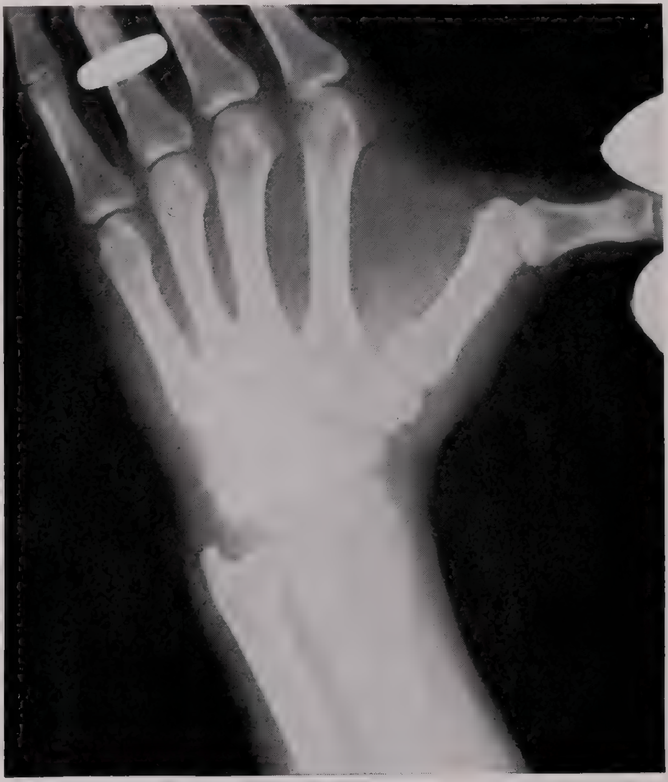

Fig. 3 (Case 3)—Stress film, left thumb.

ligament with sutures unless the joint was first fixed very securely. The injury involved the man's left hand, and he said that he had no trouble when he picked up bricks, but when he picked up heavy concrete blocks all day long, he naturally had some stiffness and soreness in this joint. I suspect that this would be true no matter how the ligaments were fixed. Time will determine whether he will continue to have trouble. If he has enough pain, I suspect the only thing to do next would be to arthrodese the joint, but we wouldn't want to do that unless we absolutely had to.

Case 4

Dr. Southall:

The next patient is a laborer who, in November 1964, fell on his left hand and suffered a fracture (Figure 4). This is a Bennett's type fracture, at the base of the first metacarpal, with lateral subluxation of the metacarpal on the trapezium. The fracture was easily reduced by applying traction to the thumb and forcing the shaft of the metacarpal inward. However, the reduction was unstable until two Kirschner wires were placed across the base of the first metacarpal for the purpose of immobilization.

Dr. Lipscomb:

I think we can just show these examples and hurry along because Dr. Southall has prepared a brief discussion of one of the means of treating this injury. A month later the wires were removed, and since then the patient has had good function.

Case 5

Dr. Southall:

The next case is that of a 27-year-old resident at our clinic who fell on the ice and then noted tenderness at the base of his first metacarpal. The roentgenogram (Figure 5 *A*) shows the fracture and subluxation of the base of the metacarpal.

Dr. Lipscomb:

In the next film (Figure 5 *B*) you can see better the small fragment that is displaced. Because he was a surgical resident, it was important to avoid the development of traumatic arthritis later. I could not get this reduced by traction and abduction of the thumb.

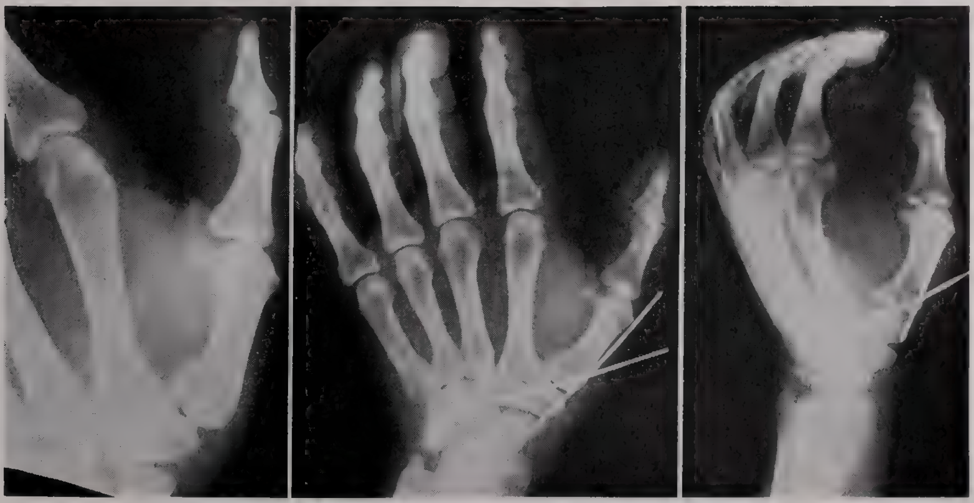

Fig. 4 (Case 4)—Bennett's fracture before and after closed reduction.

Dr. Southall:

He was placed in a cast from the distal phalanx to the midforearm, with the thumb in abduction. The following day the metacarpal of the thumb seemed to have displaced more, and skeletal traction through the distal phalanx was instituted. A 20-gauge needle was placed through the distal phalanx to act as a ferrule, and a loop of 28-gauge stainless steel wire was

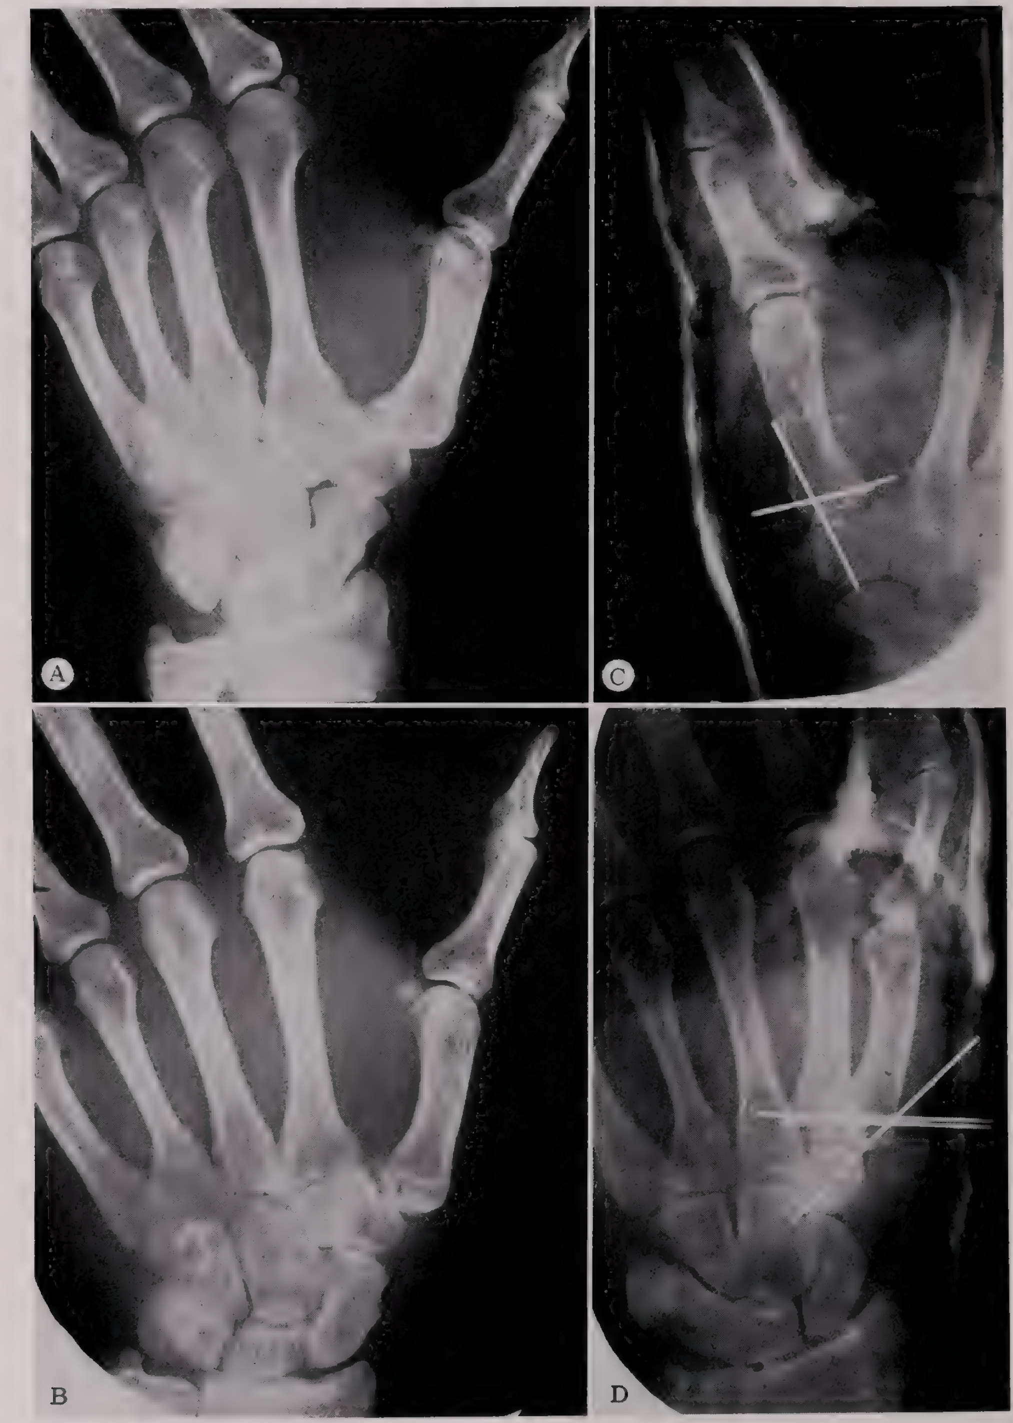

Fig. 5 (Case 5)—(A) Fracture dislocation of base of first metacarpal. (B) Preoperative position. (C) and (D) Immediately after open reduction (through cast).

threaded through this. A rubber band was attached to the loop, and an outrigger made from a coat-hanger wire was incorporated in the cast. Three days later there was still no reduction. Approximately a week after the injury, open reduction was done, and the base of the shaft of the metacarpal was pinned to the small fragment of bone with Kirschner wires (Figures 5 *C* and *D*). A month later the wires were removed (Figures 6 *A* and *B*). These roentgenograms (Figures 6 *C*, *D*, and *E*) show the function and range of motion 14 months after surgery; he had no pain at this time, and as far as we know has had no further trouble. I now want to say a few words about the Bennett fracture.

Bennett's Fracture

Dr. Southall:

Fracture subluxation of the metacarpal of the thumb was first described by Bennett in 1882. This type of fracture is most commonly the result of a fist fight. The patient strikes his opponent with his clenched fist, and the metacarpal is forced into flexion, thereby fracturing the anterior margin of the metacarpal; the remainder is then displaced backward and proximally on the trapezium. The condition also results from falls and injuries in sports. Because of the anatomic features of the first metacarpo-carpal joint, this

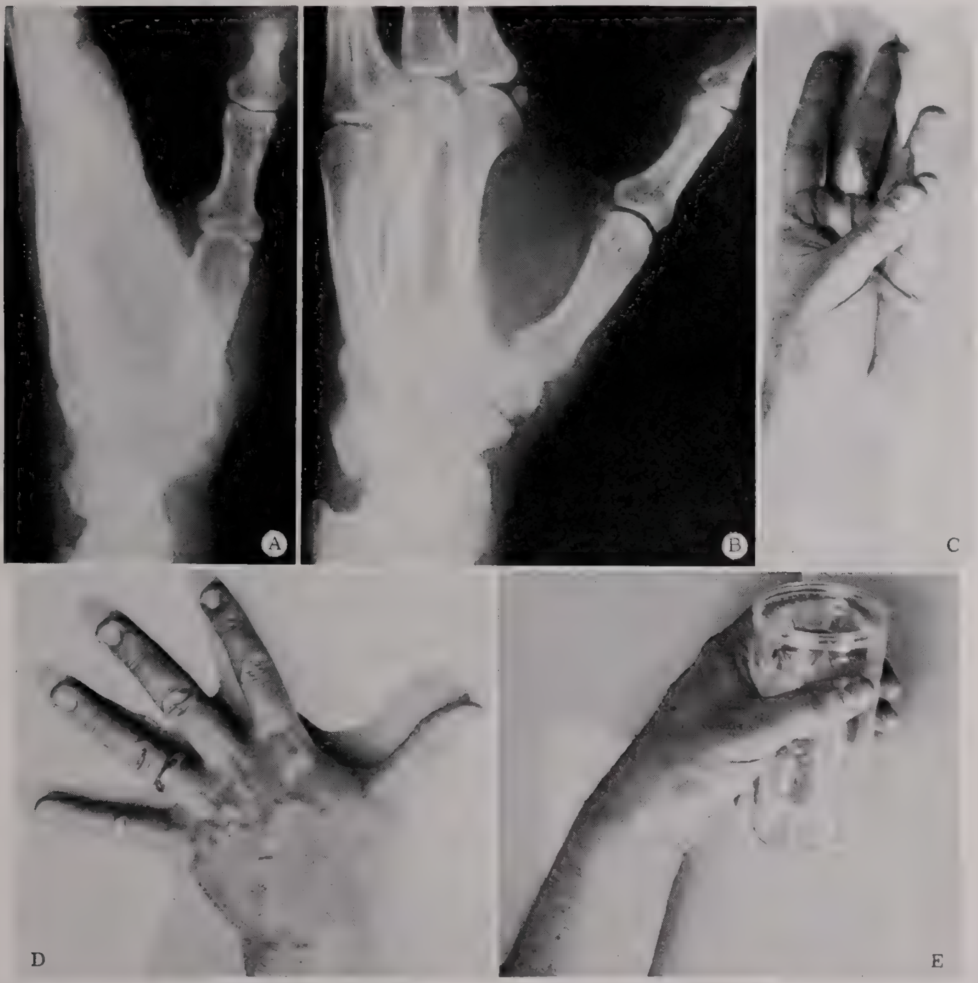

Fig. 6 (Case 5)—(A) and (B) One month after open reduction. (C), (D) and (E) Function of thumb 14 months after reduction.

fracture is easy to reduce but difficult to retain in reduction. Bennett was the first to be disappointed with the results of treatment. The end result of poor reduction may be a painful, tender swollen joint and pain on grasping. The criteria of treatment should be both anatomic and functional. There may be a poor correlation between the anatomic result as judged from the roentgenogram and the functional result as judged by the patient and his physician. There are multiple methods to maintain reduction.

First Method of Maintaining Reduction

The first is closed reduction and the use of a cast to maintain the position. Pollen[1] reduced the fracture dislocation by pressure at the base of the thumb, and then held this digit in abduction and extension and, while maintaining this position, placed the patient's thumb in an unpadded cast from the distal phalanx to the upper forearm. He reviewed the results in 31 patients and found that 29 were successfully treated. All of these patients returned to work within four months after removal of the cast. Probably the most important criterion of success is based on the patient's ability to return to his former occupation. Bennett attributes failure of the closed method to the physician's unfamiliarity with the treatment of this fracture. It is not a common fracture, and very few physicians accumulate a large experience.

Second Method

The second method depends on closed reduction and skeletal fixation. Johnson,[2] in 1944, described a method whereby reduction was stabilized by passing two wires through the metacarpal of the thumb into the metacarpal of the index finger. In 1950, Wagner[3] described a method in which he passed a wire through the base of the metacarpal into the trapezium and thereby transfixed the joint. We saw an example of this technique in Case 4.

Third Method

The third method is based on open reduction. This was first described by Lambotte[4] in 1913; he transfixed the fragments with a small nail. Disagreement exists as to which method of treatment is the best. Gedda,[5] in 1954, stated that anatomic reduction was essential for good function. Others, such as Griffiths[6] in 1964, showed that malunion is compatible with good function, although not invariably.

When deciding which method to use, we believe the surgeon should employ the technique most likely to produce and maintain anatomic reduction and, by doing so, assure an acceptable functional result, which should not be marred by development of traumatic arthritis years later, if this complication is preventable. Certainly this complication should be decreased by an anatomic reduction and healing.

Conclusion

Dr. Lipscomb:

Fracture dislocation of the base of the metacarpal of the thumb is named Bennett's fracture after Edward Hallaran Bennett of Ireland. He became Professor of Surgery at the age of 36 and, in this capacity at Trinity College in Dublin, amassed a remarkable collection of cases involving fractures, dislocations, and bone diseases. His original description of this fracture dislocation was based on five cases and was published in 1882. Even though he had no roentgenograms to guide him, his description is still accurate today.

Repeated minor episodes of trauma to the first metacarpo-carpal joint eventually may produce deformity of the thumb and disabling symptoms, and may require surgical treatment—either arthrodesis of the joint or removal of the trapezium. This seems mostly a problem of women.

Traumatic rupture of the ligaments stabilizing the metacarpal phalangeal joint of the thumb occurs, and the physician should be aware of this possibility. Good stabilization of the joint is necessary for sound healing of its ligaments. Failure to get adequate healing produces an unstable joint, a weak pinch, and eventual degenerative changes with pain.

Bennett's fracture dislocation is seen mostly in men, results from acute trauma, and is sometimes difficult to treat because it is unstable. Dr. Southall has discussed three basic methods of dealing with this problem. There is no doubt in my mind that if reduction is not accurate and well maintained, degenerative changes in this joint will result in time.

An Ounce of Prevention

Statistics show that of every dollar spent in America during a year 5 cents is spent in checking crime; 14 cents for luxuries; 1½ cents on education; ¾ of a cent on religious agencies.

Crime is increasing. A generation ago armored cars in our streets were undreamed of. Last year more murders were committed in a certain American city than in all of England, Wales and Scotland.

Add to these facts the statement of three eminent judges that of all the criminals brought before them none had attended Sunday School.

May it not be that if one cent less were spent on luxury and one cent more in fostering religious influences, two cents less would be needed for checking crime? Which would mean not only the saving of mere dollars, but of priceless human souls.

A fanatic is one who can't change his mind and won't change the subject.—Winston Churchill, 1952

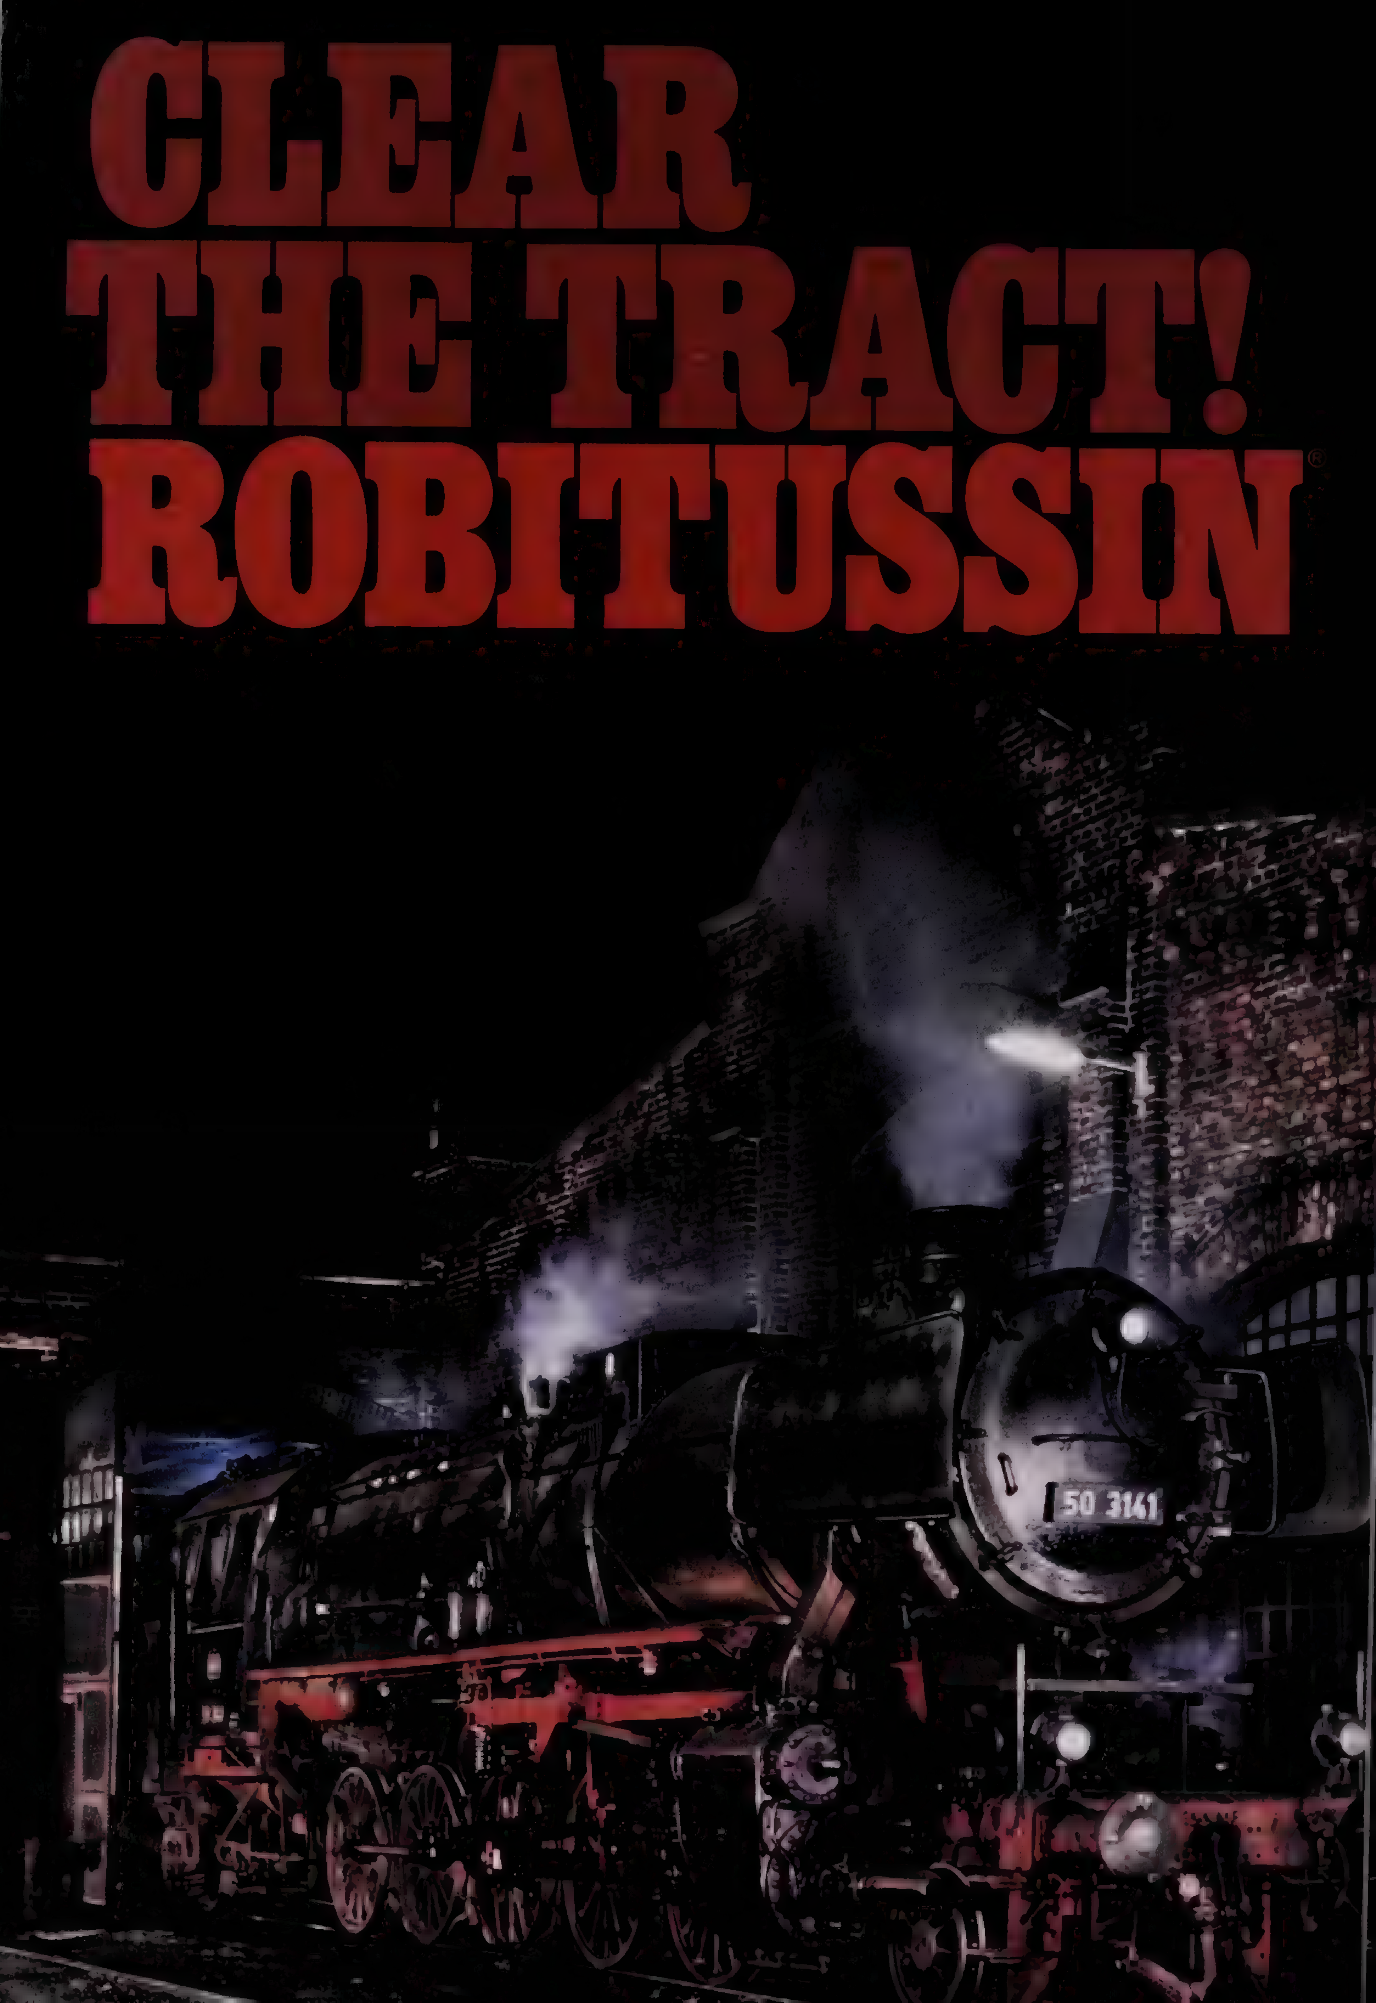
Donnagel®
For treatment of diarrhea
A. H. ROBINS

"Man's best friend" in wintertime diarrheas

In winter "flu" and viral gastroenteritis, Donnagel (4 oz. size!) can bring aid and comfort to sufferers from both diarrhea and its discomforts because it contains kaolin and pectin plus belladonna alkaloids (as in Donnatal®). Donnagel treats the whole diarrhea problem. Available on your prescription or recommendation. A. H. Robins Company, Richmond, Va. 23220

A·H·ROBINS



CLEAR THE TRACT! ROBITUSSIN®
50 3141

THERE'S A FORMULATION FOR EVERY COUGHING NEED

All five members of the Robitussin family contain glyceryl guaiacolate. This outstanding expectorant agent increases the output of lower respiratory tract fluid (R.T.F.) Increased R.T.F. volume thins mucus, thereby improving the action of bronchial and tracheal cilia and making thick, inspissated mucus less viscid and easier to raise.

For coughs of colds and "flu"

ROBITUSSIN®

Each 5 cc. contains:

Glyceryl guaiacolate	100 mg.

Alcohol, 3.5%

For unproductive, allergic coughs

ROBITUSSIN A-C® (exempt narcotic)

Each 5 cc. contains:

Glyceryl guaiacolate	100 mg.
Pheniramine maleate	7.5 mg.
Codeine phosphate	10.0 mg.

(warning: may be habit forming)

Alcohol, 3.5%

Non-narcotic for 6-8 hour cough control

ROBITUSSIN-DM®

Each 5 cc. contains:

Glyceryl guaiacolate	100 mg.
Dextromethorphan hydrobromide	15.0 mg.

Alcohol, 1.4%

Robitussin-DM in solid form for "coughs on the go"

COUGH CALMERS™

Each Cough Calmer contains:

Glyceryl guaiacolate	50 mg.
Dextromethorphan hydrobromide	7.5 mg.

Clears sinuses and nasal stuffiness as it relieves cough

ROBITUSSIN-PE®

Each 5 cc. contains:

Glyceryl guaiacolate	100 mg.
Phenylephrine hydrochloride	10.0 mg.

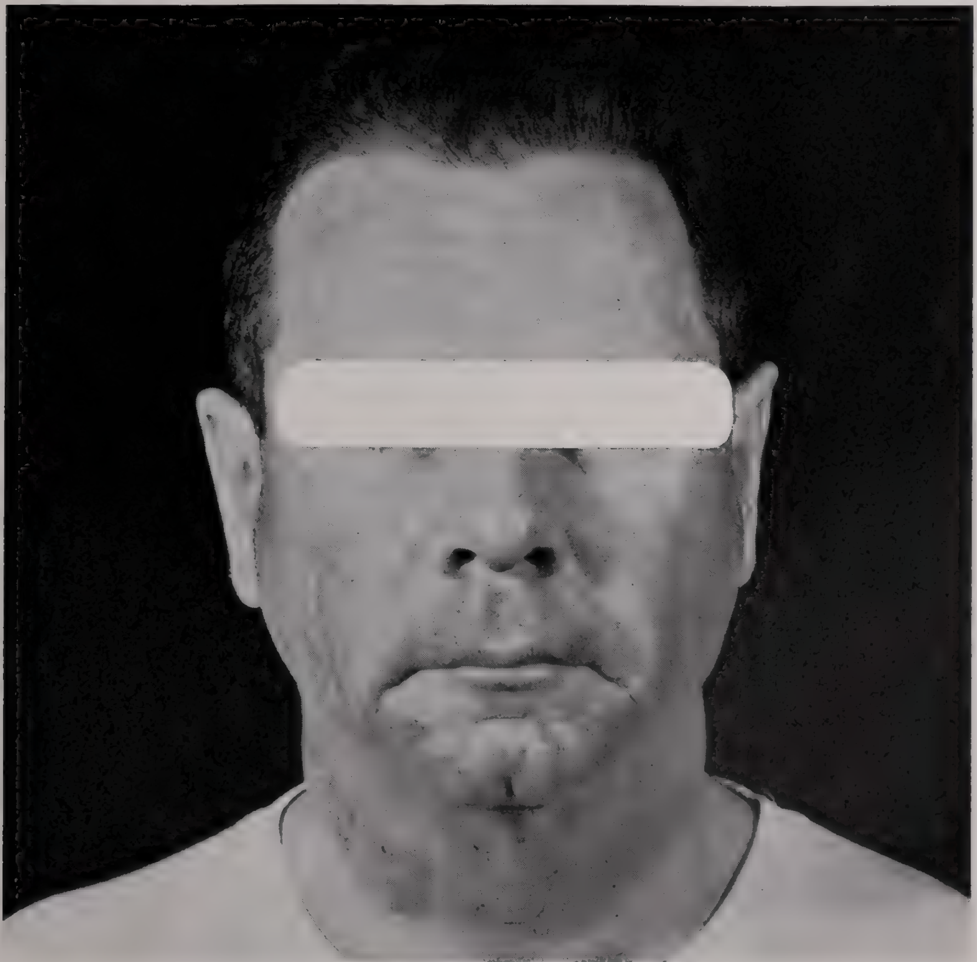
Dermatology

Cutaneous Light Sensitivity Due to Fluorescent Lights

In the past the physician was secure in the fact that his patients who had cutaneous light sensitivity would have a dermatitis only during the late spring, summer, and early fall. During the other periods of the year, the patient could return to a normal existence, engage in outdoor activity, and be free of dermatitis.

Environment

In the last 20 years, with the introduction of the fluorescent lamp, man changed significantly his indoor-light environment. Fluorescent light contains visible light and little infrared radiation; however, there are significant amounts of ultraviolet light (without far ultraviolet—sunburn wave-



Figure

lengths). Depending upon the energy (voltage) input into the bulb, the ultraviolet output may be quantitatively small or very great. Most light sensitivity eruptions are triggered by wave lengths in the ultraviolet region. Fluorescent bulbs can emit enough quanta of ultraviolet light to precipitate a dermatitis in a patient with a cutaneous light sensitivity. We can no longer be secure in our question, "Does your dermatitis appear in the spring, get worse in summer, and disappear in the fall?" Freedom from dermatitis in the colder months of the year is no longer a significant clinical finding in the diagnosis of light-sensitivity dermatitis. A careful history must be taken to evaluate the indoor light environment of the patient, both at home and at work, in order to define the total light exposure a patient has in his daily routine.

Clinical

The clinical expression of the disease will depend upon the amount of clothing worn and the amount of exposure to fluorescent lighting. The distribution of the eruption may be very bizarre, depending upon the location and use of the fluorescent light. For example, if the fluorescent light is a reading lamp, the eruption may be one-sided. Clinically the eruption looks like a contact dermatitis with sharp outlines from the protective effect of the clothing. The full spectrum of the primary clinical lesions may be present (from erythema to vesicles); however, usually erythema, papules or eczema-like eruptions are more common. Bullous lesions are rare. As the eruption becomes chronic, lichenification can take place.

Treatment

In the treatment of the patient, it may be necessary to remove the fluorescent lights in his home. If there is fluorescent light exposure at work, he may have to work under incandescent light or even change jobs. Protective sunscreen ointments may afford sufficient protection to allow the patient to work under minimal fluorescent exposure. By reducing the amount of fluorescent light exposure during late fall, winter, and early spring, some patients who have light sensitivity aggravated by fluorescent lighting can be free of their disease during this period.

Unity of the Individual

Why do doctors so often make mistakes? Because they are not sufficiently individual in their diagnosis or their treatment. They class a sick man under some given department of their nosology, whereas every invalid is really a special case, a unique example. How is it possible that so coarse a method of sifting should produce judicious therapeutics? . . . The principal grievance which I have against the doctors is that they neglect the real problem, which is to seize the unity of the individual who claims their care.*

The passion for setting people right is an afflictive disease.—Marianne Moore

Tumor Conference

Mesenteric Cysts

BENIGN MESENTERIC cysts comprise less than 1.0% of acute abdominal emergencies. A report of one such interesting case and a discussion of benign alimentary cysts follow.

Case Report

A seven-year-old white female was seen in the Emergency Room of St. Mary's Hospital, Duluth, Minnesota, on June 16, 1968, with complaints of abdominal pain 12 hours prior to

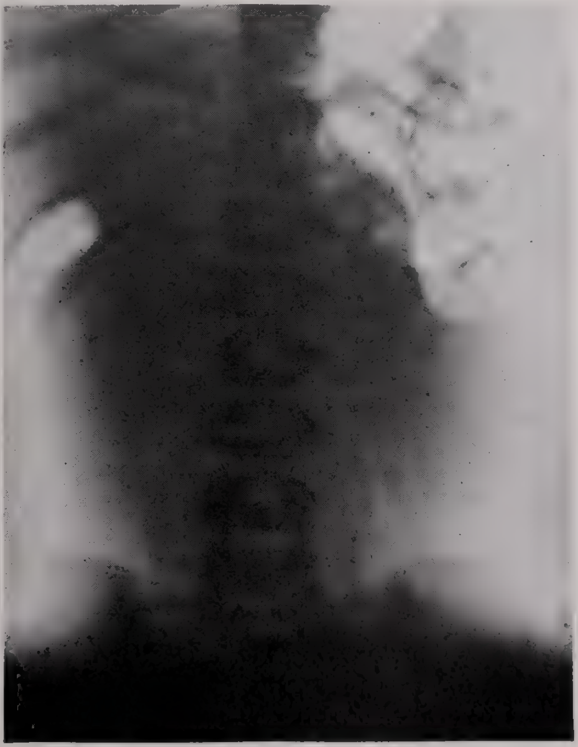

Figure 1

admission, associated with nausea and vomiting, the latter not relieving the distress. Past medical history revealed only chronic obstipation unrelieved by cathartics.

Physical examination revealed a seven-year-old girl acutely and chronically ill with a blood pressure of 110/80, a pulse rate of 98, and a temperature of 100.8. The positive physical findings, confined to the abdomen, showed moderate distention, marked pain on palpation in the right lower quadrant, with rebound but without rigidity. The bowel sounds were diminished. Rectal examination was normal.

Laboratory studies: Hgb 10.8 gm, WBC 11,900, differential showing 70% PMN, 26% lymphs, 3% monos and 1% eosinophils. Urinalysis—specific gravity 1.026, albumin 0, sugar 0, microscopic examination normal.

A chest film was read as negative (Figure 1). An x-ray photofluorogram of the abdomen revealed a large cystic mass in the right abdominal cavity with viscera compressed to the left side.

Treatment

On the evening of admission the patient underwent abdominal exploration via a large transverse abdominal incision inferior to the umbilicus. A large, 2400-gm mesenteric "clover leaf" cyst of the mid-ileum was observed, intimately associated with the bowel, and was removed with resection of 17 cm of ileum. An incidental appendectomy was also performed, along with an open end-to-end entero-enterostomy. The child made an uneventful recovery, being discharged on the fifth postoperative day.

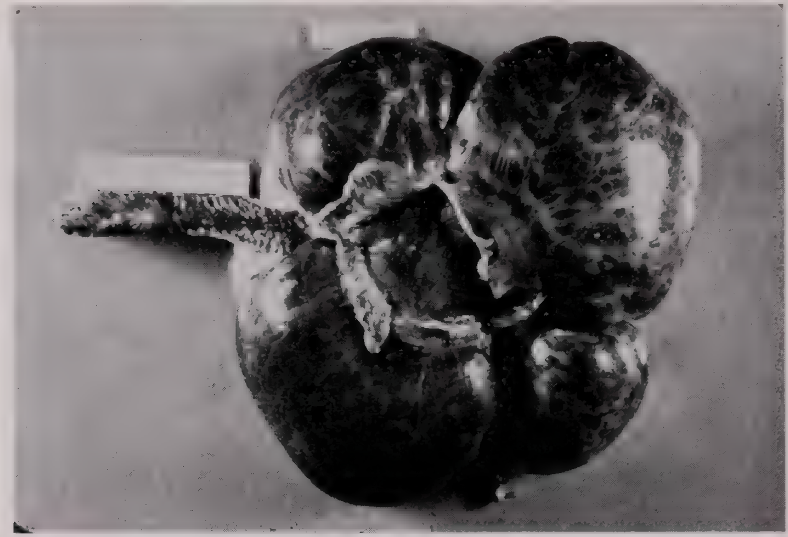

Figure 2

Pathology

A multiloculated cystic structure was present, located in the wall of the ileum, the locules intercommunicating with each other but not with the ileal lumen. Fluid content of the cystic structure revealed a hemoglobin concentration of 0.77 gm %, RBC 270,000/mm^3, WBC 2,300/mm^3 and a protein content of 3.5 gm %. The lining of the cystic structure had been destroyed and replaced by granulation and fibrous tissue with foci of cholesterol deposition and foreign-body reaction. Microscopically it could be demonstrated that the muscular wall of the adjacent uninvolved ileum had split, a portion continuing in the usual position in the segment of involved ileum, the outer half extending into and forming part of the wall of the cystic structure.

Discussion

Cysts of the mesentery are not rare lesions. In 1950 Beahrs reported approximately 600 such cases, with cystic lesions outnumbering solid ones by 2:1. The origin of mesenteric cysts still remains an enigma; but a classification from Lahey and Eikerson gives some indication as to the origin:

1. Wolffian cysts—remnants of the urogenital system
2. Lymphatic achylous cysts
3. Ectopic dermoid cysts
4. Mesocolic cysts—arising from rudiments of peritoneum
5. Parasitic or inflammatory cysts
6. Traumatic hemorrhagic cysts

One of the more comprehensive reviews of alimentary cysts by Kissane and Smith reveals these cysts to be most likely embryologically oriented. In reviewing the work of Lewis and Thyng, they noted that in the mammalian embryo of 4 mm to 23 mm the developing intestine has occasionally associated epithelial buds within the submucosa of the parent gut, which persist and may expand along the axis of the latter. The growth of the normal intestine at this time is so rapid that the common intestinal lumen to the "epithelial buds" may become focally occluded. When eventual vacuolization of the parent gut and the epithelial buds occurs, coalescence may not resume between the two future intestinal leaves; hence a persisting segment of vacuolated intestine or alimentary tract results.

One can readily see that most alimentary cysts may be explained by such mechanisms. The vast majority (76.0%) are seen in the intestine, most likely because of its greater length. In addition, because of the embryologic origin, the cysts may demonstrate any variety of duplication from complete segments of the alimentary tract to merely isolated multiloculated cysts that may, though usually do not, communicate with the parent bowel.

Complete surgical removal is axiomatic and, because of the degree of duplication that may be present, a complete search of the abdominal cavity for secondary cysts or "duplications" must be made during surgery.

Conclusion

A case of intestinal duplication in a seven-year-old girl has been presented. Excision of the cyst was performed for symptoms of acute right lower quadrant pain.

Things medical and gruesome have a singular attraction for many people.—William Osler

Help the Needy!

This patient may appear to "have everything" but, like so many people getting along in years, she may well be in need—*medically*. Though there is no evidence of organic disease, she does have symptoms (fatigue, vague aches and pains, malaise) that may be indicative of—

a need to maintain anabolic balance... to counteract declining gonadal hormone secretion and forestall premature degenerative changes related to estrogen deficiency;

a need for mood elevation... to impart a gentle emotional uplift;

a need for nutritional supplementation... to compensate for the poor eating habits and subsequent dietary insufficiency of so many older people.

For these needs, consider MEDIATRIC for your next "needy" patient... medically.

MEDIATRIC provides specific agents to fulfill a need in the three areas:

1. **Gonadal steroids** [PREMARIN® (conjugated estrogens-equine), an orally active, natural estrogen, and methyltestosterone] for physiologic and metabolic benefits.
2. **Methamphetamine** to provide gentle elevation of mood.
3. **Nutritional supplements** specially selected to meet the requirements of the elderly individual.

Mediatric®
tablets • capsules • liquid
Steroid-nutritional compound

	Each MEDIATRIC® Tablet or Capsule contains:	Each 15 cc. (3 teaspoonfuls) of MEDIATRIC® Liquid contains:
Conjugated estrogens-equine (PREMARIN®)	0.25 mg.	0.25 mg.
Methyltestosterone	2.5 mg.	2.5 mg.
Methamphetamine HCl	1.0 mg.	1.0 mg.
Cyanocobalamin	2.5 mcg.	1.5 mcg.
Intrinsic factor concentrate	8.0 mg.	–
Thiamine HCl	–	5.0 mg.
Thiamine mononitrate	10.0 mg.	–
Riboflavin	5.0 mg.	–
Niacinamide	50.0 mg.	–
Pyridoxine HCl	3.0 mg.	–
Calcium pantothenate	20.0 mg.	–
Ferrous sulfate exsic.	30.0 mg.	–
Ascorbic acid	100.0 mg.	–
		Contains 15% alcohol† † Some Loss Unavoidable.

Contraindication: Carcinoma of the prostate, due to methyltestosterone component.

Warning: Some patients with pernicious anemia may not respond to treatment with the Tablets or Capsules, nor is cessation of response predictable. Periodic examinations and laboratory studies of pernicious anemia patients are essential and recommended.

Side Effects: In addition to withdrawal bleeding, breast tenderness or hirsutism may occur.

Suggested Dosages: *Male and female*—1 Tablet or Capsule, or 3 teaspoonfuls Liquid, daily or as required.

In the female: To avoid continuous stimulation of breast and uterus, cyclic therapy is recommended (3 week regimen with 1 week rest period—Withdrawal bleeding may occur during this 1 week rest period).
In the male: A careful check should be made on the status of the prostate gland when therapy is given for protracted intervals.

Supplied: No. 752—MEDIATRIC Tablets, in bottles of 100 and 1,000.
No. 252—MEDIATRIC Capsules, in bottles of 30, 100, and 1,000.
No. 910—MEDIATRIC Liquid, in bottles of 16 fluidounces.

Advance

Sensitivity of Klebsiella, Enterobacter, and Escherichia Coli to Cephalothin

CEPHALOTHIN (7-(THIOPHENE-2-ACETAMIDO)CEPHALOSPORANIC ACID) is related to penicillin in structure and in antibacterial activity. It has also been found to be very active against strains of *Proteus mirabilis* but less active against strains of the *Klebsiella-Enterobacter** group and *Escherichia coli.*[2] Recent reports have suggested the existence of considerable variation in the sensitivity of *Klebsiella* and *Enterobacter* to this antibiotic.[3-6] A discrepancy between the recommended 30-μg disc diffusion method and the tube dilution test was noted in this laboratory in regard to the sensitivity to cephalothin of strains of *Klebsiella, Enterobacter,* and *E. coli.* The purpose of this study therefore was to determine the extent of the discrepancy by performing the two types of sensitivity tests in parallel and to explore some of the factors which might contribute to the discrepancy.

Materials and Methods

Organisms

Two-hundred-five organisms, comprising 80 strains of *Klebsiella* spp., 80 of *E. coli,* and 45 of *Enterobacter* spp. were examined. All were isolated from fresh clinical material (specimens of sputum, urine, and feces; nasal, throat, and wound swabs; and blood cultures). The strains were tested for purity and identified biochemically by the methods of Edwards and Ewing[7] as outlined for routine laboratory use by Douglas and associates.[8] No attempt was made to assign the strains of *Klebsiella* to species or to serotype the strains of *E. coli.* The *Enterobacter* strains were assigned to species according to the procedure described by Edwards and Ewing.[7] There were 28 strains of *Enterobacter cloacae,* 16 of *Enterobacter aerogenes,* and one strain not assigned. As a control, a strain of *Staphylococcus aureus* with a stable sensitivity to cephalothin (minimal inhibitory concentration, 0.19 μg/ml) was included.

Antibiotic

Powdered sodium cephalothin (Keflin)* was reconstituted with sterile distilled water, diluted with trypticase soy broth (TSB) to a concentration of 1,000 μg/ml, dispensed in aliquots of 2.3 ml, and frozen at −20 C. Prior to use, an aliquot was further diluted with trypticase soy broth to a concentration of 200 μg/ml and serially diluted twofold in trypticase soy broth. Cephalothin discs (30 μg) were obtained commercially.†

Media and Assay Methods

Tube dilution tests were performed by the method of Grove and Randall.[9] Serial twofold dilutions of antibiotic in 0.5 ml of trypticase soy broth were seeded with 0.5 ml of a 10^{-3} dilution of an overnight trypticase soy broth culture of the test strain. The final concentration of antibiotic ranged from 50 to 0.39 μg/ml. After overnight incubation at 37 C, the minimal inhibitory concentration (MIC) was recorded as that amount of antibiotic producing complete inhibition of macroscopically visible growth.

Disc diffusion tests were carried out by a modification of the method described by Ericsson.[10,11] A 150 by 25-mm plastic Petri dish containing 40 ml of Mueller-Hinton (MH) agar was flooded with 4 ml of a 10^{-3} broth dilution of an overnight broth culture of the test strain. The plate was tilted and excess fluid was aspirated. Three cephalothin discs were spaced equidistantly on the plate and the antibiotic was allowed to prediffuse into the agar at room temperature for 30 minutes. The plates were then incubated at 37 C for 18 hours. The resulting zones of inhibition were measured with a pair of sliding calipers and the average of the three zones was recorded. If the difference between the three zone diameters on a single plate was greater than 2.0 mm, the test was considered to be inaccurate and was repeated.

---

*Formerly called Aerobacter and now designated as Enterobacter according to nomenclature proposed by Ewing.[1]

*Eli Lilly and Company, Indianapolis.

†Baltimore Biological Laboratories, Baltimore.

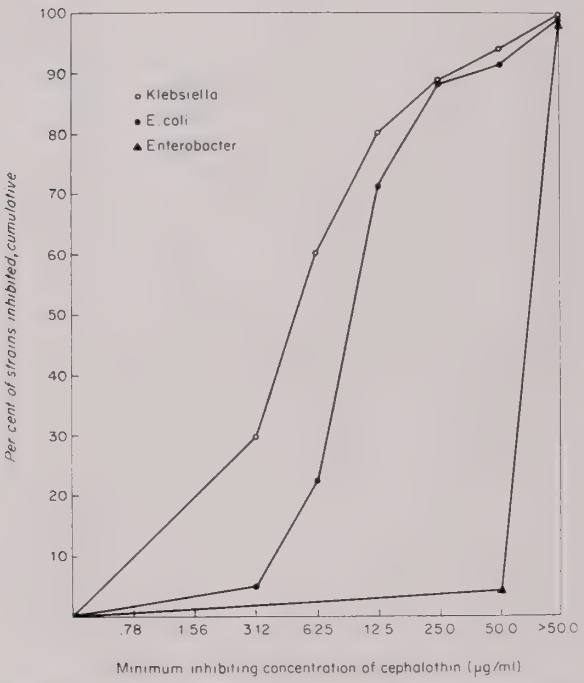

Fig. 1—Susceptibility of *Klebsiella, Enterobacter,* and *E. coli* strains to cephalothin (cumulative plot).

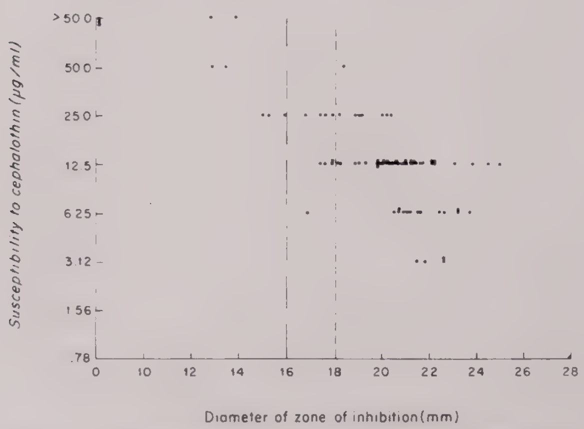

Fig. 2—Correlation of results of 30-µg disc and tube dilution sensitivity tests of 80 strains of *Klebsiella* tested against cephalothin.

To investigate the influence of different media on zone size, five *Klebsiella* spp. and six *E. coli* strains were chosen at random, and both the tube dilution and disc diffusion tests were repeated using three different media. Trypticase soy agar (TSA), trypticase soy agar with 5% rabbit blood (RBA), and Mueller-Hinton agar were used for the disc diffusion tests. Tryptose phosphate broth (TPO_4)*, trypticase soy broth, and Mueller-Hinton broth were used for the tube dilution tests. Readings were made at six, 12, and 20 hours during incubation at 37 C. Disc sensitivity tests were read at 18 hours.

Results

All 45 strains of *Enterobacter* had a minimal inhibitory concentration of 50 µg/ml or greater by the tube dilution method (Figure 1). However, seven strains exhibited zones of inhibition of 16 mm or greater, which is said to represent the minimal diameter for determination of sensitivity. These seven strains included two of *Enterobacter cloacae,* four of *Enterobacter aerogenes* and the one *Enterobacter* strain not assigned. Three strains of *Enterobacter aerogenes* had zones of inhibition of 11, 12, and 14 mm, respectively. The rest showed no inhibition.

For 64 (80%) of the 80 strains of *Klebsiella,* minimal inhibitory concentration was 12.5 µg/ml or less; for only nine (12%) was it 50 µg/ml or greater by the tube dilution method (Figure 1). With the 30-µg discs, 75 (94%) of the 80 strains exhibited zones of inhibition (of at least 16 mm), including seven strains with minimal inhibitory concentration = 25.0 µg/ml, three strains with minimal inhibitory concentration = 50.0 µg/ml, and one strain with minimal inhibitory concentration > 50.0 µg/ml (Figure 2).

For 59 (74%) of the 80 strains of *E. coli,* minimal inhibitory concentration was 12.5 µg/ml or less by the tube dilution method (Figure 1). With the 30-µg disc, 71 (89%) of the 80 strains exhibited zones of inhibition of at least 16 mm, including 11 strains with minimal inhibitory concentration = 25 µg/ml and 1 strain with minimal inhibitory concentration = 50 µg/ml (Figure 3).

---

*Difco, Detroit.

No difference in minimal inhibitory concentration related to composition of the medium employed in the tube dilution test was noted (Table 1). The "skipped tube phenomenon" described by Benner and associates[3] was noted with *Klebsiella* strain no. 899 in that at 12 hours there was growth in the tube with 6.25 µg/ml but not in the tubes with 3.12 or 12.5 µg/ml.

In disc sensitivity testing, use of 10^{-1} dilution resulted (not unexpectedly) in smaller zone diameters than with the 10^{-3} dilution (Ta-

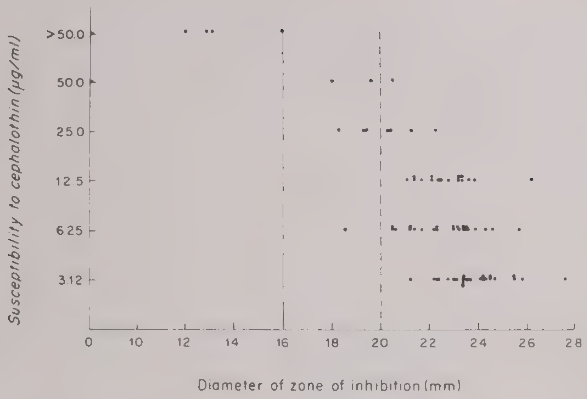

Fig. 3—Correlation of results of 30-µg disc and tube dilution sensitivity tests of 80 strains of *E. coli* tested against cephalothin.

*MH = Mueller-Hinton agar; TSA = trypticase soy agar; RBA = trypticase soy agar with 5% rabbit blood. †Small colonies in zone. ‡R = Resistant (zone diameter <10 mm).

ble 2). In addition, with the 10^{-3} dilution, no differences were noted between zone diameters on the three media used in the disc test (Table 2).

Discussion

The reported sensitivity of gram-negative bacilli to cephalothin has ranged from 3.12 to 25 μg/ml.[2,12] A clinically useful level of sensitivity is one which is readily attainable in serum and body fluids with the usually recommended doses of the drug. This level is approximately 10.0 to 12.5 μg/ml one-half hour after a 0.5-gm intramuscular dose,[2,6,13] although urinary concentrations of the drug are considerably higher than those attainable in the serum.[6] With 12.5 μg/ml or less as the criterion for sensitivity in this study, 80% of *Klebsiella* strains were sensitive, but all of the *Enterobacter* strains were resistant. These findings are consistent with those of other studies.[3-5] This marked generic difference has been ascribed to cephalosporinase production by *Enterobacter*.[3] With this same criterion, 74% of the *E. coli* strains tested were sensitive.

Although the manufacturer of the antibiotic states that any zone of inhibition around the cephalothin disc indicates susceptibility of the organism and that the zone will probably be at least nine to 10 mm in diameter,[14] our data demonstrate that, for the three groups of organisms studied, this statement is not consistent with results of parallel tube dilution tests. Bauer and associates, as quoted by Lorian,[15] defined 16 mm or greater as the tentative standard zone size for indication of sensitivity of microorganisms to cephalothins. Application of this criterion to these results would have classified 94% of the *Klebsiella* strains, 89% of the *E. coli* strains, and 16% of the *Enterobacter* strains as being sensitive, and all strains considered to be resistant by the disc diffusion method were also resistant by the tube dilution technique. Increasing the minimal zone diameter for definition of sensitivity to 20 mm in the case of *Klebsiella* (Figure 2) would have decreased the number of strains falsely judged to be sensitive by the disc diffusion method from 11 (14%) to five (6%).

On the other hand, by using this higher criterion of sensitivity, one strain considered to be sensitive by the tube dilution method would have become resistant in the disc diffusion test.

A similar 20-mm criterion for *Enterobacter* would have eliminated all the false-positive results (strains sensitive by the disc diffusion method but resistant by the tube dilution method) and would have given no false-negative results (strains sensitive by the tube dilution method but resistant by the disc diffusion method). In the case of *E. coli* (Figure 3), 11 strains (15%) were considered to be sensitive by the disc diffusion method and resistant by the tube dilution method. Increasing the minimal zone diameter for definition of sensitivity to 18 mm would have decreased this number of false-positive results to eight strains (10%); however, five strains sensitive in the tube dilution test would have become resistant in the disc diffusion test.

There thus appears to be no useful agreement between the disc diffusion and tube dilution methods for testing sensitivity of *Klebsiella* spp. and *E. coli* to cephalothin, because use of the recommended 16-mm zone of inhibition yields a significant number of false-positive interpretations and the use of a larger zone diameter yields a significant number of false-negative interpretations. With *Enterobacter* spp., false-positive results were eliminated by increasing the minimal zone size to 20 mm.

Agreement between the tube dilution and disc diffusion tests was not changed by altering the medium used in either test. Although the disc diffusion method is widely used and is simpler to perform than the tube dilution method, the results obtained by the former method may be affected by the depth of the agar,[16] method of inoculation,[17] prediffusion time,[18] variation in amount of antibiotic present in individual discs,[10] and molecular weight of the antibiotic. The tube dilution technique remains the more reliable and more accurate method, provided it is properly controlled,[9] and is therefore the criterion against which the disc diffusion method should be evaluated. This study strongly suggests that, with patients in whom *E. coli*, *Klebsiella* spp. or *Enterobacter* spp. are of particular clinical significance, sensitivity tests should be performed by the tube dilution method.

"The inconvenience of a cold"

For a cold, NTz® Nasal Spray provides rapid relief of nasal symptoms. Relief starts with the first spray which opens the inferior part of the common meatus. A second spray, a few minutes later, will shrink the turbinates to help provide sinus drainage and ventilation. Dosage may be repeated every three or four hours as needed, for temporary relief of symptoms. NTz is well tolerated but overdosage should be avoided.

As a sinusitis deterrent, NTz Nasal Spray can be used to keep the nasal passages open during a cold to help prevent development of acute sinusitis—or to help prevent the acute condition from becoming chronic.

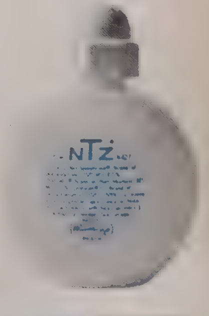
Supplied: NTz Nasal Spray, plastic squeeze bottles of 20 ml.; NTz Nasal Solution, bottles of 30 ml. (1 fl. oz.) with dropper.

NTz is more than a simple vasoconstrictor. It contains

Neo-Synephrine® (brand of phenylephrine) HCl 0.5 per cent, the major component, virtually synonymous with fast, efficient but gentle nasal vasoconstriction.

Thenfadil® (brand of thenyldiamine) HCl 0.1 per cent, topical antihistamine for reduction of rhinorrhea, sneezing or itching. It combats the allergic reactions that may occur in colds or sinusitis.

Zephiran® (brand of benzalkonium, as chloride, refined) 1:5000, antiseptic preservative and wetting agent to promote penetration and spread of the formula.



Winthrop Laboratories, New York, N.Y. 10016 Winthrop

nxiety is expected in the cardiovascular patient. little may even be desirable.

ut when anxiety is exaggerated . . . when it nterferes with sleep . . . when it aggravates ardiovascular symptoms, your help may e needed.

aturally, you'll want to reassure the patient.

nd perhaps prescribe Equanil (meprobamate) s adjunctive therapy. It helps relieve anxiety nd tension specifically, yet gently.

lmost 15 years' use has shown that Equanil s usually well tolerated as well as effective. ide effects are generally limited to transient rowsiness; serious, therapy-interrupting ide effects are rare.

Contraindications: History of sensitivity to meprobamate.

Important Precautions: Carefully supervise dose and amounts prescribed, especially for patients prone to overdose themselves. Excessive prolonged use has been reported to result in dependence or habituation in susceptible persons, as alcoholics, ex-addicts, and other severe psychoneurotics. After prolonged excessive dosage, reduce dosage gradually to avoid possibly severe withdrawal reactions. Abrupt discontinuance of excessive doses has sometimes resulted in epileptiform seizures.

Warn patients of possible reduced alcohol tolerance, with resultant slowing of reaction time and impairment of judgment and coordination.

Reduce dose if drowsiness, ataxia or visual disturbance occurs; if persistent, patients should not operate vehicles or dangerous machinery.

Side Effects include drowsiness, usually transient; if persistent and associated with ataxia, usually responds to dose reduction; occasionally concomitant CNS stimulants (amphetamine, mephentermine sulfate) are desirable. Allergic or idiosyncratic reactions are rare, but such reactions, sometimes severe, can develop in patients receiving only 1 to 4 doses who have had no previous contact with meprobamate. Previous history of allergy may or may not be related to incidence of reactions. Mild reactions are characterized by itchy urticarial or erythematous maculopapular rash, generalized or confined to groin. Acute nonthrombocytopenic purpura with cutaneous petechiae, ecchymoses, peripheral edema and fever have been reported. One fatal case of bullous dermatitis following intermittent use of meprobamate with prednisolone has been reported. If allergic reaction occurs, meprobamate should be stopped and not reinstituted. Severe reactions, observed very rarely, include angioneurotic edema, bronchial spasms, fever, fainting spells, hypotensive crises (1 fatal case), anaphylaxis, stomatitis and proctitis (1 case) and hyperthermia. Treat symptomatically as with epinephrine, antihistamine and possibly hydrocortisone. Aplastic anemia (1 fatal case), thrombocytopenic purpura, agranulocytosis and hemolytic anemia have occurred rarely, almost always in presence of known toxic agents. A few cases of leukopenia, usually transient, have been reported on continuous administration.

Meprobamate may sometimes precipitate grand mal attacks in patients susceptible to both grand and petit mal. Extremely large doses can produce rhythmic fast activity in the cortical pattern. Impairment of accommodation and visual acuity has been reported rarely. After excessive dosage for weeks or months, withdraw gradually (1 or 2 weeks) to avoid recurrence of pretreatment symptoms (insomnia, severe anxiety, anorexia). Abrupt discontinuance of excessive doses has sometimes resulted in vomiting, ataxia, tremors, muscle twitching and epileptiform seizures. Prescribe very cautiously and in small amounts for patients with suicidal tendencies. Suicidal attempts have resulted in coma, shock, vasomotor and respiratory collapse and anuria. Excessive doses have resulted in prompt sleep; reduction of blood pressure, pulse and respiratory rates to basal levels; and occasionally hyperventilation. Treat with immediate gastric lavage and appropriate symptomatic therapy. (CNS stimulants and pressor amines as indicated.) Doses above 2400 mg./day are not recommended.

Composition: Tablets, 200 mg. and 400 mg. meprobamate. Coated Tablets, WYSEALS® EQUANIL (meprobamate) 400 mg. (All tablets also available in REDIPAK® [strip pack], Wyeth.) Continuous-Release Capsules, EQUANIL L-A (meprobamate) 400 mg.

Wyeth Laboratories Philadelphia, Pa.

Equanil®

(meprobamate) Wyeth ®

The two-stage power of the pink pill for U.R.I. symptoms is nothing to be sneezed at.

The immediate and continuous-release actions built into each Novahistine Singlet can give most of your patients prompt and long-lasting relief from symptoms of upper respiratory infection, including fever, aches and pains.

Not only does Novahistine Singlet provide a vasoconstrictor-antihistamine formulation to reduce congestion and help restore normal ciliary activity; it also contains an antipyretic-analgesic compound to relieve the fever, aches and pains that so frequently accompany upper respiratory infections.

A total daily dosage of 3 or 4 tablets will normally provide the continuous relief your patient expects. Use with caution in patients with severe hypertension, diabetes mellitus, hyperthyroidism or urinary retention. Caution ambulatory patients that drowsiness may result.

Pitman-Moore Division of
The Dow Chemical Company,
Indianapolis, Indiana.

Novahistine® Singlet decongestant-analgesic

(Each tablet contains: phenylephrine hydrochloride, 40 mg.; chlorpheniramine maleate, 8 mg.; acetaminophen, 500 mg.)

Clinical Path Conference

Acute Abdominal Emergency after Gastrectomy

Robert L. Strom, M.D.:*

Case Report

A 59-year-old chronic alcoholic male was admitted to Hennepin County General Hospital on December 27, 1967, because of a long history of epigastric pain and a pre-pyloric gastric ulcer demonstrated by x-ray. He had refrained from drinking alcoholic beverages for three years; however, the pain had recently become constant and was no longer relieved by food or antacids. There was no bleeding history.

The patient had mild, mature onset diabetes mellitus which was well controlled with Orinase. His physical examination was essentially normal except for obesity and a liver which was palpable 4 cm. below the right costal margin.

Gastric x-rays and gastroscopy revealed a pre-pyloric gastric ulcer and a small hiatus hernia. Preoperative studies included a 12-hour gastric specimen of 350 ml. containing 54 mEq of free acid per liter. The gastric fluid pH was less than 4.5. After four weeks of intensive medical management failed to improve the symptoms or the x-ray picture, surgical management was felt advisable.

Exploratory

On February 7, 1968, the patient underwent exploration through a bilateral subcostal incision. Operative findings included gallstones, diverticulosis of the colon, duodenal and antral scarring and a hiatus hernia. A vagotomy was performed; definite anterior and posterior vagal trunks were identified and confirmed by frozen sections. The crurae of the diaphragm were closed behind the esophagus and the gastroesophageal angle was reconstructed by suturing the fundus of the stomach to the esophagus anteriorly and posteriorly. A 50% gastrectomy was performed with a retrocolic Billroth II type reconstruction and a short afferent loop. The rent in the mesocolon through which the loop of jejunum passed was tacked to the jejunum with interrupted sutures. A cholecystectomy was performed and the abdomen was closed. Anatomic function was demonstrated by gastrointestinal x-rays and is illustrated in Figure 1.

Discharged

On the second postoperative day the patient developed auricular fibrillation with tachycardia and hypotension which reverted to sinus rhythm with aramine, digitalis and quinidine therapy. Although urine output remained within normal limits, the BUN was elevated one week postoperatively to 76 mg.% and the creatinine rose to 4.8 mg.%. Dehydration secondary to renal tubular injury was suggested by a renology consultation. The patient responded well to rehydration, and urine output ranged from 2500 ml. to 5500 ml. per day. He was discharged on March 13, 1968, on Diabinase and ferrous gluconate.

---

*Associate Pathologist, Hennepin County General Hospital.

Readmitted

The patient did well until June 14, 1968, when he was readmitted to the surgical service after awakening with severe epigastric pain. He ate breakfast and then came to the Emergency Room where he was noted to be pale and clammy. On admission at 11 a.m. his blood pressure was 60 systolic, his pulse 120 per minute and thready, his temperature 96.4° F. The abdomen was distended, with tenderness most marked in the upper quadrants. Bowel sounds were hypoactive and then became absent within one hour. Peripheral pulses were present and no abdominal masses were palpable. A chest x-ray was normal. A flat and upright film of the abdomen showed a vague collection of fluid centrally which was considered both intraluminal and extraluminal (Figure 2).

Laboratory studies included a hemoglobin of 15.6 gm.%, a white blood cell count of 28,500 per cu. mm., and the following serum electrolytes: sodium 137 mEq/L, potassium 4.0 mEq/L, chloride 101 mEq/L, CO_2 16 mEq/L. Total serum proteins were 7.7 gm.% with albumin 4.2 gm.%. A serum calcium was 10.8 mg.% and the SGOT was 70 units. A BUN was 25 mg.% and a blood glucose measured 340 mg.%. Liver function studies included a total bilirubin of 1.1 mg.% and alkaline phosphatase of 12 KA units. The plasma amylase was 1300 Somogyi units.

A short time after admission the patient stopped breathing and was intubated and placed on assisted respiration. Little or no urine output was noted after admission in spite of fluid,

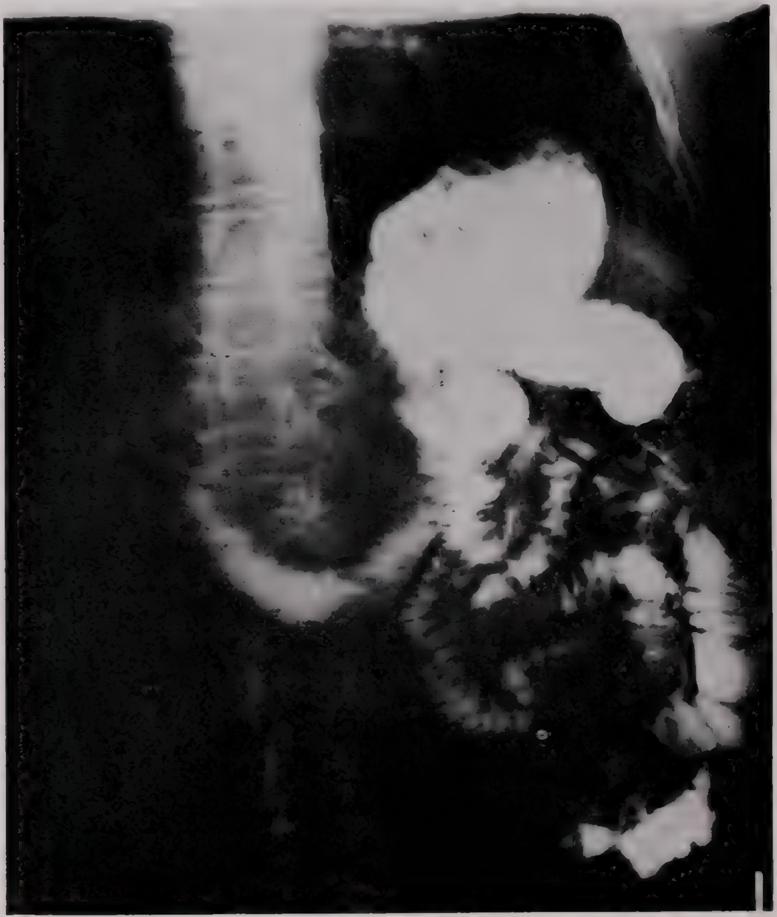

Fig. 1—Gastrointestinal x-rays during the postoperative period revealing functional retrocolic anastomosis and Billroth II gastrectomy.

plasma and blood infusions. His blood pressure was unstable with peaks of 120 mm. Hg. systolic and valleys to 80 to 90 systolic. He remained essentially anuric. Early the following day increasing abdominal distention in the presence of nasogastric suction necessitated tracheotomy and peritoneal drainage with a dialysis cannula. The peritoneal fluid was blood-tinged with an amylase of 1,050 units, and gram-negative rods were present on gram smear. Enterobacter species was cultured from the peritoneal fluid. The patient suffered a cardiac arrest and after temporary resuscitation was pronounced dead at 11 a. m. on June 15, 1968. An autopsy was performed.

Discussion

William G. Gamble, M.D.:*

We are presented with a case of a 59-year-old male, a chronic alcoholic, who succumbed of an acute abdominal process within 24 hours after admission to the hospital. Interestingly enough, this occurred four months after vagotomy and hemigastrectomy for presumed benign peptic ulcer disease.

I will begin my discussion by considering the terminal illness and reflect on the history of his preceding hospitalization, only as it is pertinently related.

I would like to discuss the differential diagnosis with specific regard to the markedly and consistently elevated serum and peritoneal fluid amylase levels. These data need to be explained in reference to the acute illness. I am not implying that one can disregard the other historical and clinical data, for these need to be closely correlated.

---

*Staff Surgeon, St. Louis Park Medical Center and Attending Surgeon, Hennepin County General Hospital.

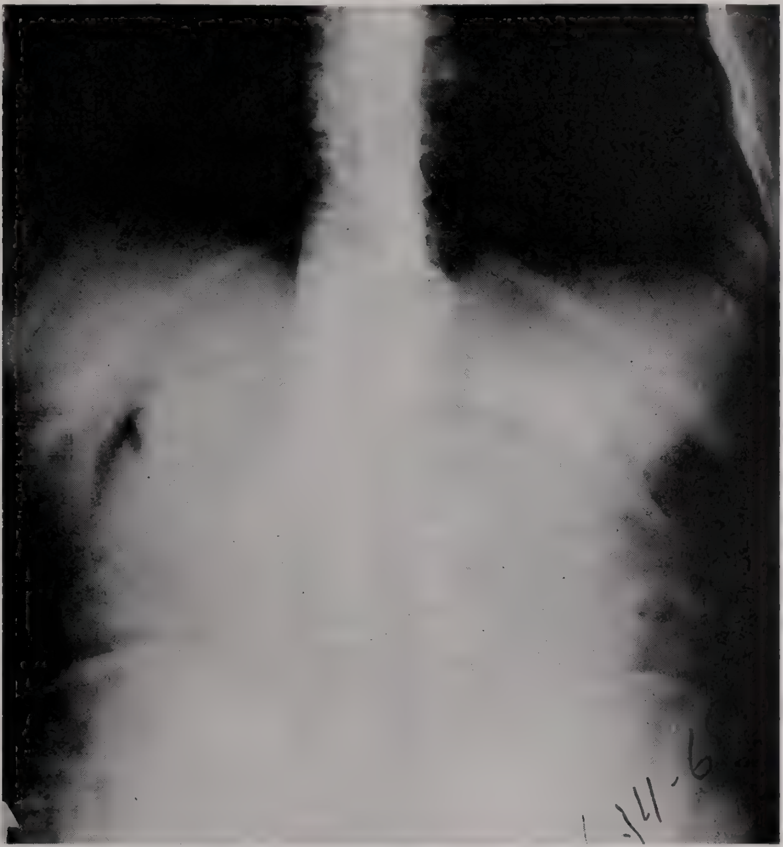

Fig. 2—Flat plate of abdomen with evidence of abdominal fluid and gas in colon.

The serum amylase determination probably represents the single most important laboratory aid in the diagnosis of acute edematous pancreatitis and acute hemorrhagic pancreatitis. Although serum amylase elevations are rather consistent in acute pancreatitis, the value of this test is limited by the fact that elevations may often occur in a variety of other acute intra-abdominal disorders. Significant elevations may also be observed in parotitis, acute renal insufficiency, and subsequent to the administration of opiates. Acute abdominal conditions, other than pancreatitis, associated with elevations in the serum amylase are pancreatic pseudocysts, acute cholecystitis, impacted ampullary calculus, perforated ulcer, strangulated intestinal obstruction, mesenteric thrombosis and acute afferent loop obstruction.

Hemorrhagic Pancreatitis

Acute hemorrhagic pancreatitis immediately comes to mind in this case because of the marked elevation of serum amylase and the presence of bloody peritoneal fluid, rich in amylase. The rapid demise of this patient with associated profound shock is compatible with fulminating acute hemorrhagic pancreatitis.

Although the specific cause of this disease is unknown, it is most commonly related to chronic alcoholism and biliary tract disease. One wonders why this patient did not develop this disease earlier since we are told he was a confirmed chronic alcoholic. If we are to believe the history, however, he had abstained from drinking alcoholic beverages for several years. Biliary tract disease would not seem to be related, because an incidental cholecystectomy was performed at his previous surgery and no mention was made of common bile duct pathology.

Postoperative pancreatitis is another consideration since this most often occurs following gastric or biliary surgery. This condition is thought to be due to operative injury of the duct of Santorini, especially in instances where this duct represents the major source of pancreatic drainage. Leakage of pancreatic secretions from an injured duct has also been implicated. But I believe this diagnosis can be ruled out on the basis of the time interval involved. This condition characteristically occurs in the early postoperative period; in fact, this feature serves to distinguish it from other postoperative complications such as leakage from the duodenal stump.

Pancreatic Pseudocyst

Pseudocyst of the pancreas is usually associated with persistent elevations of the serum amylase. This condition is a complication of idiopathic or traumatic pancreatitis and is preceded by clinical evidence of acute pancreatic disease. The absence of any prodromal illness in this case, I believe, effectively rules out this diagnosis.

Perforated Ulcer

Perforated peptic ulcer (usually duodenal) may be associated with marked elevations of serum amylase. This is thought to be due to leakage of pancreatic enzymes with rapid absorption by the inflamed peritoneal surfaces. In this case, the ulcer would have had to be of the marginal variety. Marginal ulcer occurring two months after definitive gastric surgery is distinctly uncommon in the absence of hypersecretion secondary to non-beta islet cell lesions of the pancreas (Zollinger-Ellison syndrome). The preoperative gastric secretory studies do not indicate hypersecretion of the magnitude seen in this condition. One also would not expect the peritoneal fluid to be blood-tinged, as it was in this case. The peritoneal fluid associated with perforations of the upper gastrointestinal tract is cloudy serous fluid and not serosanguineous.

Ampullary Calculus

High levels of serum amylase may be observed in patients with calculus obstruction of the common bile duct. This may or may not be associated with pancreatitis. It is explained by the "common channel theory" with regurgitation of pancreatic enzymes into the blood stream secondary to obstruction of the duct of Wirsung. Patients with this condition demonstrate chemical and/or clinical hyperbilirubinemia. One would also expect that there would have been prodromal symptoms.

Mesenteric Vascular Occlusion

Some of the highest serum and peritoneal fluid amylase values are seen in patients with infarction of the proximal small bowel secondary to transudation of pancreatic enzymes through the injured bowel wall.

Mesenteric vascular occlusion may result from thrombosis of the superior mesenteric artery secondary to atherosclerosis. Patients with this condition are usually older than our patient and generally have evidence of atherosclerosis elsewhere. Embolization involving the superior mesenteric artery may also produce this lesion, which usually occurs in patients with arteriosclerotic or valvular heart disease and cardiac arrhythmias. Although we are told that our patient developed atrial fibrillation during his previous postoperative course, he converted to sinus rhythm and did not revert to fibrillation.

Mesenteric venous thrombosis, either idiopathic or secondary to other intra-abdominal pathology, may also be implicated. Idiopathic mesenteric venous thrombosis is most often associated with evidence of other thromboembolic phenomena, but such history is absent in this case.

Finally, the mode of onset and the clinical course of patients with this condition are more gradual. Demise does not usually occur for twenty-four to forty-eight hours. Patients do not become moribund within a few hours, as this patient did.

Strangulation Obstruction

Strangulation obstruction, especially that involving the proximal small bowel, may result in marked elevations of serum and peritoneal fluid enzyme levels. The mechanism again is transudation of these enzymes through the injured bowel wall.

Strangulation obstruction is usually secondary to volvulus or internal herniation of the small bowel. Volvulus may occur around any fixed point within the peritoneal cavity, particularly in patients who have adhesions from previous abdominal surgery. Internal hernias may occur after gastric surgery and are particularly prone to follow anticolic anastomoses. The small bowel may herniate from left to right or right to left behind a long afferent loop. This may also occur posterior to the anastomosis following a retrocolic gastrojejunostomy, particularly if the gastric remnant is brought well below the mesocolon to allow space for herniation.

In this specific case we are told that the anastomosis was performed above the mesocolon and that the loop of jejunum used was sutured to the defect in the mesocolon. If the anastomosis was not done immediately at the ligament of Treitz with a maximally short afferent loop, there could have been a space behind the afferent and efferent loops to allow for internal herniation. An internal herniation of this type could certainly explain the entire clinical picture in this case and remains an excellent possibility. Although I cannot completely rule this out, I favor another diagnosis.

Afferent Loop Obstruction

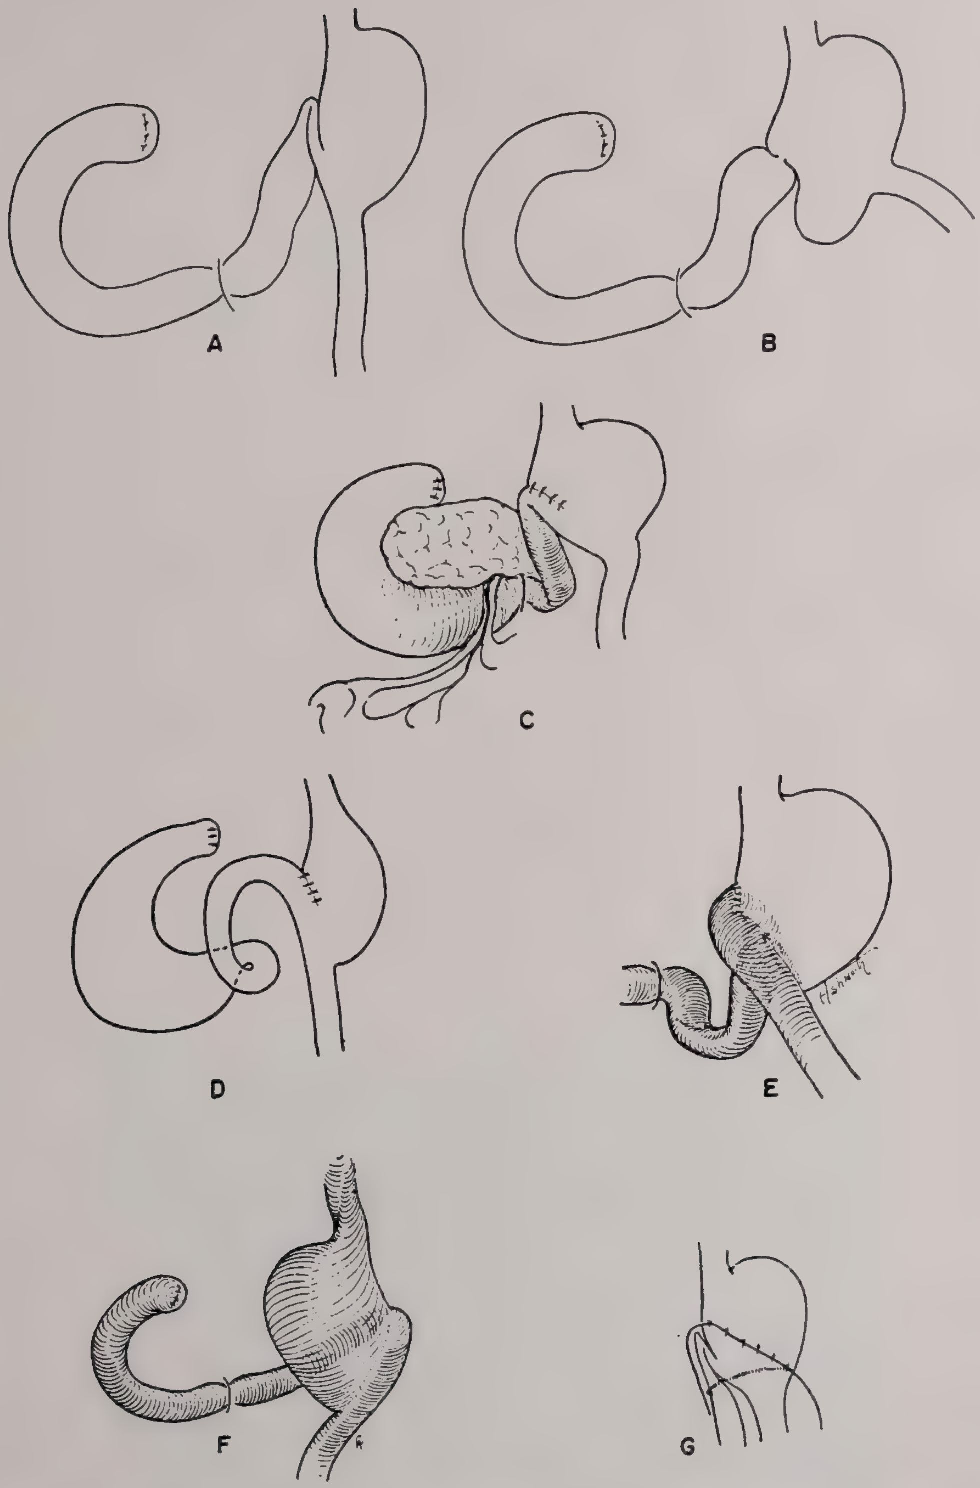
The afferent loop syndrome actually consists of a group of conditions involving malfunction of the afferent loop which are frequently not clearly separated from the numerous conditions considered under the term "postgastrectomy syndrome." Afferent loop problems have been recognized since the first gastroenterostomy was performed by Wölfler in 1881. Just four years later, in 1885, Von Hacker devised the retrocolic anastomosis in hope of circumventing some of the problems that occurred with redundant anticolic afferent loops.

The major pathologic feature of the afferent loop syndrome is obstruction or stasis which may be produced by a number of mechanisms, such as kinking at the anastomosis due to tension, volvulus of a long anticolic loop, compression of an anticolic loop by colon or omentum, and mesocolic obstruction of a retrocolic loop brought through the mesocolon. Some of the mechanisms are illustrated in Figure 3.

The afferent loop syndrome may be acute or chronic, depending on the degree of obstruction. The chronic form is seen with partial obstruction and results in symptoms of fullness, right upper quadrant pain and, most characteristically, bilious vomiting fifteen to thirty minutes following meals. The acute form, which may occur immediately postoperatively or later in the postoperative course, is due to acute afferent loop obstruction and is essentially a closed loop obstruction. It is this form that I would like to discuss further since I believe it may well be pertinent.

The mechanism of afferent loop obstruction in this case would most likely be due to mesocolic compression of the afferent loop. I presume that fixation of the gastroesophagel junction combined with 50-percent gastric resection prevented infracolic placement of the anastomosis in this obese individual. This mechanism has been implicated in similar cases and has occurred at approximately this same postoperative time interval. In fact, an almost identical case was reported from this institution in 1958 by Thal and Perry.[4] The history in this case is compatible with such a condition, particularly the fact that the patient's pain was present on awakening and was not post-cibal. It is believed that the afferent loop may become obstructed due to positional changes; in fact some patients with a less acute form of this condition find that they can avert symptoms by sleeping in various positions, usually on the left side. It would be important to know if the patient vomited, and if so, whether or not the emesis contained bile. It would also be important to know if the nasogastric tube returned bile-stained contents. The abdominal distention and tenderness localized in the upper quadrants would be compatible with this diagnosis. The x-rays which demonstrate a central fluid density and absence of bowel gas are absolutely characteristic of this condition.

The marked elevations of serum and peritoneal fluid amylase in this condition are typical, and there are two possible explanations for this. The



(Figure appeared on page 112 of Gastric Surgery by M. E. Steinberg published by Appleton-Century-Crofts of New York City and published herein with permission.)

pressure in the obstructed loop may have exceeded the secretory pressure in the pancreas; simple obstruction of the pancreatic duct may produce extreme elevations in serum amylase in the complete absence of pancreatitis. This has been demonstrated in the experimental animal and the human.[2,3] Secondly, pancreatic enzymes may have entered the peritoneal cavity by crossing the abnormally permeable gangrenous duodenal wall; the serosanguinous character of the peritoneal fluid, rich in amylase, would be considered typical.

In summary, the serum amylase concentration may prove to be a helpful adjunct in the clinical evaluation of patients with acute abdominal disease. Although elevations of the serum amylase in patients with abdominal pain generally imply a degree of pancreatitis, this may not always be the case. Blind reliance on this laboratory value may prove fatal. A recent study showed that the serum amylase level tended to be inversely related to the severity of pancreatic disease.[1] In fact, when the amylase level was over 1,000 Somogyi units there was usually a surgically correctable lesion. Interpretation of these laboratory data in the light of the total clinical picture will serve to select some cases with surgically remediable lesions.

Furthermore, I believe that the pancreas might well have been grossly and histologically normal at postmortem examination.

Final Clinical Diagnoses:

1. Acute obstruction of the afferent loop with gangrene and secondary massive generalized peritonitis
2. Possible strangulation obstruction secondary to internal herniation of the small bowel
3. Probable gram-negative septicemic shock

Pathology

Doctor Strom:

On postmortem examination, the major findings were limited to the abdomen. Approximately 800 cc. of bloody, foul-smelling fluid was present. The greater omentum was adherent to strangulated gas-filled loops of small bowel and colon.

A Billroth II type anastomosis was present in the left upper quadrant,

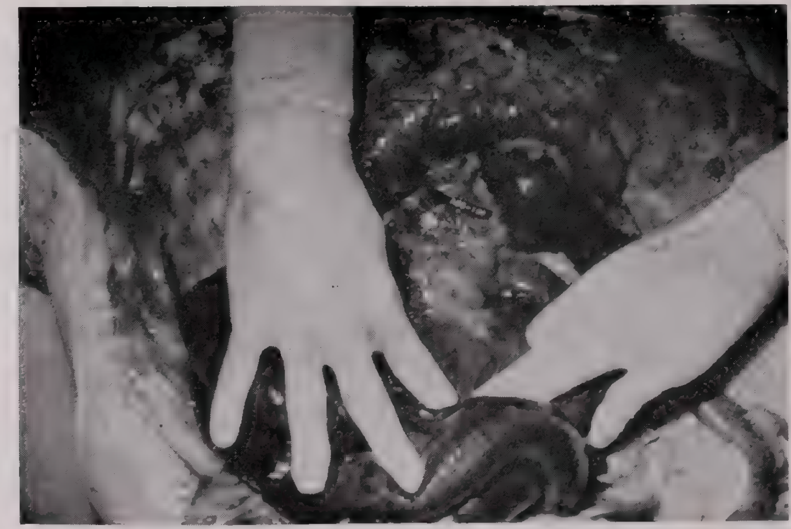


Fig. 4—The proximal loop of the anastomosis acting as an obstructing band overlying the body of the pancreas and occluding the root of the mesentery and superior mesenteric artery.

and the gastrojejunostomy was patent. The transverse mesocolon was securely in place around the proximal and distal loop of the anastomosis, and 500 cc. of clotted whole blood was present in the stomach. There was no evidence of peptic ulceration.

The most notable abdominal finding was a herniation of the distal loop of the anastomosis above the ligament of Treitz and under the transverse mesocolon. The proximal loop of the anastomosis then acted as an obstructing band overlying the body of the pancreas and occluding the root of the mesentery and superior mesenteric artery (Figure 4). The entire small bowel, right colon and transverse colon were involved in a process of hemorrhagic infarction and strangulation consistent with the distribution of the superior mesenteric artery (Figure 5). The loops of small and large bowel were blood-filled, and the devitalized bowel made the largest contribution to the plasma amylase level.

The pancreatic findings were of particular interest. The head of the pancreas was edematous and showed bilious discoloration. Focal hemorrhagic necrosis of the body of the pancreas was present under the occluded superior mesenteric artery although the tail of the pancreas was spared and changes of acute pancreatitis were minimal. The duodenal loop was dilated and showed some violet discoloration; the duodenal stump was adherent to the undersurface of the liver. There appeared to be some element of an afferent loop obstruction present.

Considerable pulmonary atelectasis and edema were present as well as bilateral hydrothorax. Focal infarction of the hepatic tissue and mild fatty metamorphosis were notable on microscopic examination of the liver. The renal cortices were pale and showed evidence of acute evolving tubular necrosis.

Serum Amylase Levels

Burnett and Ness[5] studied serum amylase levels in a series of 350 patients admitted to the hospital with acute abdominal pain. There were twelve cases of acute pancreatitis: an incidence of 3.4%; the serum amylase levels in these 12 cases varied between 1200 to 6000 Somogyi units. Burnett and Ness felt that the serum amylase level was useful in differentiating acute

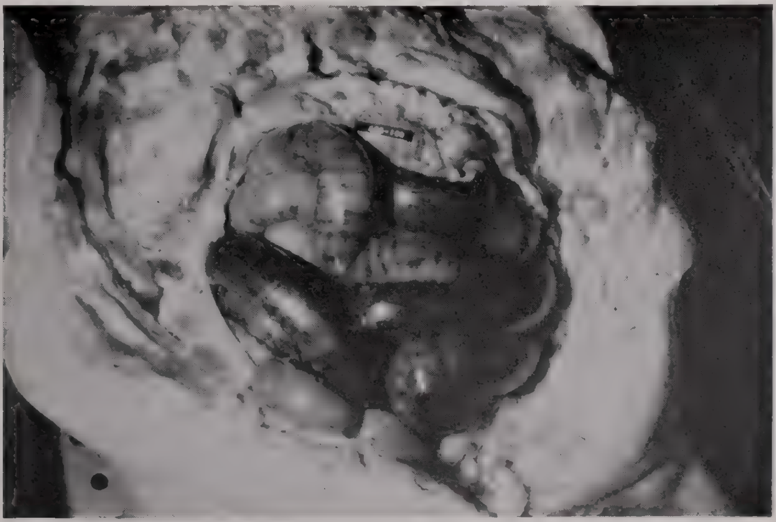

Fig. 5—Internal hernia and superior mesenteric artery thrombosis.

cholecystitis but not pathognomonic of acute pancreatitis, as high levels were also found in perforated peptic ulcer and intestinal obstruction.

A significant rise in serum amylase activity occurred in a number of cases of intestinal obstruction. In Burnett and Ness' series of 35 patients, using Somogyi's method, 19 patients were found whose values were above their normal range of 62 to 177 Somogyi units (mean 115 ± SD 33 Somogyi units). In these cases two serum amylase levels were very high: one, 1600 Somogyi units, and the other, 2000 Somogyi units. Both of these patients had extensive devitalization of small bowel accompanying the intestinal obstruction. It is postulated that the amylase of the intestinal content was absorbed by capillaries or lymphatics of the damaged bowel or from the peritoneum after seeping through the intestinal wall. The intestinal cells of the crypts of Lieberkuhn may also have contributed some desquamated amylase; amylase-producing bacteria have been cultured from fecal flora.

TABLE

Diagnosis	No. of Cases	Serum Amylase > 400 Units	Serum Amylase > 1000 Units
Acute pancreatic disease	14	14	13
Acute cholecystitis	23	2	0
Perforated peptic ulcer	31	8	2
Intestinal obstruction	35	3	2
Acute appendicitis	149	2	0
Miscellaneous	98	3	0
TOTAL	350	32	17

Burnett & Ness: Brit Med J. 2:770, 1955.

Hiatt[6] studied the mechanism of serum amylase elevation and noted that in simple mechanical obstruction in the dog, without strangulation, the serum amylase levels were not elevated. However, strangulation obstruction with necrosis of mucosa was followed by significant rises in plasma amylase values: rises which occurred in depancreatized dogs as well. He ascribed the elevations to absorption of enzymes seeping through the devitalized bowel wall into the peritoneum; the peritoneal fluids often had values for serum amylase above the plasma. These workers found no evidence of pancreatitis resulting from their maneuvers.

The mechanism of serum amylase elevation in acute interstitial and hemorrhagic pancreatitis is poorly understood. It has been found that serum amylase levels rise abruptly during acute episodes and fall sharply after 24 to 36 hours, with normal values being gradually reached in four to five days. All of us have had the experience of observing cases of acute hemorrhagic pancreatitis with normal serum amylase levels in spite of tubular necrosis and renal failure. Pancreatic duct obstruction is not uniformly present in cases of acute interstitial or hemorrhagic pancreatitis. The amount of pancreatic secretory mass appears to bear some relationship to serum amylase elevations particularly in cases of chronic pancreatitis.

Closed loop obstruction of the duodenum in the area where the pancreatic duct enters is a well-defined variety of pancreatitis which was studied by Pfeffer and his colleagues.[7] Our case today involved an afferent loop obstruction and a strangulation obstruction of the small bowel secondary to internal hernia.

Pathologic Diagnoses:

1. Strangulation obstruction of small bowel secondary

to internal herniation of small bowel after retrocolic gastrojejunostomy.

2. Afferent loop obstruction of the duodenum
3. Mechanical obstruction of the superior mesenteric artery by the proximal loop of the gastric anastomosis
4. Acute peritonitis
5. Renal tubular necrosis

Liberty

They that give up essential liberty to obtain a little temporary safety deserve neither liberty nor safety.—Benjamin Franklin

Hot under the collar...
high under the cuff.

Sometimes
he forgets he has hypertension, gets hot under the collar. . . high under the cuff.

For such patients, consider **Regroton®**

chlorthalidone	50 mg.
reserpine U.S.P.	0.25 mg.

To lower blood pressure
and allay anxiety in hypertension.

For brief summary of prescribing information, see next page.

RE-6392

Regroton® Geigy

chlorthalidone 50 mg.
reserpine U.S.P. 0.25 mg.

the once-a-day tablet for anxious hypertensives

Regroton is a combination of two basic antihypertensives designed to lower blood pressure and allay anxiety in hypertension. With Regroton he can keep his shirt on and you can keep his blood pressure down.

Before prescribing, please review carefully the indications, contraindications, warning, precautions, adverse reactions and dosage information below.

Regroton®
Each tablet contains:
chlorthalidone 50 mg.
reserpine U.S.P. 0.25 mg.

Indications: Hypertension.
Contraindications: History of mental depression, hypersensitivity, and most cases of severe renal or hepatic diseases.
Warning: With the administration of enteric-coated potassium supplements, which should be used only when adequate dietary supplementation is not practical, the possibility of small-bowel lesions (obstruction, hemorrhage, and perforation) should be kept in mind. Surgery for these lesions has frequently been required and deaths have occurred. Discontinue coated potassium-containing formulations immediately if abdominal pain, distention, nausea, vomiting, or gastrointestinal bleeding occur. Discontinue one week before electroshock therapy, and if depression or peptic ulcer occurs.
Use in pregnancy: Because chlorthalidone may cross the placental barrier and appear in cord blood and thiazides may appear in breast milk, this drug should be used with care in pregnant patients and nursing mothers. When used in women of childbearing age, the potential benefits of the drug should be weighed against the possible hazards to the fetus. Use of chlorthalidone may result in fetal or neonatal jaundice, thrombocytopenia, and possibly other adverse reactions which have occurred in the adult. Increased respiratory secretions, nasal congestion, cyanosis and anorexia may occur in infants born to reserpine-treated mothers.
Precautions: Antihypertensive therapy with this drug should always be initiated cautiously in postsympathectomy patients and in patients receiving ganglionic blocking agents, other potent antihypertensive drugs, or curare. Reduce dosage of concomitant antihypertensive agents by at least one-half. To avoid hypotension during surgery, discontinue therapy with this agent two weeks prior to elective surgical procedures. In emergency surgery, use, if needed, anticholinergic or adrenergic drugs or other supportive measures as indicated. Because of the possibility of progression of renal damage, periodic kidney function tests are indicated. Discontinue if the BUN rises or liver dysfunction is aggravated. Hepatic coma may be precipitated. Electrolyte imbalance, sodium and/or potassium depletion may occur. If potassium depletion should occur during therapy, the drug should be discontinued and potassium supplements given, provided the patient does not have marked oliguria.
Take particular care in cirrhosis or severe ischemic heart disease and in patients receiving corticosteroids, ACTH, or digitalis. Severe salt restriction is not recommended. Use cautiously in patients with ulcerative colitis or gallstones (biliary colic may be precipitated). Bronchial asthma may occur in susceptible patients.
Adverse Reactions: The drug is generally well tolerated. The most frequent side effects are nausea, gastric irritation, vomiting, diarrhea, constipation, muscle cramps, headache, dizziness and acute gout. Other potential side effects include angina pectoris, anxiety, depression, bradycardia and ectopic cardiac rhythms (especially when used with digitalis), drowsiness, dull sensorium, hyperglycemia and glycosuria, hyperuricemia, lassitude, restlessness, transient myopia, impotence or dysuria, orthostatic hypotension which may be potentiated when chlorthalidone is combined with alcohol, barbiturates or narcotics, leukopenia, aplastic anemia, skin rashes, thrombocytopenia, agranulocytosis, nasal stuffiness, increased gastric secretions, nightmare, purpura, urticaria, ecchymosis, weakness, uveitis, optic atrophy and glaucoma, and pruritus. Eruptions and/or flushing of the skin, a reversible paralysis agitans-like syndrome, blurred vision, conjunctival injection, increased susceptibility to colds, dyspnea, weight gain, decreased libido, dryness of the mouth, deafness, anorexia, and pancreatitis when epigastric pain or unexplained G.I. symptoms develop after prolonged administration. Jaundice, xanthopsia, paresthesia, photosensitization and necrotizing angiitis are possible.
Average Dosage: One tablet daily with breakfast.
Availability: Pink, single-scored tablets in bottles of 100 and 1000.

Obstetrical Seminar

Prolonged Gestation

THE PROBLEM of the postmature infant represents a disturbance in the time relations of gestation. Prolonged pregnancy was discussed in the medical literature of the 19th century, but it was not until 1902 that Ballantyne[1] brought the problem into focus. Since then there has been an increasing interest in the effects of prolonged gestation on the infant. The center of this interest has been primarily in Britain and on the European continent, but in the past 10 to 15 years increasing note of this topic has been taken in the American literature.

The physiology and symptomatology of many diseases and syndromes are controversial because there is no agreement as to their cause and even as to their existence. Postmaturity belongs to this category of conditions. Some reputable experts deny that prolonged gestation may be harmful to an infant. Those who accept the existence of such a syndrome do not agree as to its specific definition, physiology, symptomatology, or method of treatment. Some laboratory studies have been carried out to support a theory of causation, but the results of these have been promptly refuted.

The purposes of this paper are to present a review of current literature concerning the various clinical aspects of prolonged gestation, to discuss some of the laboratory investigations associated with placental function, and hopefully to draw some useful and practical conclusions from the controversy.

Definitions

The average duration of human pregnancy is usually considered as 267 days when figured from the date of conception or 280 days when calculated from the first day of the last menstrual period. However, the actual duration of pregnancy has a bell-shaped distribution, with the peak incidence of delivery occurring at 40 weeks. Statistical surveys[2] show that 12% of pregnancies go beyond the 294th day and 4% beyond 300 days. Because of this range of delivery dates, the definition of postmaturity has not been agreed on. In his original paper, Ballantyne[1] regarded as postmature any infant who was born after a pregnancy that lasted 10 calendar months (300 days). This definition is accepted by many authors,[2-6] although others[7-10] use 42 weeks or 294 days as the basis for their definition of postmaturity.

Clinical Features

In addition to defining postmaturity in terms of the duration of the pregnancy, Ballantyne[1] described the following associated findings:

1. The weight and size of the infant were almost always above average.
2. The length and head diameter were greater than normal.
3. Lanugo hair and vernix were absent.
4. Redness and desquamation of the skin was pronounced.
5. The fingernails projected beyond the tips of the digits.
6. A plentiful accumulation of subcutaneous fat deposits was present.
7. The child usually had abundant scalp hair.
8. The anterior fontanelle was usually small.
9. Ossification was advanced beyond normal in most bones of the body.
10. The lower portion of the colon was distended with meconium.
11. The bladder was usually full because the placenta was no longer functioning as an excretory organ.
12. The placenta was larger than normal, with microscopic evidence of degeneration and often calcification.
13. The umbilical cord often showed one artery almost closed.
14. The amount of amnionic fluid was less than normal and was often stained with meconium.
15. Toxemia was more common in women with prolonged pregnancy.
16. Labor was usually tedious and long.

The recent literature has included comments on most of the points that Ballantyne has discussed. Magram and Cavanagh[6] and Mead and Marcus[8] agreed with Ballantyne's observation that the size of postmature infants is greater than average; however, many other authors[2,7,11,12] have stated that in prolonged pregnancies babies are rarely of excessive size. Browne[7] and Clifford[11] have commented on the unusual appearance of the skin of these infants; they noted the frequent absence of vernix and the cracked, stained appearance so frequently seen in the skin.

Whereas the excessive placental size as observed by Ballantyne has not received comment by other authors, placental dysfunction has been mentioned most often as the primary cause of postmaturity. Mead and Marcus[8] expressed a typical opinion that placental dysfunction and hypoxia may be definite risks to the infant in a prolonged pregnancy. Clifford[11] incorporated this opinion into the following criteria for staging postmaturity: Stage I is manifested by loss of vernix, dry parched skin, and open-eyed, alert infants. In Stage II, besides the findings in Stage I, the placental function has degenerated, producing fetal distress manifested by liberation of large quantities of meconium in the amnionic fluid, and the skin and membranes are stained with meconium. In Stage III, intra-uterine anoxia is evident by the passing of meconium days or weeks before birth. It was his impression that with progression from the first stage, the outlook for the infant became worse.

Browne[7] probably has been the main spokesman for the British opinion on postmaturity. He stated that in most British hospitals postmaturity is second only to toxemia as a cause for surgical induction of labor. He found that the perinatal mortality rate was lowest at 40 to 41 weeks, that by 43 weeks it had doubled, and by 44 it had trebled. Gibberd[13] in his study of 7,965 births from 37 to 44 weeks reported a perinatal mortality rate of 1.1% in infants of more than 41 weeks' gestation. However, a weekly analysis indicated that the perinatal mortality rate at 41 weeks was 0.4%, at 42 weeks 1.3% at 43 weeks 2.8%, and at 44 weeks 4.3%. Other authors[5,8,9,14-16] supported the supposition that the perinatal mortality rate increases with prolonged gestation. Browne[7] and Mead and Marcus[8] all believed that toxemia superimposed on prolonged pregnancy carries a much greater risk to the infant.

Age and parity apparently also contribute significantly. Browne[7] stated that the risk to the infant is greater in elderly mothers and that primiparous women have more trouble with prolonged pregnancy than multiparous patients. Other writers[4,6,8,11,14,16] also concur on these two points. Browne[7] and others[8,9,16] have found that patients with prolonged pregnancy tend to have longer, more difficult labors than normal and that the first evidence of fetal distress is often seen during labor. Clifford[11] and Smith and co-workers[9] all observed that the amount of amnionic fluid in patients with prolonged pregnancy seems to be decreased significantly. Clifford[11] is the only author who commented about subsequent pregnancies in women who have had a previous infant with the postmaturity syndrome. He stated that 73% of the primigravidas whose period of gestation lasted 300 days or longer did not become pregnant during the following 10 years.

Two authors[1,5] have noted that anencephalic infants are sometimes associated with prolonged pregnancy; however, this probably is a coincidental occurrence and not a cause and effect relationship. Eastman and Hellman[2] stated that only rarely is an anencephalic pregnancy associated with increased duration of pregnancy. Evans and associates[14] stated that the incidence of fetal malposition in prolonged gestation is no greater than normal. Mead and Marcus[8] supported this observation but added that the incidence of midforceps deliveries is increased in prolonged pregnancy. Such operative interference is usually due to fetal distress or lack of progress after a long and tedious labor in which the cervix has finally become fully dilated. They also stated that there is no higher incidence of bleeding or toxemia in women whose pregnancies go beyond 42 weeks. Evans and associates[14] also emphasized that the maternal mortality is not affected by prolonged gestation.

Laboratory Data

Oxygen Supply

In an attempt to substantiate hypoxia due to poor placental function as a major etiologic factor in the postmaturity syndrome, Walker[15] in 1954 studied the oxygen supply to the fetus. His results showed that the oxygen supply to the normal infant decreases gradually up to the 40th week and rapidly thereafter. Most fetuses at 40 weeks are well oxygenated and have 100% reserve, but by 43 weeks all fetuses have low oxygenation and no reserve. When meconium is passed, the oxygen saturation in the umbilical vein is only 30%—a level that is insufficient for the fetus. But other authors[12,17] do not believe that there is enough reliable evidence to substantiate these studies.

Hormone Levels

Laboratory investigations can test the adequacy of placental function by measuring the hormone levels of the placenta. Lundwall and Stakemann[18] and Smith and co-workers[9] studied urinary estriol in prolonged pregnancy. These studies were done on 24-hour urine samples to determine the adequacy of the feto-placental complex, and the authors generally agreed that a decreasing level of estriol occurring after term was an indication of failing placental function. Levels of less than 16 mg in 24 hours were believed to be an indication for interruption of the pregnancy. If the levels were very low—about 8 mg in 24 hours—a cesarean section was done. Otherwise, induction of labor was safe. They emphasized that in borderline cases more than one determination was essential. Two or three tests showing progressively lower levels of estriol were considered very significant; levels of less than 4 mg in 24 hours were associated with fetal death in utero.

Babuna and Yenen[3] did serial tests on serum oxytocinase, which is also produced by the placenta, and found that this test was less expensive and more practical than the serial urinary estriol test because it was done on serum. They noted that in normal pregnancy the oxytocinase levels were low in early pregnancy, increased after the 16th week, reached a peak at term, but decreased in toxemia and in prolonged pregnancy.

Management

Induction at Forty-Two Weeks

Because divergent opinions exist regarding the various aspects of postmaturity, there is no uniform method of management. Browne's method[7] is typical of those in Britain who believe that prolonged pregnancy represents a risk to the fetus in utero. He induces labor surgically at 42 weeks' gestation, whatever the status of the cervix. If abundant fluid is evident when the membranes are ruptured, there is no need to worry about placental reserve. However, if the fluid is scanty, thick, and stained with meconium, he proceeds immediately with a cesarean section because he believes the child will probably not survive the stress of labor. If labor ensues after the membranes are ruptured, he does not allow the second stage to last longer than one hour. Browne[7] believes that pudendal block is the best method of anesthesia and that labor should be induced in toxemic patients after 41 weeks' gestation instead of 42. Walker[15] concluded that primiparous patients who are less than 25 years old should be allowed to go into labor spontaneously. If fetal distress develops during labor and especially if meconium appears in the fluid, oxygen should be given to the mother.

Cesarean Section

In older primiparous women or in those patients in whom a long labor is anticipated, cesarean section should be done at the first sign of fetal distress. Walker further believes that in primiparous and multiparous patients older than 25 years, labor should be induced at the end of 41 weeks' gestation, and that cesarean section is indicated at the first signs of fetal distress. If a patient had had a previous stillbirth, labor should be induced before term. Smith and associates[9] go even farther by stating that when postmaturity has been diagnosed, labor is contraindicated unless the estriol level is at least in the borderline range of seven to 12 mg in 24 hours. They believe that labor eliminates all placental reserve and that cesarean section is the only safe method of delivery for the infant.

Conservative Approach

Other authors take a more conservative approach. Eastman and Hellman[2] considered that since the hazard of postmaturity is less than the hazard of induction, most patients should be allowed to go into labor spontaneously, regardless of the length of gestation. Mead and Marcus[8] agreed with this conservative approach and commented that the proper handling of any obstetric difficulties is more important than setting a deadline for induction. Gibberd[13] in his excellent statistical study stated that if there were a perfectly effective method of induction and it was used in every pregnancy just before 41 weeks, six more babies in every 1,000 inductions would be saved. However, because no infallible method of induction is available, an attempt that fails will needlessly stress an already stressed placenta.

Conclusion and Comment

From this information, some practical conclusions can be drawn. Some infants in the 4% of pregnancies that last longer than 300 days have an increased risk of mortality—either antepartum, intrapartum, or postpartum. The two factors that seem to have a direct bearing on the outcome in the affected infants are the age and parity of the mother. Women more than 25 years old and primiparous patients seem to have babies that are more severely affected by prolonged pregnancy. The infants of multiparous patients, even though the pregnancy is prolonged, seem to suffer no adverse effects.

In gestations that last longer than 300 days, oligohydramnios or meconium-stained amnionic fluid should prompt the physician to terminate the pregnancy in the most expeditious way.

In prolonged pregnancies, when the physician expects that the infant may become compromised, serial tests of urinary estriol help determine the condition of the fetoplacental complex. There does not seem to be enough evidence yet as to the value of the serum oxytocinase test.

Because there can be adverse effects on the infant when toxemia is superimposed on prolongation of pregnancy, patients with significant toxemia should not be allowed to carry their pregnancies past the expected date of confinement.

Accurate determination of the expected date of confinement in every patient is essential and may help prevent some of the worry over prolonged gestation. In most cases of prolonged pregnancy, the difficulty is an error in the calculation of the date rather than an overdue birth. Although Naegele's rule is the accepted method of calculating this date, other means provide useful aids to confirm it. A menstrual history with special emphasis on the length of the patient's normal cycle helps isolate the actual time of ovulation in relation to the duration of the cycle.

Comparison of the size of the uterus at various times during pregnancy with the calculated duration of gestation is useful. The date of quickening should be noted. If there is any serious doubt about the length of gestation, roentgenography at 36 weeks' gestation to determine distal femoral epiphysis may be helpful. When prolonged gestation is a concern, the question often arises about the exact expected date of confinement. Routine notation of all of these factors in every patient can provide a fairly accurate estimate of the length of gestation.

Primiparous patients and those more than 25 years old should be observed very closely when their gestation goes beyond 42 weeks. Loss of weight and decrease in abdominal girth may indicate oligohydramnios. These are the patients in whom urinary estriol studies are probably indicated. Induction of labor with amniotomy and oxytocin (if necessary) is indicated if the patient goes to 43 weeks' gestation, the estriol levels are adequate, the baby seems to be of adequate size, and the cervix is "ripe." If the quantity of fluid is very small and stained with meconium, cesarean section appears to be indicated. In the patient at 43 weeks whose estriol level is borderline or low, or whose cervix is "unripe," cesarean section is the safest method of delivery.

To lengthen thy life, lessen thy meals.—Benjamin Franklin

Grand Rounds

The Multiple System Effects of Diphenylhydantoin (Dilantin)

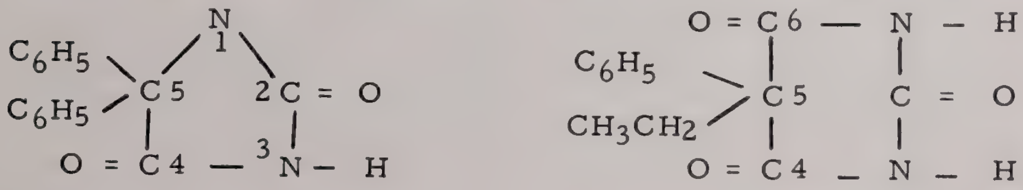
ARNOLD W. LINDALL, M.D., Ph.D.
Minneapolis, Minnesota

The anti-convulsant drug known as diphenylhydantoin (Dilantin) has been widely used since its introduction in 1938[1] for the control of seizures. It was first considered for the treatment of cardiac disorders in 1950[2]; and the use of the drug in arrhythmias became more widespread after the introduction of a parenteral preparation.[3] Like digitalis, which in some ways has effects quite the opposite of Dilantin, the cellular mechanism of the action of Dilantin is unknown. The drug has widespread systemic effects probably related to a common mechanism, which accounts for its therapeutic as well as its toxic effects.

Chemistry

Structure

Diphenylhydantoin, which is related to the barbiturate derivatives, is basically a substantial five-member ring with two phenyl groups substituted at position five. In the Figure Dilantin is compared to phenobarbital.



Diphenylhydantoin **Phenobarbital**

Figure—Structures of Diphenylhydantoin and Phenobarbital.

---

*Presented as a Medical Grand Rounds at Hennepin County General Hospital, April 16, 1968.

Solubility

It is a highly insoluble compound. In direct measurement Dill et al.[4] found a concentration of 14 micrograms/ml. at pH values from 1 to 7. This corresponds to a molar concentration of 0.55×10^{-4} M. At pH 9.1 the saturated solution (in borate buffer) was 0.6×10^{-3} M. At pH 10 it is about ten-fold more concentrated. The pKa was estimated at 9.2. The molecular weight of DPH is about 252. The sodium salt is converted to acid form in the stomach.

Absorption

In the rat, Diel et al.[4] found that oral administration of Dilantin resulted in peak plasma levels in six to eight hours. There was no delay in entering the central nervous system, although the heart concentrations lagged somewhat. At reported doses of 100 mg./kilo, brain and heart levels were 20 and 19 μg/gm. respectively, while liver and fatty tissue levels were higher. Firemark et al.[5] found that brain, plasma and cerebrospinal fluid levels were equal two minutes after parenteral administration. They also reported that brain concentrations exceeded plasma by 10-fold at 24 hours.[6]

In humans given oral Dilantin, peak plasma levels occurred after 12 hours,[4] and the half life of plasma levels was about 20 hours. In dogs the peak plasma level was four hours.

Distribution

Very small quantities of Dilantin are excreted unchanged in the urine: in the dog and human Dilantin is excreted as a hydroxylated derivative. About 50% of an oral dose was found in the urine as the hydroxylated form. An interesting recent report shows that the antituberculosis drug combination, isoniazid and para-aminosalycylic acid reduce parahydroxylation and lead to toxic levels of Dilantin when the latter drug is also being given.[8] Isoniazid and cycloserine also produce the effect, while isoniazid alone has no effect. Folic acid reverses this inhibition, apparently by acting as a cofactor in this detoxification reaction. Other excretion products are hydantoic acid and α-aminodiphenyl acetic acid.[9]

Dilantin is not easily measured, particularly in the presence of phenobarbital, but a recent method is said to circumvent this difficulty. Therapeutic levels in four humans on chronic doses of 100-300 mg. per day orally were in the range of 1-10 micrograms/ml. of plasma.[4]

Toxicity of Diphenylhydantoin

The side effects of this compound are numerous.[11] They include the well known gingival hypertrophy, nystagmus, diplopia, cerebellar signs such as ataxia, skin disorders, megaloblastic anemias, lymphatic hyperplasia, erythoid aplasia, thrombocytopenia and more recently hepatitis. In the acute administration of Dilantin for cardiac arrhythmias, sudden deaths have occurred. This may be related to elimination of a ventricular pacemaker in the presence of high-grade atrioventricular block. A number of these toxic effects will be discussed in more detail.

Megaloblastic Anemia

Megaloblastic anemia associated with Dilantin therapy was first reported in 1950.[12] The cause of this anemia would appear to be folic acid deficiency. In one clinical study folate levels below 2.1 mμ gm./ml. were seen in 35% of a group of epileptics,[13] 11% of whom had macrocytosis without anemia.

In another investigation gastrointestinal function studies were done[14,15], revealing B_{12} and xylose absorption defects in two cases, both of which responded to folic acid treatment. In a third case no clear-cut absorption defect for folate, B_{12} or xylose was found, although a glucose tolerance test before folate treatment was suggestive of malabsorption. A jejunal biopsy was not diagnostic.

Folate levels of less than 5.0 mμg. were found in 58% of 53 patients reported by Klipstein.[15] Slight macrocytosis was seen in 71% of the Dilantin-treated subjects; however, vitamin B_{12} levels were normal. The possible sites of block were reviewed. Folic acid absorption has been said to be normal in the presence of large doses of folate. While some have found increased urinary clearance of folate, this is not a uniform finding. The conversion of dihydro to tetrahydro folic acid does not appear to be affected. Herbert[17] suggested that there may be a competitive inhibition in the conversion of 5-10 methenyl tetrahydrofolic acid to 5 methyltetrahydrofolic acid. Interesting further evidence related to this hypothesis is a recent report of a reversible erythroid aplasia produced by Dilantin in a 17-year-old boy.[17] An immune mechanism was not found to be responsible. Further studies with C-14 formate showed a decreased incorporation of this compound into bone marrow deoxyribonucleic acid. Since labeled deoxynucleotides could be incorporated, in particular deoxyuridilic acid which requires methylation by tetrahydrofolic acid, one must conclude that Dilantin was not inhibiting the folic acid cofactor. The most likely site of block was at the synthesis of deoxyribonucleotides, since none of the precursors of nucleotide synthesis could be incorporated. Ribonucleic acid synthesis was not affected.

A very recent study[19] showed subnormal folic acid levels (<5.0 mμg/ml.) in 54% of 59 children on Dilantin. In a careful oral folate tolerance study in one adult with megaloplastic anemia, inhibition of the absorption of physiological doses of folate (600 μg) were observed to be related to the dose of Dilantin. In this patient, renal excretion and plasma clearance were normal. Conjugase* activity in duodenal aspirates was also normal in this case as well as in four others; however, administration of desiccated chick pancreas caused a hematological response. It was suggested that the chick extract may produce more of the diglutamate form of folic acid which can be absorbed more efficiently.

Cerebellar Degeneration

Slurred speech, nystagmus and ataxia are said to be side effects of Dilantin. The site of the pathology in these cases may be the cerebellum. Hoffmann[20] reported a case of a 28-year-old female who died after a rapidly progressive seizure disorder treated vigorously with Dilantin. At autopsy most purkinje cells had disappeared. Other changes present in the basal ganglia included perivascular cuffing. The author suggests that Dilantin was responsible. In another woman symptoms of nystagmus, ataxia and stupor were noted after large doses of Dilantin.[21] These investigators also found that rats given 200 mg./kilo of Dilantin showed loss of purkinje cells and edema of Bergmann's glia after 14 days. Cats were more sensitive, requiring about 10 mg./kilo for two weeks.

Electron microscopic studies[22] of rat purkinje cells on long-term high doses of Dilantin showed development of membrane concentric bodies (whorls of membrane-like material), shrinkage of purkinje cell bodies, dilation of endoplasmic reticulum and golgi, and increased lysosomes. The glial cells around the purkinje cells, known as Bergmann's glia, also showed morphological changes. Swollen mitochondria were commonly seen. The whorls of membranes were thought to arise from cell membrane structures. An analogy to the lipidoses such as Tay-Sack's disease was suggested because of the similar pathological membrane inclusions.

---

*Folic acid in the diet is released from polyglutamates by a conjugase present in duodenal secretions.

Hepatitis

A case of hepatitis following five weeks of Dilantin therapy was recently reported.[23] A biopsy showed hepatocellular injury. After a period of abstinance and then rechallenging the patient with Dilantin, symptoms of drug hypersensitivity reoccurred, although in this brief exposure there was no reoccurrence of hepatic chemical abnormalities.

Lymphadenopathy and Hepatosplenomegally

Although lymphadenopathy is rare,[11] its presence can be confusing in differential diagnosis. A recent report[23] described a case with follicular hyperplasia of lymph nodes and mildly depressed platelet counts after Dilantin therapy. The findings can actually mimic lymphoma or Hodgkin's disease. Seven new cases and a review of the literature were published by Saltzstein and Ackerman.[24] Non-specific hyperplasia of reticulum cells and eosinophilic infiltrations are common, as well as hepatosplenomegally. In another case hepatosplenomegally with lymphadenopathy was reported in a six-year-old child associated with Dilantin treatment. Exfoliative dermatitis and eosinophilia were also present.[26] The lymph nodes are said to be discrete and not matted; Reed Sternberg cells are absent; there is not the uniform appearance of mature lymphocytes seen in lymphosarcoma or chronic lymphatic leukemia.

Fatalities with Dilantin ingestion are rare.[27] The fatal doses in the cases reviewed were 100-200 mg./kilo.

Experimental Basis for the Use of Dilantin in Arrhythmias

The use of Dilantin in arrhythmias was established by experiments of Harris and Kukernot in 1950.[28] There have been many animal and human studies demonstrating its effectiveness. These investigations were summarized by Mercer and Osborne[29] who added a clinical study of 774 patients. They found the best response in ventricular arrhythmias associated with surgery, cardioversion, cardiac catheterization and anesthesia. In 61-82% of the patients the arrhythmia was completely controlled. But in arteriosclerotic heart disease with ventricular arrhythmias complete control was accomplished in only 53%. Supraventricular tachycardias were less well controlled, only 10% of 98 patients being completely controlled. One surprising conclusion was a high rate of success in preventing paroxysmal arrhythmias by chronic oral administration.

Dilantin has been proposed as an effective drug for treatment of digitalis intoxication by Helfant et al.[30]

The toxicity of acetylstrophanthidin was manifested primarily by prolonged atrioventricular conduction, shortened ventricular escape time and ventricular tachycardia. Dilantin converted the ventricular tachycardia and prolonged the ventricular escape time beyond control values; and there was a return of atrioventricular conduction time to near normal value. The effects of Dilantin were in contrast to procainamide, which prolonged intraventricular conduction and further prolonged atrioventricular conduction in digitalis-toxic dogs. In a companion paper[31] the same authors found that pretreatment with Dilantin increased the dose of acetylstrophanthidin necessary to produce ventricular tachycardia by an average of 122% in contrast to procainamide which had no effect. They concluded that the inotropic and arrhythmic actions of digitalis are separated by Dilantin treatment. In humans Heffant et al.[32] demonstrated that Dilantin (5 mg./kilo) significantly decreased atrioventricular conduction time by about 25% at a rate of 100. The decrease was also seen at higher rates. Ouabain-induced prolongations were readily reversed by Dilantin, but no effect of Dilantin on intraventricular conduction time was seen.

Mechanism of Action of Dilantin in Nervous Tissue

The exact effect of Dilantin on nervous tissue is unknown. The drug is used to control grand-mal seizures on a chronic basis and also for status epilepticus. However, a recent study on monkeys by Rand et al.[33] questions the use of intravenous Dilantin in status epilepticus. Directly stimulated cortical potentials were unaffected by the drug at 10 mg./kilo; epileptic foci, chemically induced, were likewise unaffected. Single cell activity in both normal and epileptic cortical cells was unchanged. Spontaneous electroencephalograms of epileptic monkeys were also unaffected. Since Dilantin has been shown to readily penetrate the brain[5] and since other studies have shown that it modifies chemical epileptic foci only when combined with hypothermia,[34] it is concluded that some chemical reorganization of Dilantin at brain-binding sites must occur. There is considerable physiological evidence that it acts at synaptic sites. In the spinal trigeminal nucleus the latency of discharge of single neurons (stimulated from a peripheral site) was increased by intravenous Dilantin.[39] At least one investigator has shown that nerve conduction per se was unaffected in chronic administration of Dilantin[36]; others have reported decreased nerve conduction or synaptic delay, increased threshold, and diminished spike amplitude.[37] In squid, axon electrical activity was altered by Dilantin only when Ca^{++} or Mg^{++} concentrations were altered in the media.[38] A study by Esplin[39] showed that Dilantin inhibits post-tetanic potentiation in cat spinal cord or stellate ganglia. Post-tetanic potentiation is essentially a measure of interneuronal connections. A period of tetanic stimulation of dorsal root fibers or afferent fibers to the stellate ganglia so conditions the pathways that a test stimulus results in an output spike of the ventral root or ganglia of larger amplitude than noted prior to tetanus. Post-tetanic potentiation may result from the partial depolarization of a larger pool of motor neurons, making them more susceptible to firing by a standard stimulus. Dilantin might inhibit post-tetanic potentiation by acting as a hyperpolarizing agent. Synaptic recovery was also found to be delayed by Dilantin. The latter finding could only be attributed to a presynaptic site, since anidromic conditioning did not show such an effect of the drug.

Direct chemical evidence of the mechanism of action of Dilantin is scarce. Woodbury[40] found in acute experiments that Dilantin reduced intracellular sodium concentration and increased sodium turnover in brain. This is consistent with an accelerating effect on the sodium-pumping mechanism with the ultimate effect of hyperpolarizing the neuronal membrane. This effect is not seen in hearts or brains of chronically treated animals.[41] A recent report[42] indicates that Dilantin has no definite measurable effect in doses of 50 mg./kilo on rat brain Na^+ and K^+-stimulated adenosine triphosphatase. It does, however, seem to potentiate ouabain inhibition of this enzyme. Sodium and potassium-stimulated adenosine triphosphatase probably represents a portion of the enzyme system involved in active transport of these ions, i.e., the sodium "pump."

Early evidence by Greengard and Mclwain[43] showed that Dilantin had no effect on resting brain cortex oxygen consumption; however, the drug inhibited the normal increase in respiration observed when the slices were stimulated. Dilantin also prevented the usual decrease in CO_2 production seen in stimulated tissue. Total lactic acid production was not affected. These results suggest some interference with mitochondrial-cytoplasmic coupling.

In a pilot experiment in our laboratory Dilantin injections (5 mg./kilo) intraperitoneally into guinea pigs for ten days had no recognizable effect on brain synapse or brain mitochondrial cytochrome oxidase, nicotinamide adenine dinucleotide diaphorase, or nicotinamide adenine dinucleotide cytochrome c reductase.[44] In other recent studies Dilantin (injected intraperitoneally) was found to have no effect on D-xylose penetration into guinea pig brain slices, while phenobarbital in contrast increased D-xylose penetration at low xylose concentrations and decreased the penetration at high xylose concentrations.[45]

Conclusion and Summary

The mechanism of Dilantin is still not understood. Evidence suggests that the drug acts at presynaptic sites of the nervous system in such a way as to hyperpolarize the cell membrane, thus making the tissue less excitable. A similar mechanism would appear to be involved at the atrioventricular node and in ordinary ventricular muscle. Evidence seems to suggest that sodium pumping gradients may be increased; however, no effect has been seen on that part of the sodium pump which we measure as Na^+ and K^+-stimulated adenosine triphosphatase. But the latter observation does not preclude an effect on the pump, since it measures only a part of the pumping mechanism. Evidence in the cerebellum suggests that membrane turnover and synthesis may be affected.

The contrast with digitalis is apparent; digitalis reduces sodium gradients and partially depolarizes cell membranes, making cells more irritable. Opposite effects from Dilantin are seen in the atrioventricular node and ventricular muscle. With digitalis some of the atrioventricular nodal effects occur via the vagus nerve. Digitalis (in particular ouabain) is well known to inhibit the sodium pump enzyme, Na^+ and K^+-stimulated adenosine triphosphatase, resulting in leakage of potassium from inside the cell and an accumulation of sodium inside the cell. These changes in ionic gradients probably account for the toxic effects of digitalis. The beneficial action of digitalis is probably not related to its inhibition of membrane adenosine triphosphatase which is considered a toxic action. The therapeutic (or inotropic) effect is somehow related to the contraction mechanism itself, perhaps to calcium ion movements between sarcoplasmic reticulum and myofibrils.[46] There must, however, be a coupling mechanism between cell membrane depolarization and the initiation of contraction, perhaps by means of the sarcoplasmic reticulum tubular system. The possibility of separating the two effects of digitalis by Dilantin is an important discovery.

Case Report

A 47-year-old white female was admitted January 12, 1967, from the emergency room with a temperature of 105° rectal and a complaint of dysphagia and garbled speech. She had been an epileptic following a head injury at age 15. She was treated by her private physician until January 11, 1967, when she came to the Neurology Clinic. Examinations at that time showed her to be lethargic and ataxic with ptosis of the right lid. Her medications included Dilantin 100 mg. three times a day and phenobarbital 100 mg. three times a day. An electroencephalogram showed a left temporal lobe epilepsy.

Physical Findings

Physical examination revealed a very pale, febrile, retarded female with flecks of dried blood about her mouth. Positive findings included a flame hemorrhage on the right temporal disk margin, blood in the posterior nasopharynx, and a grade I/VI systolic murmur with a heart rate of 130. Her bowel sounds were active. Generalized lymphadenopathy was noted. Petechiae were present on her legs and a cuff test was positive.

Laboratory Studies

Laboratory work revealed:

Hgb.	4.1 gm.%
Hcrt.	12.1 %
RBC	1.25 x 10^6
MCV	100
MCH	33
MCHC	33
WBC	1,600
Platelets (estimated)	18,000
Reticulocytes	0.5%

A bone marrow was markedly megaloblastic. The peripheral blood smear was hyperchromic and macrocytic with hypersegmented neutrophils.

The spinal fluid was normal. The total serum protein was 6.7 gm.% with 2.9 gm.% albumin. The SGOT was 49; bilirubin and alkaline phosphatase were normal. The BUN was 20 mg.%. A fibrinogen level was normal, but the prothrombin time was 26.7 seconds with a control of 12.6. Urinalysis revealed a 1+ albuminuria; urine culture was negative. Stool guiacs and stool cultures were negative. Sputum cultures showed pneumococci and staphylococcus coagulase positive. Blood and spinal fluid cultures showed only contaminants. A total lactic dehydrogenase on January 15, 1967, was 2850 mu with the heat stable form being 1218. A serum protein bound iodine was normal.

Treatment

The patient was transfused with a unit of whole blood followed by a unit of packed cells. Antibiotic therapy consisted initially of 12 million units of penicillin and 12 gm. of Keflin per day which was later decreased to 8 million units of penicillin and 8 gm. of Keflin. By the eleventh day the patient was afebrile. Urine output was excellent. Folic acid and B_{12} therapy were begun on the first day of admission. On the eighth day she developed a serious nasopharyngeal hemorrhage requiring an anterior pack, and another unit of packed red blood cells was given.

Progress

A number of interesting developments began on the fourth day, three days after the beginning of folic acid and B_{12} therapy. The serum albumin began to fall and the WBC began to rise. On the seventh day the WBC rose to 17,500 and the reticulocyte count to 4.0%. The albumin was now 1.4 gm.% and the BUN, SGOT, and alkaline phosphatase reached values of 30 mg.%, 99 units and 20 units respectively. The BUN and alkaline phosphatase continued to rise. Bilirubin rose to 2.0 mg.% total on the eleventh day. On the tenth day the cephalin flocculation and thymol turbidity tests were abnormal, but rash developed, necessitating the discontinuance of penicillin and Keflin. By now sputum cultures showed Klebsiella enterobacter. The creatinine clearance was 9 cc. per minute, although her urine output remained high.

On the twelfth day a tube feeding was started. On the thirteenth day the patient expired. Post-mortem examination revealed generalized lymphadenopathy with marked lymphocytic infiltration into the liver, kidney and spleen. There was difficulty in deciding whether the infiltration was a lymphoma or a reaction to Dilantin. The latter was the pathologist's final opinion.

The immediate cause of death was most likely inability to clear her thick mucoid respiratory secretions, a problem which had been present from the beginning.

This patient represents at least tentatively a number of complications of Dilantin treatment. There was megaloblastic anemia at this admission. Ataxia and slurred speech had been previously noted, although phenobarbital could have been partially responsible. Lymphocyte infiltration, almost indistinguishable from lymphoma, was present. Her final course showed hepatic and renal failure without eosinophilia, also loss of plasma colloid. These system failures could be due to an allergic phenomenon which she did have; however, the hepatorenal failure exactly paralleled the response of the WBC and reticulocytes to folic acid and B_{12}. One can only speculate that a Dilantin-induced folic acid deficiency held in arrest a Dilantin-induced hypertrophy of reticuloendothelial elements. When folic acid was present, the latter phenomenon was unmasked. This can be compared to the iatrogenic arrest of leukemia by aminopterin.

Touraine-Solente-Gole Syndrome

This osteodermapathic syndrome is characterized by "bull-dog scalp" lesions involving the scalp, forehead, face, and extremities, elephantiasis of long bones, periosteal lesions, and occasionally pulmonary osteoarthropathy. It was described by Touraine, Solente, and Gole in 1935. The syndrome is limited to males between 25 and 30 years of age.

These abnormalities occur in the absence of any primary disease and involve a combination of cutaneous and osseous tissues. In one reported case pachydermia with extensive folding involved the skin of the head, forehead, cheeks, hands, and feet. Periosteal thickening caused malformation of the hands, which become huge, and enlargement of the feet. These changes involved metatarsal, metacarpal, and phalangeal bones and somewhat resembled the osseous changes of acromegaly. It has therefore been suggested that this disorder may be a variant of acromegaly. The patients' general health may be unaffected. Histologic study of involved skin areas show enlargement and tortuosity of sebaceous canals and an increase in the number and size of blood vessels and elastic fibers. No specific hormonal or other therapy is known.

Physician, Cure Thyself

The Arabs, whose scepticism was not confined to matters of religion, avenged themselves to some extent by disparaging verses about doctors, such as the following on the death of Yuhanna ibn Masawayhi in A.D. 857:

"Verily the physician, with his physic and his drugs,
Cannot avert a summons that hath come.
What ails the physician that he dies of the disease
Which he used to cure in time gone by?
There died alike he who administered the drug, and he who took the drug,
And he who imported and sold the drug, and he who bought it."*

Pediatrics

The Battered Child Syndrome

Part III—Legal Aspects

PRIOR TO 1963, Minnesota had no law governing the reporting of physically abused children. Due to the concern and interest of the medical profession, an amendment was made to the law concerning reporting of gunshot injuries.[1] The recommendation for the amendment came under the direction of the Committee on Child Health of the Minnesota State Medical Association, Dr. Lane Arey, chairman.

In the 1965 legislative session a separate "battered child law" was passed which closely followed the model law as recommended by the Children's Bureau.[2,3] The emphasis for a more workable law for physicians came from the Minnesota Welfare Department and was introduced by Representative Robert G. Renner of Walker, Minnesota. The Minnesota State Medical Association strongly backed this bill.

Further minor changes of the law were made in 1967, as a result of recommendation of students at the William Mitchell College of Law, under their law improvement study (Table 1).

In Hennepin County, from 1963 to 1968, 123* cases of the Battered Child Syndrome have been reported to the Child Protection Division. Seven of these children died; two cases were brought to trial for a crime. Sixteen children were placed in foster homes by court order (legal custody of child given to the Welfare Department). One was committed to a foster home by the court after the mother voluntarily released parental rights. Five cases were handled by criminal court for prosecution of an adult assaulting a child. All defendants were found guilty (two fathers, one mother, one boy friend, one stepfather). One alleged child assault case was heard in Juvenile Court and dismissed, as the court felt evidence of abuse was without foundation.

The law's primary purpose is protection of the abused child who is unable to protect himself. It includes the physically abused child and the "neglected" child. An area which needs further definition and consideration, as suggested by Judge Lindsay Arthur,[4] is that of the emotionally neglected child. Physical abuse is not inflicted upon these children, yet the emotional abuse can be equally as devastating.

"Emotional neglect might be defined as the deprivation suffered by children when their parents do not provide opportunities for the normal experiences producing feelings of being loved, wanted, secure and worthy which result in the ability to form healthy object relationships."[5] From the legal point of view, it is most difficult, if not impossible, to legislate behavioral patterns. Reporting of physically abused children under current Minnesota Law (Table 1) is confined to health personnel whether licensed or not. The report is required to be made to the police and Welfare Department, first orally, then with a written statement. The authors feel that *all* persons, whether health personnel or not, as long as it is done in good faith, should be able to report a suspected child abuse case. Paulsen[6] has criticized this concept, feeling that "everybody's duty easily becomes nobody's duty." The report should name the child, his age, his parents or the people caring for him and their addresses, as complete a history as possible, using names, including that of the alleged assailant, a physical examination, x-ray findings, and such other data as may be pertinent (electroencephalogram, sub-dural taps, surgical results, etc.). Early reporting is essential for the Welfare Department and police to do an effective job.

As soon as a report has been received, the County Welfare Department has the responsibility to investigate the complaints and provide such protection to the child as is necessary until the investigation is completed.

---

*Compiled by Mr. Martin Coyne, Unit Supervisor, Child Protection Division, Hennepin County Welfare Department.

If a report is given in good faith the person reporting is immune from liability. If he is called to court to testify, his testimony is not a basis for libel. Thus a physician should not fear suit as a reason for not reporting a possible case of child abuse.

"Privileged communication" does not apply to child abuse cases. Even if it did, it would have to be invoked by the child, and since he is not a party to the litigation, no issue of privilege should arise. This clause avoids this possible roadblock.[3]

The last clause of the law includes a penalty for not reporting a recognized case, which in Minnesota represents a misdemeanor. The maximum penalty for this is an up to one hundred dollars fine and/or up to ninety days in jail. In Wisconsin it is one hundred dollars and/or six months. In Pennsylvania it is five hundred dollars and/or one year.[7]

The general tenor of the law is recognizance of the importance of the protection of the abused child. This is paramount in importance as evidenced by the 10 percent death rate and 30 to 50 percent recurrence rate of the problem.[8] Annually, more cases are being reported reflecting increased awareness of the reporting laws[9] and recognition of the syndrome. When cases are reported, something *is* done by the Welfare Department, and when necessary, legal proceedings are generally directed toward the benefit of the child. Punishment of the assailant usually accomplishes little. Assistance to and protection of the child are the prime goals of the Health personnel, Welfare Department, and legal officials.

Summary

The Minnesota State law concerning reporting of child abuse is discussed. Its purpose is protection of the abused child. Health personnel must report such cases under penalty of law for not doing so. Reporting constitutes *no* basis for liability. Hennepin County experience reflects that reporting does get action appropriate to the individual case.

TABLE I—MINNESOTA STATE LAW

626.554 Reporting of Maltreatment of Minors

Subdivision 1. *Declaration of purpose.* The purpose of this section is to provide for the protection of minor children who have had physical injury inflicted upon them, by other than accidental means, where the injury appears to have been caused as a result of physical abuse or neglect.

Subdivision 2. *Who makes report and to whom made.* Any physician, surgeon, person authorized to engage in the practice of healing, superintendent or manager of a hospital, nurse and pharmacist, whether such physicians, surgeons, persons engaged in the practice of healing, superintendent or manager of any hospital, nurse and pharmacist be licensed or not, shall immediately report all cases of physical injury to children inflicted by other than accidental means which come to their attention where the injury appears to have been caused, as a result of physical abuse or neglect. Such cases shall be reported to the appropriate police authority as defined in section 626.53 and the county welfare agency. The appropriate police authority, upon receiving such a report, shall immediately notify the county welfare agency. Provided however, that no provision of this section shall be construed to mean that a child is neglected or lacks proper parental care solely because said child's parent, guardian, or custodian in good faith, selects and depends upon spiritual means or prayer for the treatment or cure of disease or remedial care of such child.

Subdivision 3. *Nature and Content of Report.* An oral report shall be made immediately by telephone or otherwise and followed as soon thereafter as possible by a report in writing, to the appropriate police authority and the county welfare agency. Such report shall contain the names and addresses of the child and his parents or other persons responsible for his care, if known, the child's age, the nature and extent of the child's injuries including any evidence of previous injuries, and any other information helpful in establishing the cause of the injuries and the identity of the perpetrator.

Subdivision 4. *Responsibility of county welfare agency* The county welfare agency shall investigate complaints of neglect and abuse of children and offer protective social services in an effort to protect the health and welfare of these children and to prevent further abuses.

Subdivision 5. *Immunity from liability.* Anyone participating in good faith in the making of a report pursuant to this section shall have immunity from any liability, civil or criminal, that might otherwise be incurred or imposed. Any such participant shall have the same immunity with respect to participation in any judicial proceeding resulting from such report.

Subdivision 6. *Evidence not privileged.* Neither the physician-patient privilege nor the husband-wife privilege shall be a ground for excluding evidence regarding a child's injuries or the cause thereof, in any judicial proceeding resulting from a report pursuant to this section.

Subdivision 7. *Penalty for this violation.* Anyone knowingly and willingly violating the provisions of this section is guilty of a misdemeanor.

Laos

Responsible humans don't avoid decisions. Our problem is sifting out those decisions which concern priority matters. Perhaps our whole life is a struggle to discover what really is important in terms of history and mankind's struggle to find justice, freedom, and meaning in life.

The Advent Season reminds us that God is constantly coming to us in the form of people all over the world who are not reaching their human potential. Inasmuch as we are able, we have accepted our responsibility to live for these and all humanity. This commitment gives us the freedom, and the obligation, to ask you to consider four decisions among your priorities for the coming 30 days:

1. Find a new LAOS volunteer—maybe your family dentist or physician, or a teacher who could give two months during the summer, or even yourself.
2. Arrange for some group who does not know about LAOS to see our filmstrip during 1969.
3. See if you can get LAOS in the budget of your church.
4. Seriously consider investing $15 or more of your own funds in LAOS.

We hope that you will say yes to at least two of these decisions.

Classified advertising rates are twenty (20) cents a word; minimum monthly charge $5.00; key number, fifty (50) cents additional.

Replies to advertisements with key numbers should be mailed in care of Minnesota Medicine, 375 Jackson, St. Paul, Minn. 55101.

WANTED: Young physician for association leading to partnership with four well established General Practitioners in fast growing suburb of St. Paul. Excellent clinic facilities in nearly new, partnership owned, well equipped, medical center building. Contact: A. Eugene Muller, M.D., North St. Paul Medical Center, 2579 East 7th Avenue, North St. Paul, Minnesota 55109.

THREE MAN group in North West Wisconsin Resort, State Conservation and Retirement Area needs two more physicians adequately to serve their practice. Facilities offered are three-room physician suites, X-ray and lab under AMT technician, RN-only nursing personnel. New accredited thirty-two bed hospital and forty-six bed nursing home. Deer and duck hunting, fishing within five minutes of town. Internist most needed; generalists welcomed. Will meet any reasonable salary request. Partnership after one year. Write: MINNESOTA MEDICINE—365; 375 Jackson St, St. Paul 55101.

GENERAL SURGEON interested in some general practice to associate with a 2-man partnership in a rich agricultural community in southern Minnesota. Modern hospital and new clinic building. Hunting, 9-hole golf course, swimming pool. Salary open and full partnership as soon as desired. Write: MINNESOTA MEDICINE—405, 375 Jackson, St. Paul 55101.

INTERNIST AND GENERAL PRACTITIONER wanted to join a five-man clinic group in Minneapolis. Complete laboratory and X-ray with board roentgenologist. Excellent hospital staff associations. Salary arrangement to start with, early partnership. Write MINNESOTA MEDICINE—289; 375 Jackson, St. Paul, 55101.

GENERAL PRACTITIONER wanted. Exceptional opopportunity for one or two. Present Doctor leaving for V.A. Hospital. 5000 active files, 50 bed nursing home. Hospital 15 minutes, College 30 minutes. Clinic and equipment available. Contact Dr. Wm. Alcorn or John Franta, Wabasso, Minn.

G.P. AND INTERNIST for five-man clinic. New building, good hospital, city of 14,000 in heart of lake district. Good schools, junior college. Write: MINNESOTA MEDICINE—420, 375 Jackson St., St. Paul.

WANTED: General practitioner to join two young general practitioners in well-established practice in suburban St. Paul. Excellent office space with lab, x-ray, and emergency room. Salary negotiable, with an association leading to early partnership opportunity. Write MINNESOTA MEDICINE 412, 375 Jackson St., St. Paul 55101.

EXPANDING EIGHT-MAN CLINIC IN NORTHWESTERN WISCONSIN has immediate openings in General Practice, Internal Medicine and Urology. New clinic building; three accredited hospitals; large branch of the University of Wisconsin; population 33,000. Liberal first year salary, early partnership. Contact Milton Finn, M.D., 3600 Tower Avenue, Superior, Wisconsin 54880. Tel.: 715-392-8111.

THE WEST MEDICAL CLINIC has an opening for a General Practice Physician. This is a five man group that conducts a practice near downtown St. Paul and also has the Airport Medical Clinic at Wold Chamberlain Field, Twin City International Airport. Both clinics have full laboratory and X-ray services with technologists covering both fields.

The Airport Medical Clinic does industrial, occupational and Aviation medicine. FAA examinations are conducted at both clinics.

The clinic located near downtown St. Paul has a practice limited principally to internal medicine, pediatrics, as well as occupational and industrial medicine. There is only a limited practice of obstetrics and no surgery.

Salary is open and opportunity for partnership is available. Write: West Medical Clinic, 539 W. Seventh Street, St. Paul, Minnesota 55102. Phone: Area Code 612-227-9341.

ASSOCIATE urgently needed in busy general practice. Excellent clinic and hospital facilities. Salary open. Partnership after 1 year. Klefstad Clinic, Greenbush, Minn. Call collect: Lloyd H. Klefstad, M.D., Tele. 218—782-5275 or 4725.

TWO MAN GROUP needs a third general practitioner in a fast-growing West St. Paul area. Begin with salary and assume early partnership. Contact N. W. Howe, M.D., or E. J. McEllistrem, M.D., 1246 Gorman, West St. Paul, Minn. 55118 Telephone: 224-8001.

WANTED: G.P. to join clinic serving population area of 12,000. City has new hospital, new clinic building, two nursing homes, new Jr-Sr high school, new swimming pool, rich farming area in Red River Valley. Fishing and hunting nearby; metropolitan city close by. Salary open and partnership if interested. Write or call Warren Clinic, Warren, Minnesota 742-6231, area code 218.

GENERAL PRACTITIONER wanted to join well-established practitioner. New clinic building—90 miles east of St. Paul—city of 14,000. Early partnership with full hospital facilities. Ideal location. L. W. Picotte, M.D.; Chippewa Falls, Wisconsin.

(Continued on page 378)

in cerebrovascular disorders

Arlidin increases blood flow

Arlidin decreases cerebral vascular resistance, increases cardiac output, helps maintain mean arterial pressure.

Arlidin helps control vasoconstriction, vasospasm, and ischemia.

Arlidin may thus relieve symptoms of cerebrovascular insufficiency, such as vertigo, lightheadedness, and mental confusion.

Arlidin also increases blood flow to the eye and inner ear to help manage ischemic disorders of those organs.

Arlidin is well tolerated and relatively free of severe adverse reactions.

DOSAGE: Usual effective dosage ½ to 1 tablet t.i.d. or q.i.d.; increased, if necessary, to 2 tablets t.i.d. or q.i.d. Parenterally, 0.5 cc. by subcutaneous or intramuscular injection; increased gradually to 1 cc. one or more times daily, as needed. SIDE EFFECT: Occasional palpitation. PRECAUTIONS: Use with caution in the presence of a recent myocardial lesion, paroxysmal tachycardia, severe angina pectoris, thyrotoxicosis. CONTRAINDICATION: Acute myocardial infarction. SUPPLIED: Tablets, 6 mg., scored; bottles of 100 and 1000. Parenteral, 5 mg. per cc., 1 cc. ampuls (5 per box); 10 cc. multiple-dose vials (1 per box). CONSULT PRODUCT BROCHURE.

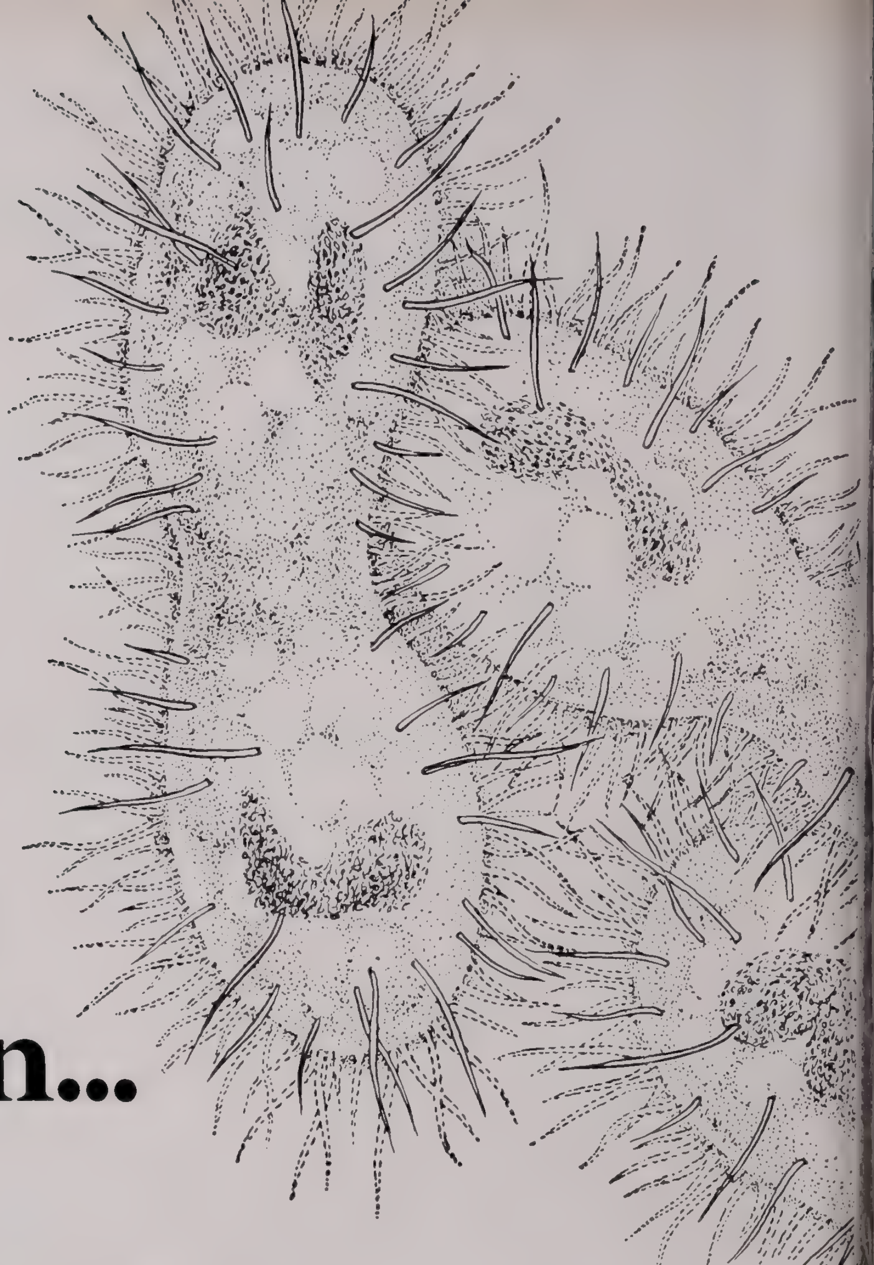
DECREASES
ARTERIAL
RESISTANCE



A high index of suspicion... E. coli

How high is the "index of suspicion" for *E. coli* in urinary tract infections?

Recently it has been estimated that about 86 per cent of positive cultures in first attacks of urinary tract infection are *E. coli.*[1] It has also been noted that "The coliform group, especially *E. coli*, accounts for approximately 90 per cent of initial infections...."[2]

Consider wide-spectrum Gantanol® (sulfamethoxazole) for its high "index of confidence"—its proven effectiveness against *E. coli* and other sensitive gram-negative and gram-positive organisms. Therapeutic levels of Gantanol in blood and urine are achieved within 2 hours after a 2-Gm starting dose, with ready diffusion into interstitial fluids. Responsive infections generally clear within 5 to 7 days, with relief of symptoms usually seen within 24-48 hours.

Gantanol also earns its high "index of confidence" because Gantanol therapy is relatively free from complications, including the problem of bacterial resistance or superinfection.

Convenient, economical dosage schedule: *b.i.d.*

References: 1. Vernier, R. L., in Patient Care Feature: *Patient Care, 1*:20 (Feb.) 1967. **2.** Beeson, P. B.: "The Infectious Diseases," in Beeson, P. B., and McDermott, W. (eds.): *Cecil-Loeb Textbook of Medicine*, ed. 12, Philadelphia, W. B. Saunders Company, 1967, p. 230.

Before prescribing, please consult complete product information, a summary of which follows:

Indications: Acute and chronic urinary tract, respiratory and soft tissue infections due to susceptible microorganisms; prophylactically following diagnostic instrumental procedures on genitourinary tract.

Contraindicated in sulfonamide-sensitive patients, pregnant females at term, premature infants, or newborn infants during first 3 months of life.

Warnings: Use only after critical appraisal in patients with liver or renal damage, urinary obstruction or blood dyscrasias. Deaths reported from hypersensitivity reactions, Stevens-Johnson syndrome, agranulocytosis, aplastic anemia and other blood dyscrasias. In closely intermittent or prolonged therapy, blood counts and liver and

For a high index of confidence... Gantanol® (sulfamethoxazole) in antibacterial therapy

Artist's rendition of E. coli. As with most strains of E. coli, these have flagella and are motile.

kidney function tests should be performed. Clinical data insufficient on prolonged or recurrent therapy in chronic renal diseases of children under 6 years.

Precautions: Occasional failures may occur due to resistant microorganisms. Not effective in virus and rickettsial infections. Sulfonamides not recommended for therapy of acute infections caused by group A beta-hemolytic streptococci. At present, penicillin is drug of choice in acute group A beta-hemolytic streptococcal infections; although Gantanol has produced favorable bacteriologic conversion rates in this infection, data insufficient on long-term follow-up studies as to its effect on sequelae of rheumatic fever or acute glomerulonephritis. If other treatment cannot be used and Gantanol is employed in such infections, *important that therapy be continued in usual recommended dosage for at least 10 days.* Observe usual sulfonamide therapy precautions, including adequate fluid intake. Use with caution if history of allergies and/or asthma. Follow closely patients with renal impairment since this may cause excessive drug accumulation. Need for indicated local measures or surgery not obviated in localized infections.

Adverse Reactions: Depending upon the severity of the reaction, may withdraw drug in event of headache, nausea, vomiting, urticaria, diarrhea, hepatitis, pancreatitis, blood dyscrasias, neuropathy, drug fever, Stevens-Johnson syndrome, skin rash, injection of the conjunctiva and sclera, petechiae, purpura, hematuria and crystalluria.

How to turn a 14-year-old boy into a hardened criminal.

Just forget your keys in your car one day.

Tempt some fourteen-year-old boy into going for a joyride.

Oh, he could be a good kid – just weak.

And taking your car might be the first time he's ever broken the law.

But the minute he hops behind that wheel and turns the key, his life may be ruined.

He'll drive around for a few hours, endangering the life of every man, woman and child who crosses his path.

He might be caught the very first time he takes a car. Or if he's not caught by the police he'll leave your car somewhere and decide to do it again, and again, until the day he does get caught.

Teen-agers steal more than 1,000 cars every day.

The U. S. Department of Justice and your state and local law-enforcement agencies are concerned.

They know that taking a car for a joyride is just the first step.

Our prisons are filled with men who started out this way. They went on to become thieves, muggers, and even killers.

You can do something to help solve this terrible problem.

Whenever you get out of your car, even for a second, take your keys. Lock your car.

Every time you do this you may keep a good boy from going bad.

Don't help a good boy go bad. Lock your car. Take your keys.

Abstracts, Briefs and Commentaries

CANCER OF THE COLON: THE INFLUENCE OF NO-TOUCH ISOLATION TECHNIC ON SURVIVAL RATES

It has been long suspected that cancer may be disseminated through the blood stream by the trauma of surgical removal. Tyzzer, investigating breast tumors in mice, suggested that cancers of the breast may be explosive. In 1952 Barnes described a special technic for resection of the right colon. He advocated ligation of the vascular pedicles with division of the vessels before handling the cancer-bearing segment. Cole et al. (1954) reported finding cancer cells in the portal venous blood of a perfused resected cancer-bearing segment of the colon. This gave rise to their suggestion that the vascular pedicle be ligated before bowel resection. In 1955 Fisher and Turnbull reported cancer cells in the portal venous blood of eight of 25 resected segments (for cancer) of the colon.

In 1953 Turnbull, Jr., adopted a technic in which the vessel pedicle is ligated with lymphatics before the tumor is palpated, coining the term no-touch isolation for the procedure. In every cancer of the colon operated on by Turnbull, this technic was employed; five other surgeons employed the conventional method. Cancers of the colon were defined as located more than 5½ inches above the anus and were divided into four groups: Stage A- tumor confined to colon and its coati; Stage B- tumor extension into pericolic fat; Stage C- tumor metastases to regional mesenteric glands; Stage D- tumor metastases to liver, lung, etc.

Data on 896 patients were suitable for analysis, with an operability rate of 96%. Six hundred and sixty-four were treated by the author, using the no-touch technic; five other surgeons operated on 232 patients, employing the conventional technic. The resectable rate was 84.2% in both groups. The five-year survival rate was 46.9% for all 896 patients, which is unusually high (usual rates 25-35%.) Deaths from metastatic cancer were more frequent during the first two years after the conventional technic resection, most of them due to metastases to the liver. It is suggested that fatal hepatic metastases may be due to operative manipulation of the cancer-bearing segment.

The survival rates for both methods are about the same after two years; but the true value of the no-touch technic is obvious when the survival rate of the two methods is compared for longer periods of time. The five-year survival of Stage C- cancers (regional glands involvement) is 57.84% by the no-touch method, but 28.06% by conventional methods.

Note: Many years ago Dr. R. E. Farr, with whom I was associated, strongly advocated the no-touch technic in general surgery whenever possible. It is especially desirable when dealing with carcinoma and perhaps infections. It seems definite, as shown by Cole and others, that malignant cells and bacteria can be expressed through both venous and lymphatic tracts.

GYNECOMASTIA

By definition gynecomastia implies a circumscribed potentially reversible enlargement of the male breast resulting from a combination of causes and a variety of histologic changes.

Gynecomastia results from a hormone imbalance which may likewise be produced by a variety of conditions. Most of these result in the production of an imbalance of the estrogens or endrogens.

Among the most common underlying diseases are hypertension, diabetes mellitus, cirrhosis of the liver, bronchogenic carcinoma, rheumatoid arthritis, generalized non-specific dermatitis, chronic pyelonephritis, arteriosclerotic heart disease and congestive failure. In most of these instances an abnormal production of estrogen has been stimulated by the disease or the medication that has been prescribed.

IN-PATIENT CHILD PSYCHIATRY AT THE UNIVERSITY OF MINNESOTA

A full-time psychiatric service to children has been included at the University Medical School and Hospitals since 1938. This was initially out-patient; an in-patient service for children began operating in 1952. We provide training for psychiatry residents who rotate through the service, for psychologists, and for medical students.

Our goal is primarily that of diagnosis and, occasionally, extended treatment of psychiatric disorders in children and younger adolescents. Each patient is given a complete study which includes a detailed medical and psychiatric history, a physical examination, psychological testing and, where indicated, a neurologic consultation. We have found it best to have adequate contact with the parents or parental substitutes before admission so that they are familiar with our program and will cooperate with us.

The following diagnostic categories were most frequent: 34% of the children were listed as adjustment reaction of adolescence, and 24% as adjustment reaction of childhood. Nineteen percent were diagnosed as a primary mental retardation.

We are planning to keep some children for a longer period of time and to provide residential treatment for them. They will be selected on the basis of our patient population and staff interest; we have not yet decided if we will concentrate on long-term treatment of a specific disorder.

Michael F. Koch, M.D.
Minneapolis, Minnesota

TOXIC MEGACOLON IN TRANSMURAL COLITIS REGIONAL COLITIS, CROHN'S DISEASE

Toxic dilatation of the colon or toxic megacolon is recognized as the most dreaded complication of fulminating chronic ulcerative colitis. It is also a dread complication of transmural colitis (Crohn's disease of colon). In general the patients with toxic megacolon in transmural colitis were women less than 35 years of age, the range being from 16 to 64 years. Symptomatology fell into two classes: those with a relatively short history of disease, one to six months, and those with a long history of remitting disease. The clinical features resembled exactly the disorder when observed in the course of chronic ulcerative colitis, including fever, disproportionate tachycardia, cramping abdominal pain, abdominal distention, leukocytosis, hypoalbuminemia and hypokalemia. Medical management in these cases was extensive and included adequate intravenous therapy to maintain fluid, electrolyte and protein levels, together with the appropriate antibiotics, corticotrophin, and steroids. In many cases surgical intervention was necessary. In some cases where the patients' condition permitted, they were treated by subtotal or total colectomy and ileostomy; in the more severely ill patient ileostomy and transverse colostomy proved to be life-saving. Pathologic examination of these specimens revealed evidence of fulminant disease, clearly transmural, but with less fibrosis than is usually seen in transmural colitis. Most of the specimens were of a nongranulomatous variety.

AMEBIC GRANULOMA OF THE COLON, RECTUM AND ANUS

The 11 cases presented clearly show the necessity of very thorough examinations of the stools for ameba in all cases of anal, rectal or colonic disturbances, especially the chronic ones, in which a mass or ulceration is found. If amebas are discovered together with a filling defect in the colon, an ameboma should be suspected and therapeutic trial with antiamebic drugs is indicated before operation is performed. The great majority of amebomas disappear completely within a month of treatment. It is also worthy of emphasis that both amebic colitis and ameboma may coexist with a carcinoma of the colon. I feel that all this is very important in this jet age when transportation is so fast and easy that hundreds of people travel daily back and forth from areas where amebiasis is endemic and are exposed to the disease. Since amebic granuloma is often and easily mistaken for other inflammatory lesions or neoplasms of the anus, rectum and colon the surgeon must never underrate the importance of the early history; and exhaustive search for amebas must be made in order to avoid disastrous operations which unfortunately still take place.

TESTICULAR TORSION

Angell reports 16 recent cases of torsion of the testicle. Disturbingly few cases are diagnosed in time to save the organ. Many are wrongly treated, masquerading as epididymitis, and proceed unchecked to testicular atrophy. Two mistaken beliefs are responsible: that torsion is uncommon and that it seldom resembles inflammation.

An appreciation of the anatomical anomaly in torsion of the fully descended testicle is essential for correct diagnosis and treatment. The two layers of the tunica vaginalis, which normally invest the testis alone, extend upward to cover the whole epididymis and the cord, sometimes as high as the inguinal canal.

In addition, the testis is often separated from the epididymis by a lengthened mesorchium, longest at the upper pole, which enables the testis to lie horizontally when the patient is standing. Or it may be that, although the epididymis is closely applied to the testis, the structures of the lower part of the cord are loosely adherent to the epididymis and thus allow the horizontal disposition of the whole testicle. In this series the anomaly was always bilateral, and the general view seems to be that this is the rule.

The patients' ages ranged from eight to 30. The majority were teenagers; one was under 10, three were over 20. The right testis was affected in 11 patients, the left in five.

All the patients seen during an attack were febrile. Temperatures ranged from 99° F within a few hours to 103° F later. In one patient abdominal pain and vomiting preceded other symptoms for a whole day, and appendicitis was suspected.

In all the 13 patients examined standing, the unaffected testicle could be seen lying horizontally. This sign could be clearly demonstrated even in cases with much scrotal redness and edema.

In only four of the 16 cases was the correct diagnosis suspected by the doctor who first saw the patient; eight were diagnosed as epididymitis, one as hysteria, one as appendicitis, one as spermatocele; and in one no diagnosis was offered. Moreover, seven were initially diagnosed and treated as epididymitis after admission to a surgical ward, for periods varying from a few hours to 14 days.

Regardless of fever, boys and young men with painful scrotal swellings, however inflamed these may look, should be examined standing up in spite of the additional pain this may cause. If the unaffected testicle is seen to lie in a horizontal plane, no diagnosis but torsion should be entertained.

MODERN TREATMENT, VOLUME 5 #4 Treatment of Fluid and Electrolyte Imbalance Special Article, Current Treatment of Clinical Tetanus Guest Editor: David D. Thompson, M.D., Authors: Herman A. Christensen, M.D. and Deloran L. Thurber, M.D., Publishers: Hoeber Medical Division, Harper & Row, 49 East 33rd Street, New York, New York 10016. Price: $16.00 per yr.

The July issue of Modern Treatment contains 110 pages devoted to Fluid and Electrolyte Therapy and a special section of 25 pages on the Current Treatment of Clinical Tetanus. There are 15 contributing authors whose material is edited by David D. Thompson, M.D., Professor of Medicine, Cornell University, Medical College, New York.

This particular issue of Modern Treatment is a very useful and, I believe, well-designed handbook of quick reference on Fluid, Electrolyte and Acid Base Disturbances. Editorial headings and title arrangement make for convenience as a handbook. The short but meaty sections constitute a quick reference source.

The section on the Treatment of Clinical Tetanus brings one up to date on all modern aspects of treatment in this catastrophic disease. A very satisfactory summary is followed by a list of some seventeen references for more detailed information.

SKIN REACTIONS TO PRIMARY IRRITANTS IN PATIENTS WITH HAND ECZEMA (AN INVESTIGATION WITH MATCHED CONTROLS) —By Alf Bjornberg, Oscar Isacsons, Tryckeri AB, Goteborg, Sweden, 1968, 208 pages.

Primary irritants often cause a dermatitis upon contact with either normal or eczematous skin. They include alkalis, acids, and other related substances causing cytotoxic damage. This is in contrast with contact allergens which cause a dermatitis through an indirect immunological reaction.

Primary irritants play an important role in occupational dermatitis. Recent studies show that at least half of all occupational dermatitis is due to these substances. Weinberger in 1950 demonstrated that 80% of occupational dermatoses in his series were due to primary irritants. The monograph under review here attempts to answer several important questions regarding primary irritant dermatitis.

It is interesting that in Bjornberg's study he defined hand eczema morphologically but did not classify it as to etiology. However, dyshydrotic and atopic dermatites were excluded. The primary irritants to be tested were carefully controlled as to concentration, and care was taken that exactly the same site on all individuals was tested. This precaution was taken because there appear to be variations in regional skin reactivity to various primary irritants.

This study concluded that there was no increase in skin reactivity to primary irritants in those patients whose hand eczema had been healed for at least three months. However, it was demonstrated that even a localized eczema, when active, may increase the skin reactivity to some primary irritants but not to others. An important finding was that the alkali neutralization and alkali resistance were unaltered even in patients with localized hand eczema. This finding is important for those who would use these tests either as a prophetic or diagnostic tool.

THE CARE OF THE RHEUMATOID HAND (Second Edition)—By Adrian E. Flatt. 234 pages. 112 illustrations. Published by The C. V. Mosby Company, 1968. Price $14.00.

Dr. Flatt has shown great enthusiasm and more than fair success in his development of metallic prosthetic replacement for metacarpophalangeal and proximal interphalangeal finger joints. From his experience at the University of Iowa comes this fine little book aimed directly at the hand surgeon. His descriptions of surgical solutions to rheumatoid hand problems are delightfully clear and brief, with excellent illustrations. The text is of lesser interest to the internist or general practitioner except to inform him of the early surgical treatment available to his patients. The last thirty-five pages outline a ten-year follow-up of various operative procedures in many patients.

Recommended for the orthopedic or hand surgeon as a textbook to be followed. The discussion of operative indications and technique and of expected end results leaves very few questions unanswered.

Robert M. Barnett, M.D.
Minneapolis, Minnesota

ACHROMYCIN® V
TETRACYCLINE

Contraindications: Hypersensitivity to tetracycline.

Warning: In renal impairment, since liver toxicity is possible, lower doses are indicated; during prolonged therapy consider serum level determinations. Photodynamic reaction to sunlight may occur in hypersensitive persons. Photosensitive individuals should avoid exposure; discontinue treatment if skin discomfort occurs.

Precautions: Nonsusceptible organisms may overgrow; treat superinfection appropriately. Tetracycline may form a stable calcium complex in bone-forming tissue and may cause dental staining during tooth development (last half of pregnancy, neonatal period, infancy, early childhood).

Side Effects: *Gastrointestinal*—anorexia, nausea, vomiting, diarrhea, stomatitis, glossitis, enterocolitis, pruritus ani. *Skin*—maculopapular and erythematous rashes; exfoliative dermatitis; photosensitivity; onycholysis, nail discoloration. *Kidney*—dose-related rise in BUN. *Hypersensitivity reactions*—urticaria, angioneurotic edema, anaphylaxis. *Intracranial*—bulging fontanels in young infants. *Teeth*—yellow-brown staining; enamel hypoplasia. *Blood*—anemia, thrombocytopenic purpura, neutropenia, eosinophilia. *Liver*—cholestasis at high dosage.

Upon adverse reaction, stop medication and treat appropriately.

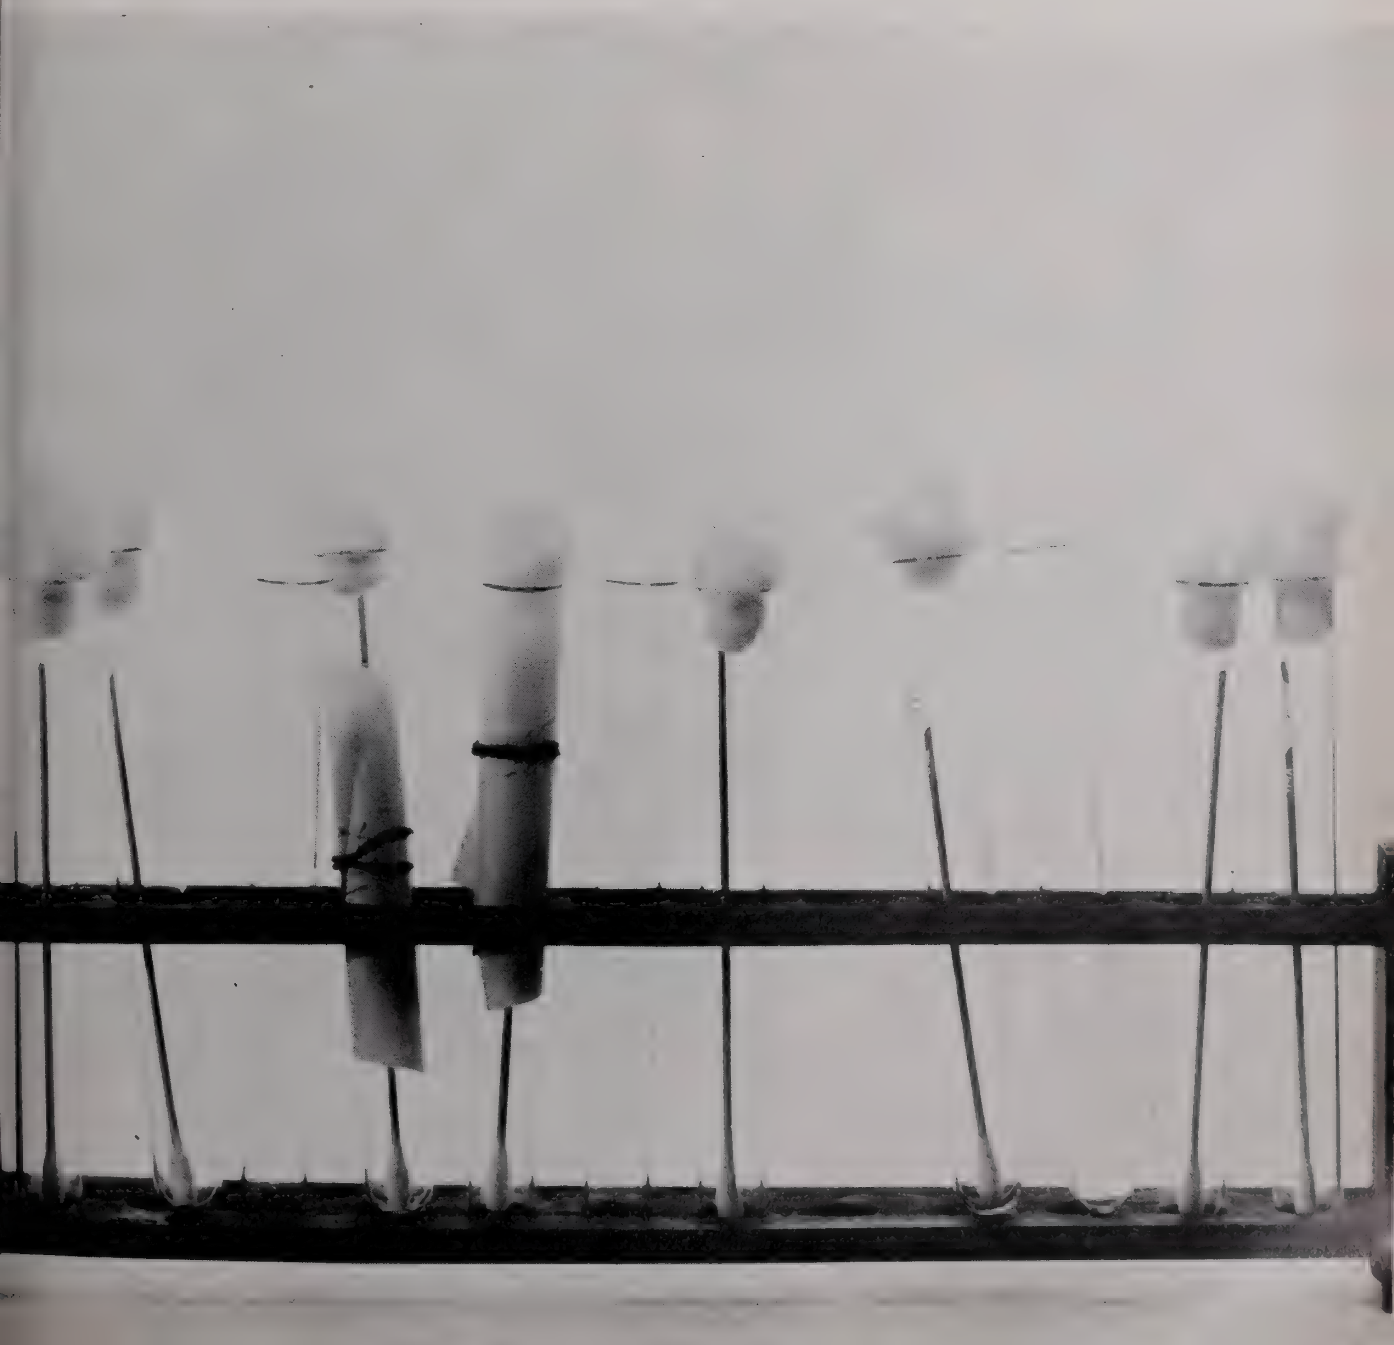
ACHROMYCIN® V
TETRACYCLINE
Lederle

The price differential is inconsequential.



rtofrane®, desipramine hydrochloride
ications: For relief of depression.
ntraindications: Do not use drugs
the M.A.O.I. class with Pertofrane.
perpyretic crises or severe con-
sive seizures may occur;
tentiation of adverse effects can be
ious or even fatal. When sub-
tuting this drug in patients
eiving an M.A.O.I., allow an
erval of at least 7 days. Initial
sage in such patients should be
v and increases should be gradual
d cautiously prescribed.
rning: Activation of psychosis may
casionally be observed in schizo-
renic patients. Do not use in

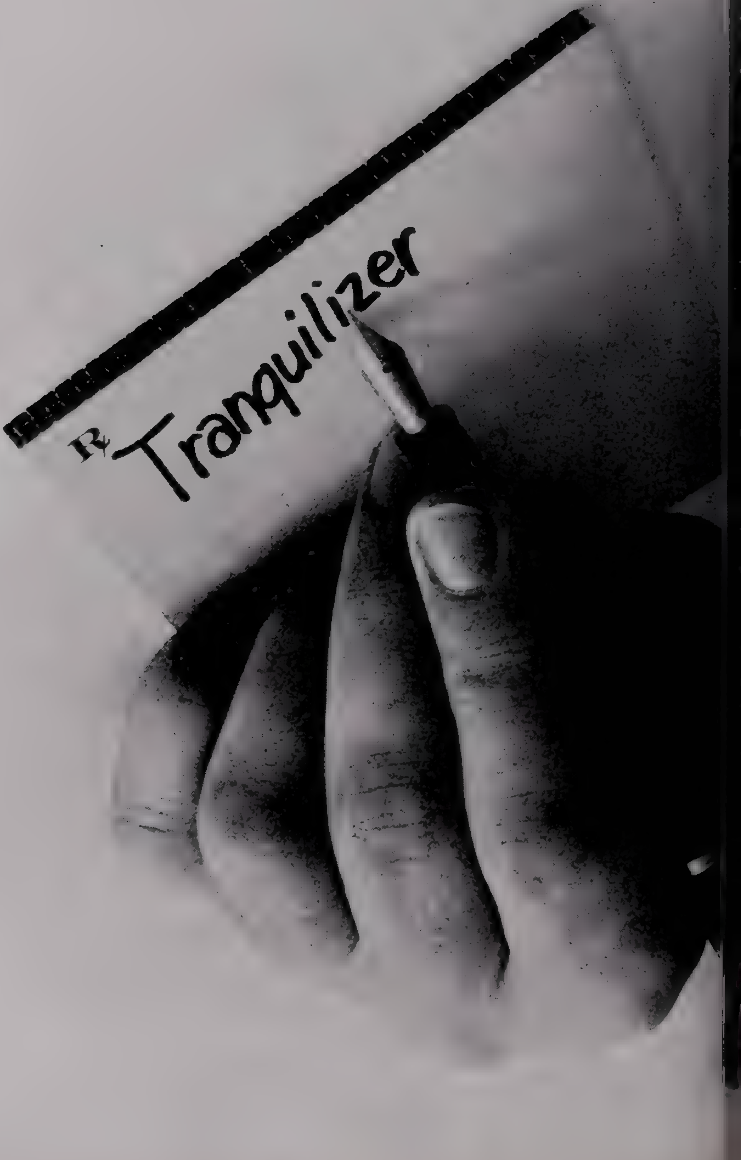
patients under 12 years old, and do not use in women who are or may become pregnant unless the clinical situation warrants the potential risk.

Precautions: Careful supervision and protective measures for potentially suicidal patients are necessary. Discontinuation of therapy or adjunctive use of a sedative or tranquilizer may be necessary in the presence of increased anxiety or agitation, hypomania or manic excitement. However, phenothiazines may aggravate the condition. Atropine-like effects may be more pronounced (e.g. paralytic ileus) in susceptible patients and in those receiving anticholinergic drugs (including antiparkinsonism agents). Carefully observe patients with increased intraocular pressure. Prescribe cautiously in hyperthyroid patients and in those receiving thyroid medications. Cardiovascular complications (myocardial infarction and arrhythmias) are potential risks since they have occasionally occurred with imipramine, the parent compound. Desipramine may block the pharmacologic activity of guanethidine and related adrenergic neuron-blocking agents. Hypertensive episodes have been observed during surgery in patients on desipramine therapy.

Before prescribing the drug, the physician should be thoroughly familiar with prescribing information, with the literature, with all adverse reactions, with the diagnosis and management of depression, and with the relative merits of all measures for

You decide who needs how much

PRESCRIPT



treating the condition.
Adverse Reactions: Dry mouth, constipation, disturbed visual accommodation, anorexia, perspiration, insomnia, drowsiness, dizziness, headache, nausea, epigastric distress, and skin rash (including photosensitization) may appear. Since orthostatic hypotension has occurred, carefully observe patients requiring concomitant vasodilating therapy, particularly during the initial phases. Other adverse reactions include tachycardia, changes in EEG patterns, tremor, falling, mild extrapyramidal activity, neuromuscular incoordination, epileptiform seizures. A confusional state (with such symptoms as hallucinations and disorientation) occurs occasionally and may require reduced dosage or discontinuance of therapy. Rarely, transient eosinophilia, slight elevation in transaminase levels, transient jaundice, or liver damage have occurred. If abnormalities occur in liver function tests, discontinue drug and investigate. Occasional hormonal effects, particularly decreased libido or impotence and instances of gynecomastia, galactorrhea and female breast enlargement have been observed. Urinary frequency or retention may occur. The drug should be discontinued if agranulocytosis, bone marrow depression, jaundice, thrombocytopenia, or purpura occur.
Dosage: 25 to 50 mg. t.i.d. The maximum daily dose is 200 mg. Continue maintenance dosage for at least 2 months after obtaining satisfactory response. Generally, elderly and adolescent patients should be give low doses.
Availability: Pink capsules of 25 m in bottles of 100 and 1000.

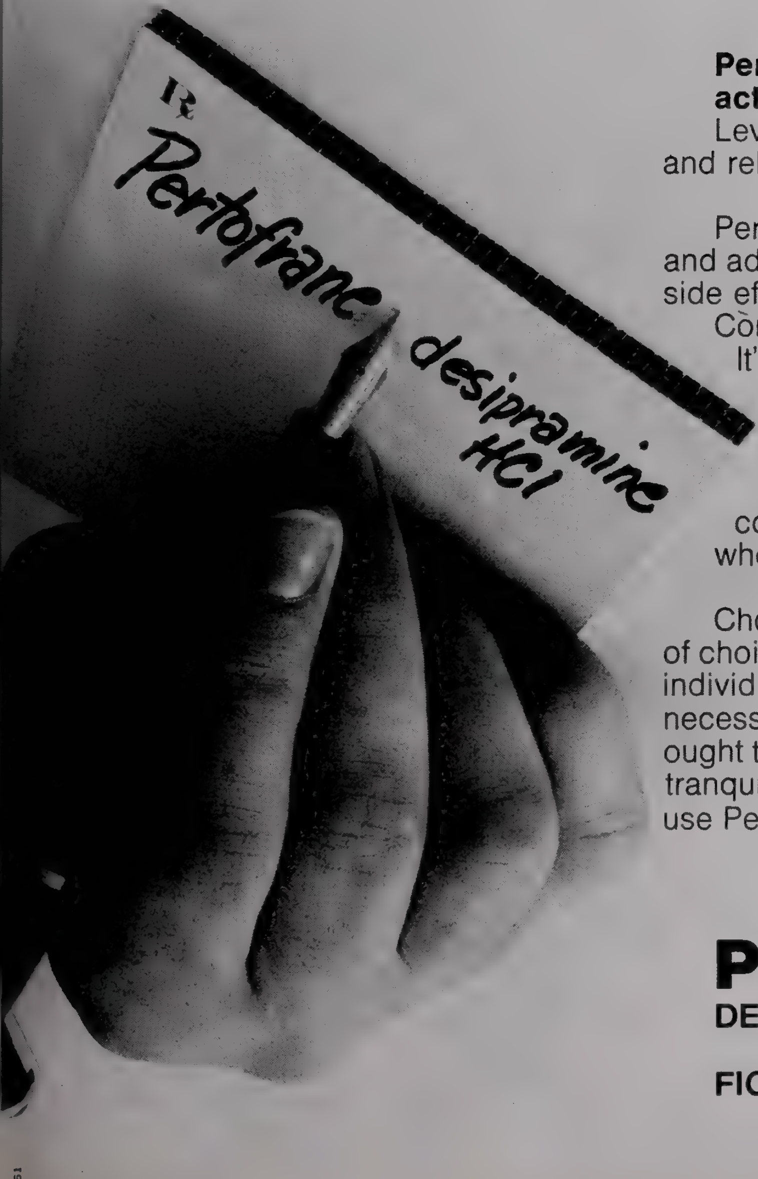
antidepressant and how much tranquilizer-

ON POWER



Pertofrane can give rapid antidepressant action often within 3 to 5 days.
Levels of psychomotor activity, patient outlook and related somatic complaints may improve.

Pertofrane is well tolerated by most patients and adverse reactions are usually mild. A few seriou side effects have been reported infrequently. Consult full prescribing information before usin It's summarized above.

Anxious Depressives...
May require adjunctive use of tranquilizers; but they don't always fit ready-made drug combinations. Isn't it better for *you* to decide who needs how much of which drugs?

Choose Pertofrane and pick your tranquilizer of choice. With this "combination", control the individual drug dosage adjustments that may be necessary for proper therapy. Isn't that the way it ought to be? Please remember, phenothiazine tranquilizers may aggravate depression, and never use Pertofrane with an MAO inhibitor.

General Practitioners

General Practice

IS IT DEATH—OR—REJUVENATED LIFE—for the General Practitioner? The Chief of Otolaryngology at an Eastern school predicted Death: "This year of the big look at medical education recognizes that general practitioners will soon be a thing of the past. No longer should medical schools be designed to produce general practitioners . . ."[1] The Millis Report on the other hand foresees Rejuvenated Life: "It is time for decisive action to increase greatly the number of physicians who will devote their professional careers to the highly competent provision of comprehensive and continuing medical services. . . . If organized medicine does not take the leadership in meeting this problem, others will."[2] The ad-hoc committee of the AMA feels that the American public does want and need a large number of well qualified family physicians if the people are to receive the maximal benefits from American Medicine.[3] Such controversy, particularly as it becomes more vocal, is certainly focusing on the fact that two distinct philosophies have emerged today. The one, Complete Specialization; the other Family Practice with consultant referrals. The problem really comes down to the question: Can the best medical care for the people of the United States be given by the family physician with referrals to the appropriate consultant, or can the people get the best care by taking each problem directly to a specialist. Being General-Practitioners and vitally interested in the controversy, we decided to gather statistics and to formulate an explanation from data acquired in our own general practice which present the story to medical educators and students.

Basics of the Study

We are a three-man group, in general practice for about ten years and on the staffs of three hospitals. We have capable professional personnel who handle the nursing and laboratory procedures very efficiently. Our facilities and equipment allow us to practice office medicine in a careful, thorough manner. We chose to tabulate our segment of general practice; every office visit made to our three-man general-practice group over a period of twelve months.

The following table is the compilation of these visits. There are 24 categories and each is listed in the order of its frequency. These categories are based on a combination of regional body systems and pathological state systems. Category 25, "Allergy," lists separate visits for desensitization injections. Category 26, "Immunization," is a part of well baby or school physical visits (diphtheria, pertussus, tetanus, polio, etc.). Category 27, "Antibiotics and Others," tabulates injections of a therapeutic nature for already listed visiting patients.

Problems

The greatest problem in establishing meaningful categories to properly explain the work load of a General Practitioner defies categorization or fragmentation because its essence is the care of the whole person in relation to his family and environment. In reality, a patient visit frequently includes more than one aspect of illness or concern.

Rarely does one treat a specific aspect of illness without including relationship to family and environment. The psychosomatic aspect of medicine is so common that we were perplexed how to indicate it and concluded by eliminating it as a category. During a two-week period one member recorded the patients referred to a consultant, and these represented 4% of his cases seen during those two weeks.

Emergency room and in-patient hospital care, although a major part of Family Practice, were not included in this study, though we do have a hospital practice which totaled 6,833 visits for the year. These 6,833 visits included cases in all major and most minor branches of medicine and surgery.

There is the inevitable human error in recording all the cases seen. The main office listed 17,713 visits, while we three doctors tabulated only 15,674: an error of 12%. The

first six categories make up almost 50% (49.1%) of all the visits. We were surprised to note that we had performed 330 exhaustively complete examinations which included rather extensive laboratory work.

Unfortunately we did not total the percentage of unusual cases, but a listing of a few of the unusual cases follows:

Pediatrics

Neurogenic diabetes insipidus
Viral encephalitis with bulbar-paralysis
Agammaglobulinemia
Scleroderma neonatorum—3 cases

Surgery

Carcinoid of the rectum (primary)
Fracture of odontoid process—traumatic
Acute ruptured duodenal diverticulum—peritonitis
Acute abdomen — first post-partum day — carcinoma ascending colon with perforation. One year later a second primary carcinoma of the sigmoid colon was found.

Medicine

Addison's disease—two cases
Mondor's Syndrome
Bilateral polycystic kidneys—age 39
Thyroiditis—several cases

Ob-Gyn

Primary carcinoma pericardium—6 mo. pregnant
Third trimester bleeding—transverse—presentation —placenta previa
Serous cystadenocarcinoma of the ovary

Knowing the Family.

Medical care is not just diagnoses and prescriptions. It is knowing the family: the members, their relationship, their finances, their philosophies. It is knowing their environment: their home, their place of work, their schools, their places of leisure. The social aspects of living must be included in medical care lest the results be unsatisfactory. In our particular office we acknowledge the family as the unit of social relationship by having family folders, which allow family data to be immediately available for correlation.

Medical Clerks and Midwives?

If we accept the prediction that the death knell of the General Practitioner has been sounded and that all medicine must be specialized, we then inherit the problem of the patient having to make his own diagnosis prior to choosing the appropriate specialist. One solution has been to educate "medical clerks," but would their diagnosis be an improvement over a Family Physician's? The specialist who says the General Practitioner must not deliver babies proposes to educate midwives to take the place of the General Practitioner. Would this be an improvement in obstetric care? We hear the cry for more pediatricians. Would it be an improvement to eliminate the pediatric care that can be given by the general Practitioner? Who then would take care of the children; who would supervise the school health programs and the preventive-medicine programs?

Most important, the more specific the Specialties become the more fragmented becomes medical care and the more like an "It," a disease problem, becomes the patient. Although there is great emphasis on the need for comprehensive care or patient oriented care, this seems far from actuality at many medical schools. There is a great tendency to encourage earlier and earlier specialization in the medical school curriculum; it has already entered the third year training in some schools. Further along there are great pressures to encourage a non-rotating internship. And now that the student has segregated himself quite thoroughly from relation to the total patient, he completes his training in a residency which confines his thinking to the same field. Is it any wonder that the absurdity of an M.D. completing his internal medicine residency without ever doing a single pelvic has actually occurred? This is quite a contrast to a few years ago when many medical educators were quite definite about the excellence of a year in Family Practice prior to entering a specialty field.

The Hill Foundation and the legislators have shown interest in the need for family physicians and for their training, and out of their findings a recommendation was made to establish the Department of Family Practice at the University of Minnesota to substantially increase the number of family physicians. The U. of M. Medical School officially founded a Department of Family Practice in 1967. It was with keen interest and great hope that the practicing physicians of the state looked toward this new department of medical education. Its doors have not opened as yet—and reasonably so—for the result must be *excellence*.

Training

It is most interesting that Sir William Osler in 1892 spoke on this subject at the University of Minnesota. "The aim of a school should be to have these departments in the charge of men who have, first, *enthusiasm*, that deep love of a subject, that desire to teach and extend it without which all instruction becomes cold and lifeless; secondly, a *full personal knowledge of the branch taught;* not a secondhand information derived from experimental work. . . . Thirdly, men are required who have a *sense of obligation*, that feeling which impels a teacher to be also a contributor."[6]

The faculty and the curriculum and the attitudes must inspire students to enter Family Practice. It must be developed courageously, unmindful of the pressures of special disciplines which would minimize and belittle the effective scope of its care. "It is time for a revolution, not a few patchwork adaptations."[8] Graduate schools still think their primary problem is to ensure professionalism and to train men to do replicate research. The more professionalized men become the more they tend to work on questions which will advance the discipline and the less they care about questions which have genuine significance for the scholar or for laymen outside the university. That the discontent with self-centered professionalism will allow change to creative and socially relevant scholarship is only a hope at this time.[9]

Conclusion

General or Family Practice is a valuable, efficient means of quality medical care. But, can the family practitioner be expected to have the knowledge to care for the wide variety of medical problems which present themselves in his practice. No, he cannot be expected to treat *all* problems as best possible, but, he can be expected to treat *all common* problems as best possible. *Common* is used here to denote frequent occurrence and familiar situations. This includes serious as well as minor illnesses—myocardial infarction, diabetes mellitus, as well as tonsillitis, inguinal hernia, etc. There is the *common* in every field of medicine. The *common* from each field can be delineated, defined and combined to make up the "Core Content" of Family Practice. Because a Family Practitioner can direct his attention to these *common* illnesses, it is thoroughly feasible for him to know and be able to give the best treatment for them. The unusual, the unfamiliar illness, can again be best treated through the General Practitioner for he is eminently better qualified than the patient to choose the best consultant when referral is advisable.

He can eliminate spending time and money on multiple visits to a number of specialists who, in turn, can then devote their valuable time to those cases which need the intensity of their specific knowledge.

Cancer Family Syndrome

The Medical Genetics Section of the Department of Preventive Medicine and Public Health at Creighton University School of Medicine, Omaha, Nebraska, is interested in the study of patients showing an increased incidence of any histological variety of cancer in their families. Of particular interest to us is the cancer family syndrome, characterized by: (1) increased frequency of adenocarcinoma of all sites, particularly of the colon and endometrium, (2) early age at onset of cancer, (3) increased occurrences of multiple primary malignant neoplasms, and (4) autosomal dominant inheritance.

We are currently updating two large cancer families having the above characteristics who live primarily in the Midwest, in middle and northwestern Missouri, Iowa, Nebraska, Colorado, Michigan, Indiana, and Illinois. The initial phases of the investigations of the families have been published (Lynch, H. T., et al.: Hereditary Factors in Cancer; Study of Two Large Midwestern Kindreds, Arch Intern Med 117:206, 1966).

Physicians with patients known to have a familial cancer background may write to Henry T. Lynch, M.D., Associate Professor and Chairman, Department of Preventive Medicine and Public Health, Creighton University School of Medicine, 657 North 27th Street, Omaha, Nebraska 68131.

We invite your cooperation in our studies which will include a genealogical and medical investigation of the entire kindred in each case. All information obtained will be shared with family physicians in order to facilitate cancer control.

Special Article

The Doctor, His Emotions and His Heart

BARNEY M. DLIN, M.D.
Philadelphia, Pennsylvania

FROM TIME IMMEMORIAL, the heart has symbolized the care of the soul and the center of man's deepest emotions. Feared and respected, the heart is the organ of sudden death. The cardiovascular system is involved in the phenomenon of emotional life, especially in the expression of anxiety, the most common of all patient complaints. The emotions can alter pulse rate, stroke volume, cardiac output, blood pressure, blood clotting, blood shift, and blood chemistry. Little wonder, then, that passions and attitudes play a major role in the precipitation and aggravation of cardiovascular disease.

For over a century and a half occasional reports appeared in the literature delineating the connection between the emotions and coronary disease. In 1901 Sir William Osler stated that he believed emotion was the most common but least serious cause of angina pectoris. In describing the "coronary type," he pointed out: "It is not the delicate neurotic who is prone to angina, but the robust and vigorous in mind and body, the keen and ambitious man, the indicator of whose engine is always set at 'full speed ahead.' There is indeed a frame and facies at once suggestive of angina—the 'well-set man of from 45–55 years of age, with military bearing, iron-gray hair and florid complexion.'" Osler also commented on the high frequency of this affection among doctors, stating: "Yet, if hard work alone was responsible, would there not be a great many more cases? Everyone of these men (doctors) had an added factor—worry."

Emotional Factors

Anecdotal observations by astute clinicians are valuable; most are made on the acute effect of emotions in precipitating angina and/or sudden death. It was not until the middle of this century that systematic studies of the emotions and the heart were started.[18] Dunbar, in a psychiatric study of 22 patients, described a typical personality profile. Arlow also found a clear-cut constellation of personality traits in patients with coronary disease. Both found evidence for compulsive, competitive striving and concluded that the character structure of the patient predisposes to coronary occlusion. Dunbar referred to the "coronary personality" consisting of "compulsive striving, hard work, self-discipline and great need to get to the top." Both emphasized the psychodynamic importance of the patient's childhood conflicts with authority; Arlow described an early competitive relationship with a much feared and envied parent (usually the father). He states that the characteristic defense mechanisms used in dealing with this focal conflict were repression and identification, but that they served their purposes inadequately.

Environment

Master and Jaffe (1952), studying the factors in the onset of coronary occlusion and coronary insufficiency, amassed considerable evidence to show that coronary occlusion is not initiated by events in the external environment.

In a large series they found that about one half of the attacks began during sleep and rest, and since the majority of persons spend half the day this way "these activities may be considered coincidental."

Miles, Waldfogel, Barrabee, and Cobb (1954) could find no convincing evidence that the personality exhibited by the coronary patient, as compared to the control subject, could be implicated as a significant factor in the genesis of coronary artery atherosclerosis. They concluded that the similarities between the groups were more striking than were the differences. Miles et al. assumed that coronary occlusion can be precipitated by severe emotional stress but did not concern themselves with this question.

Social Pressures

In 1957 Weiss, Dlin, Rollin, Fischer and Bepler found little evidence to support the concept of a "coronary personality." Rather it seemed that the features attributed to a "coronary personality" might be personality characteristics influenced by cultural factors such as family emphasis on education, ascent in the social scale and material success. Focus of this study was to determine whether patients with coronary artery disease were more subject to emotional stresses prior to the occlusive episode than a matched group. Study of the personality and life situation of patients in an acute coronary occlusion group showed that gradually mounting tension of emotional origin, years or months in duration, occurred prior to the onset of the occlusion. Such tension was manifested by increased smoking and drinking, irritability, anger, insomnia, indecisiveness, social withdrawal and increased dependency on spouse, obsessive thinking, preoccupation with body symptoms, inability to concentrate, disturbances in memory, impotence, depression and fear. These tensions were primarily present in patients under 60 years of age.

A study[8] of 3500 men enrolled in a predictive study of clinical coronary heart disease revealed that certain emotional and environmental factors were dominant: a compulsive drive, aggressiveness and ambition, profound impatience, and immersion in multiple vocational and avocational pursuits fraught with self-imposed deadlines. These men were further noted to exhibit characteristic motor mannerisms in jaw and facial musculature, speech, and hands. Brum, Wolf and others[1,2,3] studied the social aspects of coronary heart disease in two adjacent, ethnically different communities. They found the more homogeneous and stable of the two communities was found to have a lower incidence of treated mental illness; they also noted, as have many others, that social and cultural factors influence the incidence of coronary heart and other diseases.

Heart Attacks—"The Doctor's Disease?"

Aside from Osler's mention of doctors' susceptibility to coronary disease, this area of investigation has remained almost unexplored; only a few[4,5,6,9,11,16,17] have ventured into this field. Perhaps this reluctance to involve ourselves in this area of study stems from personal attitudes.

Who among us has not been shaken by the sight or knowledge of one of our colleagues struck down by a heart attack? For days after, many of us slow down, smoke less, seem more concerned about caring for ourselves. Then, as the fears are denied or repressed, there is a gradual drift back to the increasing demands of work and, like the shoemaker with the shoeless children, we continue to neglect our own physical and mental welfare. Physicians are the great rationalizers and deniers, driven by the altruism of their calling.

The Young Physician

Startling observations[5,6] were made based on cold statistical data from the file of the American Medical Association. The average age of the active physician is 46 years. The young physician entering his profession at an average age of 25 has 43½ years of life ahead of him. In mid-life, at age 45, he may expect a further quarter century of lifetime. Almost 12 additional years remain to the average physician attaining age 65, a frequent age of retirement.

Young physicians have only a slightly greater expectation of life than white persons of the same ages in the general population, but this advantage, one fourth of a year, is lost even before middle mid-life. From age 30 on, the prospective lifetime for the physician is somewhat less than for white persons in the general population, but the differences are not significant. Diseases of the heart and coronary vessels account for 40.7% of the total deaths, far exceeding all other causes. If the recorded death rates from diseases of coronary arteries are considered alone, the ratio of the mortality of physicians to that of white males reaches the high figure of approximately 181%!

The authors conclude that this excess cannot be accounted for entirely by better diagnosis and certification of causes of death. They also suggest that causative factors may be operative though not immediately apparent. They further surmise that the *special activities and burdens of the profession*: the call to service at any time, the constant guard against varied infections, and the need for mental alertness, may well impose unique strains. Hence they recommend minimizing the stresses of the profession so that physicians may achieve the benefits which their favorable position makes possible. From a social and economic viewpoint the untimely death of a physician represents a serious waste because of the important service that is lost and because of the large investment involved in preparation.

General Practitioners

In a statistical study of British physicians between the ages of 35-64 years, Morris, Heady and Barley (1952) made the startling observation that the incidence of coronary disease in 1947-50 among general practitioners was almost twice as high as for all the rest of the profession. Using life-table methods and presuming that the present incidence will continue unchanged, the authors estimate that of 1000 practitioners, aged 35-45, some 20-25 will have a clinical attack of coronary disease before the age of 50; almost another 40 between ages 50-55, another 60 between ages 55-60, and a further 70 between ages 60-65. In other words, medical practitioners under 45 years of age who have not had symptoms of coronary heart disease have approximately a 20% chance of having an attack before age 65.

Other Specialists

From the analysis of 2587 questionnaires completed by physicians, Russek[15,16,17] found that in general practitioners coronary disease was three times more prevalent than in dermatologists and pathologists, thus confirming his thesis that *emotional stress of occupational origin* is one of the important etiologic factors in the genesis of coronary artery disease. Emotional stress of occupational origin may be far more significant than heredity, dietary fat, tobacco, obesity and physical exertion. At the time of the attack, 90% of the coronary subjects (as compared to 20% of the controls) were holding down two jobs, working more than 60 hours a week, or experiencing unusual fear, insecurity, discontent, frustration, restlessness or inadequacy in relation to employment. Extending his original physician survey, Russek compared physicians, dentists and lawyers engaged in general practice or in selected occupational specialties. General practitioners in each field showed coronary rates two to three times higher than those of specialists selected for study.

Testimonials To My "Heart" Attack

Most patients who have suffered from a coronary attack can put the finger on the cause. While recuperating from a heart attack in 1957, Lyndon Johnson told ranch callers that his attack began when he blew his top at an impertinent prying reporter.

Recently Dr. Irvin Page discussed his coronary attack. He recalls that events leading up to the fateful night had been particularly arduous; the turmoil of preparing for a meeting, the rush to the airport, the frustration and worry about plane service, etc. overshadowed the pains in his left chest. In spite of being slim, physically active, and moderate in food and tobacco, he admitted to having inner tensions which he outwardly disguised. Dr. Page now wisely recommends for himself the advice he has been giving his patients over the years. "Take the pressure off. Work at your own pace. Set your own priorities."

Methods of Control

Our approach to the study of patients suffering from acute myocardial infarction does not lend itself to classification according to personality types. More important is the emphasis upon the dynamic factors of personality and the setting in which the illness manifested.

Physicians with a cardiac disorder ordinarily are not referred for emotional help as frequently as non-physicians; they usually enter psychotherapy on their own initiative and for other reasons. In the course of treatment it may be discovered that there was a history of coronary occlusion which the physician has previously glossed over.

The physician is really no different from other human beings. The nature of his work causes him to formulate certain ideas about health, sickness and death and to develop special defenses to cope with the demands of work. He is subject to the same latent forces which affect any other human being.

The fact that the physician is twice as likely to have heart disease as a non-physician and the fact that the general practitioner stands three times the chance the specialist does indicates particular vulnerability related to problems of maladaptation; failure to adjust to the emotional demands of his work and the intrinsic conflicting forces therein.

Heart attacks do not just happen. In the majority of patients, increasing conflict and stress has been building up for months and years. Perhaps the patient was not aware of it, or if he was, he ignored it. No doubt his wife knew about it but felt helpless to do anything. When the attack comes, a significant percentage of patients recognize it as inevitable, accept it and make some kind of adjustment. The person who can't or won't is in trouble! Little wonder that the commonest complication of the heart attack among physicians is emotional! Laboratory and experimental evidence for emotional stress resulting in bodily changes is clear, but the ability to integrate our knowledge into effective medical practice is not as easily demonstrable.

Gradually Mounting Tensions

Significant Events

Significant events in the life of the individual usually occur approximately three years prior to the coronary insult. The great majority of these events involve unusual circumstances among persons in close relationship to the patient (e.g., losses or separation, death, serious illness or surgery) accompanied by emotional distress which forces him to make a major adjustment. Failure to do so results in symptoms.

Somatic Symptoms

About one year prior to the coronary episode, there appears a cluster of somatic symptoms—aches, pains, headaches, gastrointestinal distress, sexual difficulties, especially impotence, fatigue, insomnia, etc. with failure to adjust.

Some months before the coronary, further significant events involving the patient occur: e.g., an accident, terminating an affair, planning a big trip, reaching retirement, all endowed with a great deal of personal concern and identification, adding further insult to the patient. Such patients may develop cardiac phobias and fears, though repeated electrocardiograms indicate no evidence of cardiac involvement. There are commonly observed behavioral patterns indicating struggle, defense, submersion, or capitulation.

Games Doctors Play

The Conspiracy of Silence

Most examining physicians avoid the areas of inquiry which deal with emotional conflicts. Similarly, most patients keep their emotional conflicts to themselves for reasons of shame, embarrassment, guilt, etc. Thus, a non-verbal mutual conspiracy of silence is established. It is essential for the examining physician to provide the opportunity for the patient to speak about his personal conflicts and problems. He must listen and then offer judgments or solutions as to how the problems can be met. Most problems can be resolved in this manner; others will need psychiatric consultation for brief or prolonged therapy. Experience has demonstrated that the majority of emotionally-ill post-coronary patients, and especially physicians, need brief psychotherapy. Seldom do they get it!

Variable History

It is not uncommon for one patient to present three different histories to three different doctors, consciously or unconsciously slanted to suit the examining doctor; the variations depend upon who the listening physician is, what the patient feels the physician expects to hear, how hurried the interview is, what the circumstances are, etc.

The following three histories were taken from a physician patient by a medical resident, cardiologist, and psychiatrist respectively. In the first two histories, the patient made reference to nervous problems. Both examiners, however, avoided exploration in this area.

Case Histories

Case History: By Resident

C.C.: Myocardial infarction.

H.P.I.: "46-year-old white male physician in good health until two weeks ago when he noticed an elevation of blood pressure. *This caused him some anxiety* since this was a first occurrence. He then went on a cruise where he suffered some dyspnea. He didn't think much about this, but later had an electrocardiogram which showed some minor changes. He rested until return to port and was then admitted to hospital."

F.H.: Father died of myocardial infarction, rest negative.

Soc. Hist.: Smokes two to three cigarettes per day, rest negative. Remainder of history unremarkable.

Comments: This is a typical medical history given by a doctor patient who was not about to tell the resident anything except the "essential" medical data.

Case History: By Cardiac Consultant

"This 46-year-old physician states that, *aside from occasional nervousness* and a spell which he thought was due to heart disease in 1957, he regarded himself as well until two weeks prior to admission. Ten years ago he was conscious of an uneasiness in his left lateral chest wall. The uneasiness radiated to the precordial and midsternal regions. He suspected heart disease, saw his physician who took an electrocardiogram and reassured him. In recent months he has had *considerable emotional distress,* the nature of which he has not discussed with me.

Two weeks before admission he was *"pushing hard"* and under considerable tension, when he again felt queazy. He felt that his pulse was irregular. His blood pressure was 230/120. Frightened, he called his doctor. By the time the doctor arrived, the patient's pulse was regular and his blood pressure normal. Everything seemed fine and he was told that he might go on his vacation. At the resort he was quite upset, took his blood pressure almost every two hours. Because of shortness of breath, he saw a doctor where an electrocardiogram was taken. Repeat tracings were normal. The patient felt panicky. A cardiologist told him that his heart was normal. The patient then consulted his own doctor and was admitted to hospital upon return from vacation.

F.H.: Mother is well. Father died of infarction. Only sibling is well.

Soc. Hist.: Eight years ago stopped smoking, *but two months ago started in again because of his emotional tension."*

Comments: The patient provided a number of clues as to problems, including an initial "brush off" which the cardiologist responded to by noting significant tension—which he ignored.

Case History: By Psychiatrist

(Consultation requested by patient)

"Patient was a soft-spoken, gentle person lying calmly in bed surrounded by books, plants, television, radio, nurse, etc. He appeared relaxed and in full control of his emotions.

On my first visit he expressed fear of when the next attack would come. He had been thinking about the onset and was disturbed because he didn't recognize it. Lately he began to feel uncomfortable; he felt his tensions mounting and he was beginning to "think" again.

He stated that for the past year he had been sexually involved with a female patient, and although he has had many previous sexual affairs, this was the first which caused him so much turmoil. He noted feelings of tension, frustration, jealousy, suspicion, apprehension, excessive attachment, etc. He planned a trip to get away from this involvement, and it was in this setting that the feelings described in the history occurred.

Since he has been in the hospital recovering from his heart attack, he notes that he has been thinking of nurses in a sexual way. As he related this, he was visibly tense and shaky. His composure was gone. He stated that his father died while on his first day at work following his first coronary. The patient has been thinking more of his father while in the hospital. He notes also that there are similarities between himself and his father, including the dates and ages related to their respective coronary episodes. As the day of discharge approaches, the patient becomes increasingly anxious, fearing that he, too, may die on the first day back to work as did his father."

Comments: The above data was there for the asking; the clinician need only take the time to ask and listen.

The Doctor As Your Patient

As one physician said following his coronary, "Physicians, as a rule, are poor patients; they know too much and therefore never fully accept the guidance of a doctor as other sick people do. On the other hand, they are unable to approach their own case objectively; they are necessarily biased, and it is more difficult for them to adjust to a diseased condition." (Pinner and Miller . . . "When Doctors Are Patients.")

It has been clearly shown that the treatment received by a physician-patient usually differs from that given the lay-private patient. This may be particularly true of a physician with a coronary insult because the doctor in charge often fails to maintain his objective and empathic role. The patient has difficulty too, either hesitating about making demands on his medical colleague, knowing how overworked he is, or feeling compelled to prescribe for his own treatment by making suggestions and recommendations. For example, the question of a coronary angiogram was left up to the doctor-patient by a consulting cardiologist because the patient was also an astute clinician. "What a hell of a way to treat a patient!" said the doctor-patient.

Generally, physicians who are patients do not want to share the burden for diagnosis and treatment of their heart disease. They are too sick, too afraid, too concerned; they do not trust their own judgment and are not likely to take offense if the therapist does not consult with them on each procedure. But should they react with anger or hurt or resentment at being treated like any other patient, this reaction should be discussed candidly and viewed as a potentially serious obstacle to the doctor-patient relationship. The most reassuring thing that any physician can do for an ill colleague is to take charge. He and his family need the same kind of attention accorded any patient.

Remember the old saying, "The doctor who treats himself has a fool for a doctor and a fool for a patient."

Buckle Up

Many freeway accidents are caused by cars pulled off the road because of mechanical failure. If you plan to use a freeway on your next trip, prepare your car for continuous high speed driving conditions.

Before you go, brakes, exhaust system, windshield wipers and lights should be operating properly. Tires should be in good condition and properly inflated for continuous high speed travel. Fill the fuel tank and check water, fan belt, oil and battery.

On the road stop every two hours to have fuel, water, oil and tire condition checked. You will have to leave the freeway for these stops. Watch for signs indicating exits to service areas.

Learn what your gas gauge means. Know how much gas your tank holds when full, half full, etc. Know how many miles your car can go on a gallon of gas. Too many emergency stops on highways are due to running out of gas. Tire trouble is another of the most common causes.

Green Medicinals*

Herbs for the Liver

Ecclesiasticus said: The Lord hath created medicines out of the earth and a wise man will not abhor them.

Therapeutic herbs for the liver include bogbean, gooseberry, lilac, mandrake, snapdragon, and thistles. For anyone with a taste for gooseberries the following relish can be prepared.

Green Gooseberry Relish

Put into a preserving pan four quarts of green gooseberries, five pounds of brown or white sugar, and a little water. Boil until nearly cooked, then add another five pounds of sugar, a tablespoonful of powdered cloves, the same of powdered cinnamon, and a pint of vinegar, and boil till finished. It should boil three or four hours.*

---

In Memoriam

Death is delightful. Death is dawn,
The waking from a weary night
Of fevers unto truth and light. —*Joaquin Miller*

EDMUND M. McLAUGHLIN, M.D.

Dr. Edmund M. McLaughlin, 91, one of the founders of the Winona Clinic, died November 28. Born in Owatonna, Minnesota, Dr. McLaughlin graduated from McGill University Medical School, Montreal, in 1903.

He was a fellow in the American College of Surgeons and a member of the American Medical Association and the Winona County Medical Society. He was a 50 Club and Life Member of the Minnesota State Medical Association.

Dr. McLaughlin is survived by his wife.

GEORGE E. FAHR, M.D.

Dr. George E. Fahr, 86, former medical chief at the Minneapolis General Hospital and head of the University of Minnesota Heart Clinic, died December 3. He had retired from both positions in 1950 but had kept active as a consultant and medical specialist at the Anoka State Hospital until six years ago.

Dr. Fahr was credited with introducing the electrocardiogram into wide use in this country.

He was born in Meadville, Pennsylvania, and graduated from the University of Chicago in 1904.

He is survived by his wife, a daughter and two sons.

RUSSEL EDWARD CARLSON, M.D.

Dr. Russel E. Carlson, 51, Stillwater physician, died November 16. He was born at Montrose and graduated from the University of Minnesota Medical School in 1939.

He was a member of the Washington County Medical Society and had been president of that society in 1955 and 1958. Dr. Carlson was a former member of the Professional Liability Committee of the Minnesota State Medical Association and had served as a delegate to that Association from 1959 through 1966. He was a member of the American Medical Association.

Dr. Carlson is survived by his wife, one son and five daughters. Dr. Vernon Carlson of Buffalo, Minnesota, is his brother.

THOMAS MOE, M.D.

Dr. Thomas Moe, 75, Moose Lake physician, died October 27. Born in St. Paul, Dr. Moe graduated from the University of Minnesota Medical School in 1924. In 1925 he and Mrs. Moe moved to Moose Lake where he took over the operation of the Moose Lake Community Hospital. Dr. Moe had been a surgeon and physician for the Moose Lake area for the past 43 years.

He was a member of the St. Louis County Medical Society and the American Medical Association and a Life Member of the Minnesota State Medical Association.

Dr. Moe is survived by one daughter and two sons.

HENRY E. BINET, M.D.

Dr. Henry E. Binet, 79, Grand Rapids retired physician and surgeon, died November 13. He had lived in Grand Rapids 52 years. Born in Marquette, Michigan, Dr. Binet attended the Northwestern University Medical College.

He was a fellow of the American College of Physicians and Surgeons, member of the Range Medical Society, former member of the Itasca County Hospital and Welfare Board, member of the American Medical Association and an Associate and 50 Club Member of the Minnesota State Medical Association.

Dr. Binet helped establish and build an occupational therapy pavilion at the Itasca County Nursing Home and a nursing home chapel which is named after him.

He is survived by his wife, a daughter and a son.

GEORGE I. BADEAUX, M.D.

Dr. George I. Badeaux, 80, Brainerd surgeon, died October 29. Born in Brainerd, Dr. Badeaux was a lifetime resident.

For many years he served as secretary of the Upper Mississippi Medical Society, was a fellow in the American College of Surgeons, Member of the American Medical Association and a 50 Club and Life Member of the Minnesota State Medical Association.

He is survived by his wife and three sons.

LEONARD M. LARSON, M.D.

Dr. Leonard M. Larson, 72, tuberculosis specialist, died October 19. Born in Minneapolis, Dr. Larson received his medical degree from the University of Minnesota Medical School.

He was a member of the Hennepin County Medical Society and the American Medical Association and an Associate Member of the Minnesota State Medical Association.

He is survived by his son and a daughter.

FRANCIS J. LEPAK, M.D.

Dr. Francis J. Lepak, Duluth physician for nearly 60 years, died January 6. He was 86. Born in Gnesen Township, he was a graduate of the Northwestern University Medical School.

Dr. Lepak was a member of the St. Louis County Medical Society, the American Society of General Practitioners and the American Medical Association. He was a 50 Club and Life Member of the Minnesota State Medical Association. He was on the staff of St. Mary's, St. Luke's and Miller hospitals.

He is survived by three sons.

E. LAWRENCE MEYER, M.D.

Dr. E. Lawrence Meyer, 86, well-known Minneapolis physician, died July 2. Born in St. Louis, Missouri, Dr. Meyer attended the University of Minnesota Medical School where he obtained his medical degree in 1905.

He was a member of the Hennepin County Medical Society and the American Medical Association and a 50 Club and Life Member of the Minnesota State Medical Association.

He is survived by his four grandchildren.

JOSEPH E. HALPIN, M.D.

Dr. Joseph E. Halpin, 63, Rush City physician, died January 1. Born in Alma Center, Wisconsin, Dr. Halpin graduated from the Marquette University Medical School. He came to Rush City in 1930 and practiced medicine there until his death.

He was a member of the East Central Minnesota Medical Society, the Minnesota State Medical Association and the American Medical Association.

Dr. Halpin is survived by his wife and two sons.

WALLACE A. GLEASON, M.D.

Dr. Wallace A. Gleason, St. Paul surgeon, died December 26. Born in Hillsboro, North Dakota, Dr. Gleason attended and graduated from the University of Minnesota Medical School.

He was a member of the Ramsey County Medical Society, the Minnesota State Medical Association and the American Medical Association.

Dr. Gleason is survived by his wife and three sons.

After the Winter . . . God Sends the Spring

Springtime is a season
Of Hope and Joy and Cheer,
There's beauty all around us
To See and touch and hear . . .
So, no matter how downhearted
And discouraged we may be,
New Hope is born when we behold
Leaves budding on a tree . . .
Or when we see a timid flower
Push through the frozen sod
And open wide in glad surprise
Its petaled eyes to God . . .
For this is just God saying—
"Lift up your eyes to Me,
And the bleakness of your spirit,
Like the budding springtime tree,
Will lose its wintry darkness
And your heavy heart will sing"—
For God never sends The Winter
Without the Joy of Spring.

Helen S. Rice

Meetings and Announcements

There is no great concurrence between learning and wisdom.—Francis Bacon.

FEBRUARY

Scott-Carver County Medical Society, Regular Meeting, Wagner's Supper Club, Jordan, 6:30 P.M., February 4.

Thirty-Second Annual Meeting
The New Orleans Graduate Medical Assembly

The thirty-second annual meeting of The New Orleans Graduate Medical Assembly will be held March 10, 11, 12, 13, 1969, headquarters at The Roosevelt Hotel.

Nineteen outstanding guest speakers will participate and their presentations will be of interest to both specialists and general practitioners. The program will include fifty informative discussions on many topics of current medical interest, in addition to a clinicopathologic conference, medical motion pictures, round-table luncheons, and technical exhibits. This program is acceptable for three and one-half (3½) prescribed hours and twenty-eight (28) elective hours by the American Academy of General Practice. An interesting and enjoyable program of entertainment for visiting ladies has been planned.

Electroencephalography Course

A course in Current Problems in Electroencephalography: Advances toward their Solution; Date: March 13-15, 1969, Place: Houston, Texas. Sponsors: The American Electroencephalographic Society and Baylor University College of Medicine. For further information contact: Dr. Peter Kellaway, Baylor University College of Medicine, Texas Medical Center, Houston, Texas 77025.

(Continued from page 349)

ST. PAUL: Spacious suite in new split-level building, partitioned for medical offices. Other level occupied by dentist. Excellent location adjacent to large shopping center. 1504 White Bear Avenue, 774-7144.

Oxboro Medical Clinic for sale in Bloomington, Minnesota's third largest city. Earn attractive return while current lease expires in four years. Clinic comfortably houses 11 doctors, each with 3½ examination rooms. Central air conditioning, adequate parking, and much more. Contact Towle Real Estate Co., 333-2445, Area Code 612.

GENERAL PRACTITIONER WANTED: To associate with Physician-Surgeon in Owatonna, a Southern Minnesota community, 25,000 population. Clinic building 3 years old; with five large treatment rooms; lab; x-ray; central supply; two doctors' offices; pharmacy; and business offices. Located next door to 85 bed City Hospital. Good opportunity for partnership. Contact: O. W. Roberts, M.D., 920 South Cedar Street, Owatonna, Minnesota. Phone 451-4630.

EXPERIENCED GENERAL PRACTITIONER: Available for Locum Tenens. One or two week periods. After April 1st. Solo practice preferred. Write Minnesota Medicine 385, 375 Jackson, St. Paul, Minn. 55101.

RESIDENTS IN PSYCHIATRY: Vacancies for July 1, 1969. Three years approved eclectic residency program with emphasis on community psychiatry, milieu, individual and group therapy. 350 inpatients; large outpatient dept.; children's unit; excellent senior staff; affiliation with University of Iowa. Stipend $15,000 for residents with Iowa license or immediate eligibility for regular license. Stipend for foreign graduates who must have ECFMG, $12,240. Federal stipend available to physicians with four years non-psychiatric training or experience following internship amounting to $15,000 annually, of which $3600 is tax exempt. Enthusiastic and dynamic training and treatment programs that are best understood by a personal visit. Write or call W. C. Brinegar, M.D., Supt., or William Blyth, M.D., Mental Health Institute, Cherokee, Iowa.

NINETEEN-MAN Wisconsin group located in college community of 40,000 with excellent hospital facilities is seeking additional associates in the following areas: (1) Internal Medicine, (2) General Practice, (3) Pediatrics and (4) Orthopedics. For further information please contact D. R. Griffith, M.D., Midelfort Clinic, Eau Claire, Wisconsin 54701.

GENERAL PRACTICE AVAILABLE. Retiring because of age. Fine clientele. Progressive town of 50,000 with large referral area. Excellent Hospital and University facilities. Air conditioned offices in good location. Contact T. Q. Benson, M.D., 1524 Walnut Street, Grand Forks, N. D.

INTERNIST: Board certified or eligible. 269-bed General Medical and Surgical Hospital in Michigan's Upper Peninsula. Licensure any state, salary dependent upon background and qualifications. Excellent benefits for retirement, vacations, sick leave, and professional improvements. Non-discrimination in employment. Contact Chief of Staff, VA Hospital, Iron Mountain, Michigan 49801.

SECOND GENERAL SURGEON needed by busy twelve man specialty group in attractive Minnesota community of 15,000; unique industrial, business and recreational center close to the Twin Cities; ideal family environment with all cultural and recreational facilities available; new clinic and new hospital; weekend coverage assured; terms negotiable; paid interview. Write or call collect: Administrator, The Interstate Medical Center, P.A., Red Wing, Minn. Tel. No. 388-3503.

OB-GYN—Join group of 4 GP's. Immediate work load: Time off assured. Early partnership opportunity. Well equipped clinic, established in 1962, recently expanded, in growing community of 7,000, 30 minutes from downtown Minneapolis-St. Paul. Fully accredited 116 bed hospital in community. Call or write J. E. Ponterio, M D. (612) 445-1305.

PROFESSIONAL OFFICE SPACE over 500 or 1000 sq. ft. carpeted, paneled, new dec. in new bldg. Hwy. #13 & 35 W., Burnsville. Doctors urgently needed for this area. reas. rent. Tel. 454-1233.

Physicians mend or end us; but though in health we sneer, when sick we call them to attend us, without the least propensity to jeer.—Lord Byron

A human being is an ingenious assembly of portable plumbing.—Chrisopher Morley.

A conservative is a man who just sits and thinks, mostly sits.—Woodrow Wilson.

Minnesota Medicine at a Glance

The Anatomy of the Facial Nerve—*Kullmann and Cody* Page 213

The makeup and distribution of the facial nerve is described.

Abdominal Aortic Aneurysm—*Gambill* Page 227

There have been many cases reported in which an abdominal aortic aneurysm has ruptured into the duodenum with fatal results. The present case exhibits features which made the true diagnosis obscure even to experienced physicians. The pain was slowly progressive and confined to the lower abdomen. There was consistent loss of weight and strength suggesting malignancy. Confirmatory laboratory tests of pancreatic malignancy were present. If the patient had not elected to defer exploration, perhaps the outcome would have been happier.

Open Heart Surgery—*Kiser et al.* Page 231

Four patients with an average age of 75 are presented who successfully underwent open heart valvular surgery.

Three Basic Brain Models—*Buckley* Page 235

The phylogenetic development of the primate nervous system basically involved the integration of three brains: (1) the reptile brain; (2) the early mammalian or visceral brain; and (3) the primate brain or neocortex. The author traces the historical appearance of three conceptual brain models that led to a more complete understanding of the functioning of the primate central nervous system including the mind.

Pernicious Anemia in North American Indians—*Olin and Harrington* Page 243

Two cases of pernicious anemia in North American Indians of mixed parentage are reported from the Fargo Clinic and Neuropsychiatric Institute. The disease is rare among among Indians, Eskimos, and Orientals. The authors found no previous cases reported and believe the disease among Indians is inherited from admixture of genes from Caucasians.

Acute Neurological Deterioration Following Lumbar Puncture—*Long et al.* Page 247

The necessity of a diagnostic test is measured principally by whether its results will affect the plan for investigation or treatment of a patient. The authors re-emphasize the importance of this rule in the use of lumbar puncture by citing six cases in which adverse side effects followed this procedure when it was employed ill-advisedly. The conditions under which it may be required and the precautions that should be observed are discussed.

The Doctor, His Emotions and His Heart—*Dlin* Page 369

Dr. Dlin calls our attention to the increased incidence of cardiac disorders among physicians. His suggestions for re-orienting our schedules, work obligations, etc., are timely, as are also his suggestions for the physician who cares for a colleague with a cardiac insult.

Hospital

MARCH, 1969

Special Issue

Wilford Hall USAF Hospital
Lackland Air Force Base, Texas

For the "Cheater Eater"

Formulas: Each 'Dexamyl' *Spansule* capsule No. 1 contains 10 mg. of Dexedrine® (brand of dextroamphetamine sulfate) and 1 gr. of amobarbital, derivative of barbituric acid (Warning, may be habit forming). Each 'Dexamyl' *Spansule* capsule No. 2 contains 15 mg. of Dexedrine (brand of dextroamphetamine sulfate) and 1½ gr. of amobarbital (Warning, may be habit forming).
Before prescribing, see complete prescribing information in SK&F literature or *PDR*.
Contraindications: Hyperexcitability, undue restlessness, hyperthyroidism, porphyria; in patients on MAO inhibitors.
Precautions: Use with caution in patients hypersensitive to sympathomimetics or barbiturates and in coronary or cardiovascular disease or severe hypertension. Excessive use of the amphetamines by unstable individuals may result in a psychological dependence. Rarely, symptoms of toxic psychosis (hallucinations, confusion, panic states, etc.) may occur with amphetamines, usually after prolonged high dosage. In these instances, withdraw the medication. Use cautiously in pregnant patients, especially in the first trimester.
Adverse Reactions: Overstimulation, restlessness, insomnia, g.i. disturbances, diarrhea, palpitation, tachycardia, elevated blood pressure, tremor, sweating, impotence and headache.
Supplied: In bottles of 50.

Dexamyl®

brand of dextroamphetamine sulfate and amobarbital

Spansule®

brand of sustained release capsules

curbs appetite
encourages normal activity
dispels diet discouragement

LACTINEX®

TABLETS & GRANULES

- **to help restore and stabilize the intestinal flora**
- **for fever blisters and canker sores of herpetic origin**

Lactinex contains both *Lactobacillus acidophilus* and *L. bulgaricus* in a standardized viable culture, with the naturally occurring metabolic products produced by these organisms.

Lactinex has been shown to be useful in the treatment of gastrointestinal disturbances, and for relieving the painful oral lesions of fever blisters and canker sores of herpetic origin.[1,2,3,4,5,6,7,8]

No untoward side effects have been reported to date.

Literature on indications and dosage available on request.

When he needs an antibiotic
he may be a candidate for

DECLOSTATIN® 300

Demethylchlortetracycline HCl 300 mg
and Nystatin 500,000 units
CAPSULE-SHAPED TABLETS Lederle

b.i.d.

o guard susceptible patients against intestinal monilial overrowth during broad-spectrum therapy—the protection of ystatin is combined with demethylchlortetracycline in ECLOSTATIN.

For your susceptible candidates, prescribe DECLOSTATIN -the broad-spectrum therapy that prevents monilial vergrowth.

ffectiveness: Because its antibacterial component is DECLOMYCIN emethylchlortetracycline, DECLOSTATIN should be equally or more ffective therapeutically than other tetracyclines in infections caused by tracycline-sensitive organisms. The antifungal component, Nystatin, rotects against superinfection by antibiotic-resistant fungal overgrowth particularly monilia) in the intestinal tract.

ontraindication: History of hypersensitivity to demethylchlortetracyine or nystatin.

arning: In renal impairment, usual doses may lead to excessive accumlation and liver toxicity. Under such conditions, lower than usual doses re indicated, and, if therapy is prolonged, serum level determinations ay be advisable. A photodynamic reaction to natural or artificial sunght has been observed. Small amounts of drug and short exposure may roduce an exaggerated sunburn reaction which may range from eryema to severe skin manifestations. In a smaller proportion, photolergic reactions have been reported. Patients should avoid direct posure to sunlight and discontinue drug at the first evidence of skin iscomfort. Necessary subsequent courses of treatment with tetracyines should be carefully observed.

Precautions: Overgrowth of nonsusceptible organisms may occur. Constant observation is essential. If new infections appear, appropriate measures should be taken. In infants, increased intracranial pressure with bulging fontanels has been observed. All signs and symptoms have disappeared rapidly upon cessation of treatment.

Side Effects: Gastrointestinal system—anorexia, nausea, vomiting, diarrhea, stomatitis, glossitis, enterocolitis, pruritus ani. Skin—maculopapular and erythematous rashes; a rare case of exfoliative dermatitis has been reported. Photosensitivity; onycholysis and discoloration of the nails (rare). Kidney—rise in BUN, apparently dose related. Transient increase in urinary output, sometimes accompanied by thirst (rare). Hypersensitivity reactions—urticaria, angioneurotic edema, anaphylaxis. Teeth—dental staining (yellow-brown) in children of mothers given this drug during the latter half of pregnancy, and in children given the drug during the neonatal period, infancy and early childhood. Enamel hypoplasia has been seen in a few children. If adverse reaction or idiosyncrasy occurs, discontinue medication and institute appropriate therapy. Demethylchlortetracycline may form a stable calcium complex in any bone-forming tissue with no serious harmful effects reported thus far in humans.

Average Adult Daily Dosage: 150 mg q.i.d. or 300 mg b.i.d. Should be given 1 hour before or 2 hours after meals, since absorption is impaired by the concomitant administration of high calcium content drugs, foods and some dairy products. Treatment of streptococcal infections should continue for 10 days, even though symptoms have subsided.

GENERAL INFORMATION

Authors

Send manuscripts, subscriptions and communications for consideration to MINNESOTA MEDICINE, 375 Jackson Street, St. Paul, Minnesota 55101. Telephone 222-6366.

Illustrations, photographs, tables, graphs, and pen and ink drawings are encouraged.

All manuscripts will be edited and stylized to conform to the format used in MINNESOTA MEDICINE.

Minnesota Medicine Award

An award will be given at the annual meeting to the author of the most meritorious manuscript for the preceding year.

Readers and Reviewers

The right is reserved to reject material submitted for reading or advertising columns. The views expressed in this journal do not necessarily represent those of the Minnesota State Medical Association or any of its constituents.

Advertisers and Subscribers

118th Annual Convention
AMA
NEW YORK CITY
JULY 13-17, 1969

The magnetism and the grandeur that characterizes New York City will provide a superb setting for AMA's 118th Annual Convention in July. Plan to attend now and look forward to five memorable and stimulating convention days in a city of unlimited excitement.

Continue your postgraduate education with a varied program of • four General Scientific Meetings on Chronic Pulmonary Insufficiency and Problems of Air Pollution, Human Sexuality, Impact of Medical Education on Patient Care, and Physical Fitness and Aging • 23 Section Programs • Color Television • Medical Motion Pictures • and over 700 scientific and industrial exhibits. The nation's outstanding medical authorities will lecture and discuss the significant advances in today's medicine.

In addition the AMA TV network will present more than 40 hours of convention programming.

Reserve now for the Scientific Awards Dinner in honor of the Scientific Award Winners—Wednesday, July 16, 1969. Since space is limited, we suggest you make your reservations before June 30, 1969. Tickets are $10.00 each, payable in advance.

The complete scientific program, plus forms for advance registration and hotel accommodations, will be featured in JAMA, May 26, 1969.

President's Letter

Our Notable Predecessors

"The skill of the physician shall lift up his head and in the sight of great men he shall be in admiration." (Ecclesiasticus 38:3)

THE PHYSICIAN can take pride in his lineage. Stone Age surgeons set fractures and with their flint tools, amputated digits and extremities and trepanned skulls (to release demons). Ancient Egypt had physicians for various parts of the body. Outstanding physicians were deified—in Egypt, Imhotep, and in Greece, Aesculapius (who sired daughters Hygeia and Panacea and was surgeon-in-chief of the Argonauts in search of the golden fleece). Hippocrates (460 B.C.) treated dislocations of the hip, shoulder and jaw. Celsus (14 A.D.) has been called the father of plastic surgery; his De Re Medicina was one of the first printed medical books, and that in 1478.

Claudius Galen (born in Greece about 130 A.D.) was outstanding in his day and for fifteen centuries thereafter. Not without conceit, he credited Hippocrates but stated, "His knowledge in some subjects is not sufficiently extensive; he is often obscure after the manner of the ancients; in order to be concise, he opened the road, but I have rendered it passable." It was said, "Galen was the last of the Greeks and when he spoke no more, the voice of the ancient world was hushed. Galen was the final star that shone in the twilight of antiquity, and when his effulgence was extinguished, there settled over Europe a darkness that was not lifted for many centuries."

Limitations of time and space permit mention of only a few of the great physicians. Herophilus (anatomy) and Erasistratus (physiology) publicly dissected live condemned criminals. Dioscorides was an army surgeon in the service of Nero—a great botanist, he praised the merits of opium. Abu Bekr Mohammed el-Razi (Rhazes, 865-925), a Persian, performed tracheotomies, set fractures, used animal gut sutures, and founded many hospitals. Ibn Sina (Avicenna, 980-1037), also Persian, was to the Moslems what Galen was to the Romans. From the great medical school in Salerno (established by Benedictine monks on the advice of Arab physicians) came the Regimen Sanitatis Salerni (presumably authored by John of Milan). Incidentally, this was a base hospital for the Crusaders.

John of Murfield (England—late 1300's) is remembered for the couplet:

> "When Physick's dearly bought, it doth much healing bring,
> But when 'tis freely given, 'tis ne-er a useful thing."

Ambroise Paré (1510-1590) "restored surgery to a worthy place." John Hunter (1728-1793) was an outstanding English Army and Naval surgeon. Corvisart (1755-1821) was physician-in-ordinary to Napoleon. Joseph Lister (1827-1912) made surgery safe. Crawford Long introduced ether (1842) and James Young Simpson chloroform (1847); Oliver Wendell Holmes coined the term anaesthesia.

Guy deChauliac (14th century), sometimes called the father of modern surgery, wrote in his Chirurgia Magna:

It's almost as if you were there to give an injection of penicillin

V-Cillin K®, Pediatric dependable oral penicillin therapy

Potassium Phenoxymethyl Penicillin

Description: V-Cillin K, the potassium salt of V-Cillin® (phenoxymethyl penicillin, Lilly), combines acid stability with immediate solubility and rapid absorption. Higher, more rapid serum levels are obtained than with equal oral doses of penicillin G.

Indications: Streptococcus, pneumococcus, and gonococcus infections; infections caused by sensitive strains of staphylococci; prophylaxis of streptococcus infections in patients with a history of rheumatic fever; and prevention of bacterial endocarditis after tonsillectomy and tooth extraction in patients with a history of rheumatic fever or congenital heart disease.

Contraindication: Penicillin hypersensitivity.

Warnings: In rare instances, penicillin may cause acute anaphylaxis which may prove fatal unless promptly controlled. This type of reaction appears more frequently in patients with a history of sensitivity reactions to penicillin or with bronchial asthma or other allergies. Resuscitative drugs should be readily available. These include epinephrine and pressor drugs (as well as oxygen for inhalation) for immediate allergic manifestations and antihistamines and corticosteroids for delayed effects.

Precautions: Use cautiously, if at all, in a patient with a strongly positive history of allergy.

In prolonged therapy with penicillin, and particularly with high parenteral dosage schedules, frequent evaluation of the renal and hematopoietic systems is recommended.

In suspected staphylococcus infections, proper laboratory studies (including sensitivity tests) should be performed.

The use of penicillin may be associated with the overgrowth of penicillin-insensitive organisms. In such cases, discontinue administration and take appropriate measures.

Adverse Reactions: Although serious allergic reactions are much less common with oral penicillin than with intramuscular forms, manifestations of penicillin allergy may occur.

Penicillin is a substance of low toxicity, but it possesses a significant index of sensitization. The following hypersensitivity reactions have been reported: skin rashes ranging from maculopapular eruptions to exfoliative dermatitis; urticaria; and reactions resembling serum sickness, including chills, fever, edema, arthralgia, and prostration. Severe and often fatal anaphylaxis has occurred (*see* Warnings). Hemolytic anemia, leukopenia, thrombocytopenia, and nephropathy are rarely observed side-effects and are usually associated with high parenteral dosage.

Administration and Dosage: Usual dosage range, 125 mg. (200,000 units) three times a day to 500 mg. (800,000 units) every four hours. For infants, 50 mg. per Kg. per day divided into three doses.

See package literature for detailed dosage instructions for prophylaxis of streptococcus infections, surgery, gonorrhea, and severe infections.

How Supplied: Tablets V-Cillin K® (Potassium Phenoxymethyl Penicillin Tablets, U.S.P.), 125 mg. (200,000 units), 250 mg. (400,000 units), and 500 mg. (800,000 units).

V-Cillin K® (potassium phenoxymethyl penicillin, Lilly), Pediatric, for Oral Solution, 125 mg. (200,000 units) and 250 mg. (400,000 units) per 5 cc. of solution (approximately one teaspoonful). [042567A]

Anterior Spinal Fusion

PAUL W. MYERS, Colonel, USAF, MC*

"THE NOVELTY OF A METHOD naturally leads to the enthusiasm of its exponents, and the claims which are first put forward need to be tempered by the experience gained with time.[11]† With this consideration in mind, our experience with the anterior fusion operation is presented.

Indications

The anterior approach to vertebral bodies and intervertebral discs, as well as to the cervical canal and its contents, has become the established method for managing the following conditions: (1) drainage of paravertebral cervical abscesses, and (2) removal of partially destroyed bodies caused by malignancies, intradural extramedullary anterior extensions of benign neoplasms, crushed or comminuted vertebral bodies caused by trauma, damaged discs caused by trauma, central disc fragments, posterior spondylotic ridges compromising the canal, osteophytes compromising nerve root takeoff, and soft lateral fragments.

No current operative method constitutes a less morbid approach to the anterior cord surface and those structures lying anterior to it than the anterior operation. Some surgeons have advocated the anterior route for cervical cordotomy also, but our experience with this operation is limited.

The soft lateral extruded disc can be removed easily by an anterior or a posterior approach. There are proponents of each technique, and no valid argument can be made for either method because both are equally effective.

The indications and problems attendant on the anterior approach in the cervical region are identified as the result of a study of the first 213 of 297 patients seen between November 2,

---

*From the Neurosurgery Service, Department of Surgery, Wilford Hall USAF Hospital, Lackland Air Force Base, Texas.

†Bowsher, D.: Cerebrospinal Fluid Dynamics in Health and Disease, American Lecture Series, Springfield, Ill.: Charles C. Thomas, Publisher, p. 8, 1960.

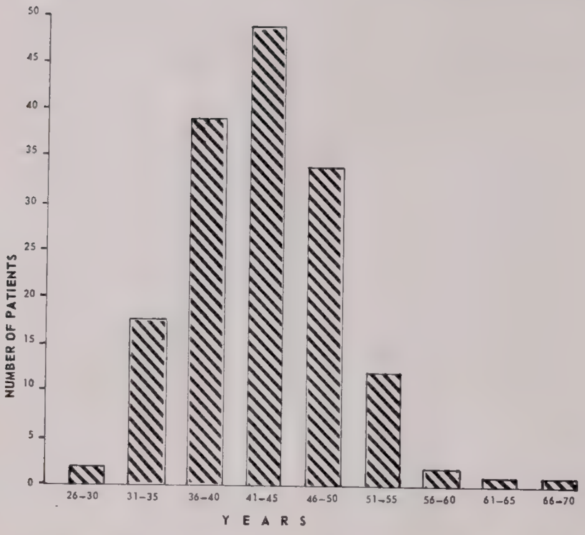

Fig. 1—Distribution of patients by age.

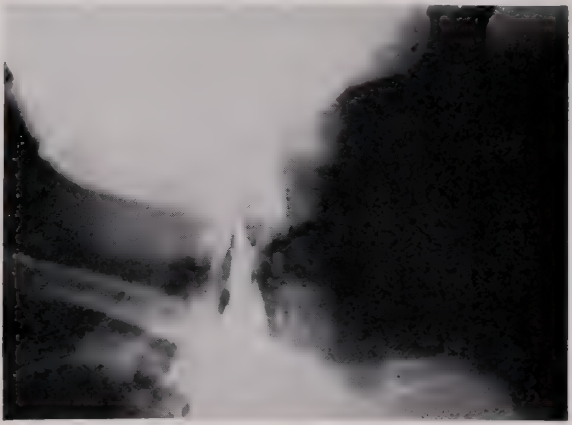

Fig. 2—Oblique view, myelogram of soft lateral disc. (Soft fragment C6/7)

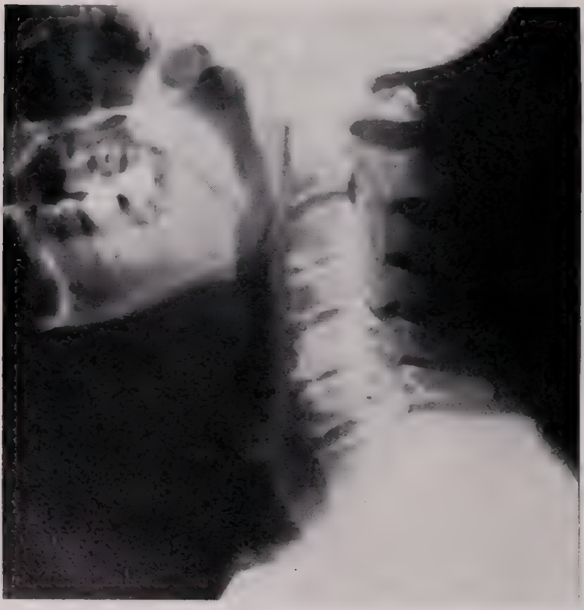

Fig. 3—Spondylosis C5/6, preoperative lateral view.

1961, and July 1, 1968. The most recent 84 patients, seen between July 1, 1967, and July 1, 1968, have not been followed long enough for an adequate evaluation. However, reference will be made to the technique used in some of the later patients.

This paper will discuss only three indications for anterior spinal fusion: (1) relief of root compression caused by "hard" or "soft" discs, (2) myelopathy produced by spondylotic bars, and (3) management of fractures and/or fracture-dislocations. The management of complications encountered will be described. The other indications for the procedure will become the basis for a later paper.

Cervical Disc Disease

Like that of other investigators, our experience indicates that patients with nerve root compromise present fairly typical clinical findings, consisting of neck and/or shoulder pain, radiating arm pain, and extension of that pain to certain finger groups.

Localization Not Specific

Paresthesia of the digits is common, but localization of this complaint is of no value. Fifty-nine of the 158 patients in this group with disease clearly confined to one level noted radiation of pain, paresthesias or numbness to some fingers. Twenty-four patients noted involvement of the thumb and index finger when the level affected was C5/6, and 21 had the same distribution with the disease at C6/7. Five with disease at C5/6 and nine with disease at C6/7 noted problems in the fourth and fifth fingers.

Muscle Weakness

Muscle weakness is of greater localizing value. When the deltoid, shoulder abductors, pectoralis major, or biceps are weak, the problem is invariably at C5/6, but on rare occasions it may be at C4/5. Weakness of the triceps indicates that the C6/7 level is affected. The rapidity of onset of arm weakness has attracted our attention, for it can become extensive within a few hours. Absence of diminution of reflex is supportive. The distribution by sex in the present series of patients is 135 males and 23 females. The distribution by age is shown in Figure 1.

Hard vs. Soft Discs

Cervical disc disease of the hard or soft type is a disease of the middle decades, as the age distribution reveals. If a patient has spondylosis but remains asymptomatic until he is 50 years of age, most likely he will have no difficulty unless he is involved in a traumatic episode.

Myelography has localized the disorder accurately in 157 of the 158 patients; only one had an unsuccessful myelogram. In the few instances when discography was used, it has served to correlate the myelographic findings and has been done at time of operation.

The 158 patients studied have had a combination of both soft and hard disc problems. One fourth of these (38 patients) known to have spondylosis also had free fragments. Identification of fragments can be facilitated by injection of indigo carmine into the disc prior to cleaning out the interspace. These fragments have been over and under the root primarily in the axilla, but some out toward the foramen (Figures 2 through 7).

One-hundred and sixty fusion operations have been done on 158 patients (Table 1). Two patients have been fused at two different levels on separate occasions. Eleven (6 percent) had been operated previously by the posterior approach. One patient had been operated at another clinic and two previously

at this hospital, including one operated twice within ten days. It is significant to note that nine had recurrent symptoms of the same type in the same arm and that seven have had this recurrence in less than two years. The intervals in four patients have been nine, four, three and three years, respectively; two have had their symptoms in the contralateral extremity.

Single level fusions have been done on four at the same level of the posterior approach, (i.e., the same root), and all of them had shown myelographic defects originally. Five patients with initial single level disease have been found to have additional adjacent level defects on a later myelogram. Two-level fusions have been done; these patients have had complete relief. One patient, with a C6/7 block and extensive multiple level disease, had been decompressed from behind at the myelographic block level and one higher, but failed to obtain relief. Six weeks later a three-level fusion was done; the patient became symptom-free. One patient who had had two levels operated from behind returned four years later with the same complaint and the same findings. A repeat myelogram disclosed defects at three levels (C4/5/6/7). A three-level fusion has afforded only minimal relief; however, he is working. There has been no return of intrinsic muscle bulk in the hands.

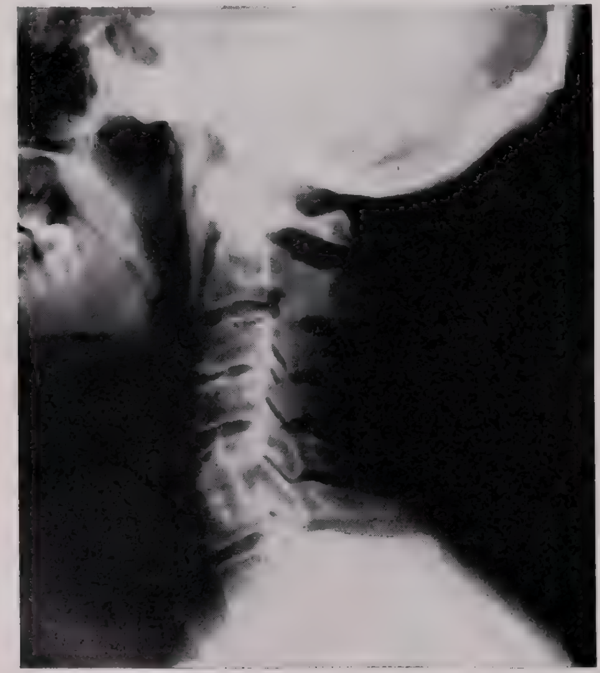

Fig. 7—Spondylosis, postoperative.

Experience with fusion operations indicates that 10 of the 11 patients have had relief of arm and shoulder pain, paresthesias and weakness (Table 2). In addition, one patient who had had a previous anterior fusion at C5/6 elsewhere had recurrent symptoms three months later. Operation after a myelogram showing a C6/7 defect has resulted in removal of a large fragment. Two patients operated at this hospital have required re-operation at another level three years and ten days later, respectively. Re-operation in one patient has been performed because of persistence of severe pain along the medial scapular border, and another adjacent level fused; no free fragment had been overlooked. The patient had gained relief eventually, when osteomyelitis caused a loss of the graft. This patient is discussed under Complications.

Observations on Procedure

Performing anterior fusions in the hard and soft disc group has given an indication of what results can be expected. (1) Vigorous work about the C6 root often produces permanent numbness of the tip of the thumb. (2) Return of the reflex is unpredictable; if it does return, this will occur within 30 days. (3) Atrophy and/or weakness of the intrinsic muscles of the hand may not improve, but gradually worsen. (4) The majority of the patients have immediate relief of pain. (5) Return of shoulder and arm strength is usually rapid, but it is difficult in some patients to determine whether this return of strength is based solely on relief of pain. (6) One of the most common early complaints in this disease is pain along the medial scapular border; for lack of a better term, this well localized area of pain has been labeled "Myer's Point." (7) In patients who have extensive arm weakness and atrophy, improvements are seen as early as three months postoperatively. (8) Removal of free fragments by a laminectomy does not guarantee relief of pain if associated spurs are present. (9) Marked angulation at the graft site occurs infrequently but does not seem to alter the results. (10) Numbness of all fingers indicates both C6 and C7 root compression. (11) Free fragments usually are found when the posterior longitudinal ligament has been torn spontaneously. (12) Any bone used for fusion other than autogenous iliac crest is more likely to prolong the development of a solid fusion.

Incision

Many surgeons on the staff of the Neurosurgery Service have performed the anterior fusion operation, but technique has varied little. If a one-level or two-level fusion is to be performed, the lateral transverse incision on the right side of the anterior neck seems to be efficacious, for two levels can be reached with ease through this approach. If the fusion requires more than two levels, an incision is made along the medial border of the sternocleidomastoid similar to that used for exposure of the carotid artery. The incision can be lengthened in either direction, and several levels can be done with ease. It is important not to be too vigorous with an inferior dissection at the depths of the wound, because recurrent laryngeal nerve palsies have occurred with exuberant traction.

Identification of Interspace

The attack on the interspace begins with radiographic identification. A needle is inserted into the interspace and a cross-table film taken. When the proper space has been identified, indigo carmine is injected in order to identify readily any free disc fragments from the coloring of the material. The Hall air drill has been used more extensively in order to obtain a symmetrical opening between the vertebral bodies.

Removal of Material

Then curettes are taken to remove the disc material. Transverse bars are curetted away, or a Cloward punch is used. The posterior longitudinal ligament is removed when ridges or osteophytes are present. In patients who have relatively acute soft disc disease, the posterior longitudinal ligament is usually disrupted, and if so, it is removed. The standard Cloward instrument is used to remove the iliac bone dowel. Our experience has indicated that when doing more than one level, the dowels cannot "kiss" one another, for, if this occurs, angulation will develop. Use of the Hall drill permits extremely accurate placement of the hole. Angulation can be prevented by allowing plenty of good cervical body to remain between the grafts.

*Severe multiple level spondylosis.

†Intrinsic atrophy remains, occasional neck pain.

‡Operated 2X posterior within 10 days.

Removal of the posterior longitudinal ligament may produce severe neck pain, usually at the base, and radiation into the shoulders. This pain may last three to five days, but it has disappeared by the seventh day in all patients. Blood dissecting along the epidural space may be the cause.

Bone Graft Fusion

It is possible to remove a graft at a later date and replace it with a subsequent solid fusion. Patient No. 57 had a three-level fusion, and his persistent postoperative arm pain led the surgeon to believe that the C6/7 space had not been cleaned out adequately and the roots decompressed. Two weeks after the first operation the C6/7 plug was removed and the space curetted thoroughly. The graft was replaced and the patient was relieved of pain.

Selective myelography has been done several months after surgery in a few patients. The defects seen originally have been absent. In time fusion per se will not melt away lateral foraminal spurs.

Results

The initial chief complaint of each patient in the group was noted. Nine percent complained of arm paresthesias, six percent noted weakness as the first problem, and 85 percent had pain in the shoulder and/or arm. Many had a combination of complaints, but only the chief complaint was listed for this part of the study.

Follow-up periods ranged from five months to six years. Patients seen at intervals of less than five months were not included except in the "immediate relief" group. Fifteen patients had paresthesia as the most significant complaint; eleven noted immediate relief the day after surgery. Seven patients were followed for longer than five months; five of these had excellent results: they were symptom-free. Two patients were judged fair; they still had residual symptoms.

Ten patients complained initially of weakness. Only two were seen for five months or longer; one had an excellent return of muscle strength and the other, a fair return.

Of 133 patients who presented with shoulder and/or arm pain, 121 (90 percent) obtained immediate relief by the first or second postoperative day.

Sixty-seven patients were followed for longer than five months. Thirty-nine patients had excellent results: they were asymptomatic; 21 had mild to minimal symptoms and were considered to have a fair result; and the condition of the other seven was unchanged and, therefore, poor.

Trauma

The 32 patients treated for trauma consisted of 29 males and three females (Figure 8); 73 percent of their injuries occurred when they were less than 30 years of age. Twenty-five patients were injured in automobile accidents, four while diving and three by falls.

Although it is impossible to differentiate fracture types, bony injuries have been assigned to three broad categories. There were eight subluxations, eight fracture-dislocations, and 16 comminuted-compression fractures.

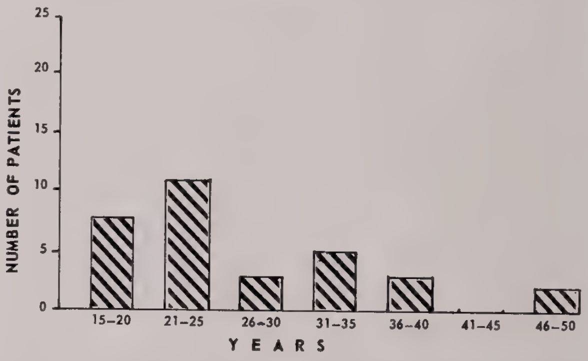

Fig. 8—Distribution by age of patients with trauma.

Absence of Neurologic Correlation

The degree of neurologic injury has no correlation with bony injury (Table 3). For purposes of simplicity the "upper-lower extremity" includes quadriplegia and quadriparesis, "upper extremity" is reserved for patients with arm involvement only, and the last category is "no deficit." Six of the nine patients in the last group complained of significant pain; three had radiating arm pain, and three had persistent neck pain prior to fusion. This small sample represents a most fortunate group of patients. Only two of the eight major injuries were complete; five patients became ambulatory, and one patient, a female, developed quadriparesis after two posterior fusions had failed. A complete 90-degree angulation of C5 on C6 developed. Reconstruction of the neck was done after a posterior laminectomy, and the cord was found to be a ribbon. With traction applied, an anterior approach was done three weeks after the laminectomy. Half of the C4 body and all of the C5 and C6 were removed, and a strut graft was inserted. One and one-half years later the patient had no neck or arm pain. She had complete bowel and bladder function, she could feed herself, and she could ambulate a few steps with assistance. A Brown-Sequard sensory pattern remained with atrophy of intrinsics and a basic quadriparesis. It should be emphasized that not a single one of the five patients was considered to have become ambulatory as a result of the anterior cervical fusion. All of them had either a temporary quadriplegia that had improved markedly before operation, or a quadriparesis that did not preclude ambulation.

Frontal Exploration and Fusion

The author believes that all bony injuries of the neck require frontal exploration and subsequent fusion regardless of the severity or the type of neurologic injury. Patients with complete or partially complete cord injuries benefit from surgery which allows early rehabilitation. This is the single most important factor in the management of these patients. Prolonged traction does not guarantee bony fusion. An eggshell callus was noted in one patient four months after injury; his C6 body had also slipped forward and become badly angulated, with the result that he was quite unstable.

Often realignment is possible in patients who have angulation associated with subluxation. Skeletal traction is applied before fusion, but realignment is not always successful. Patient No. 1 was angulated and subluxed (C6 on C7), but seven months later he was unchanged. Experience of this type has led to body removal and insertion of "bread loaf" grafts. These are pieces of iliac crest with cortical bone on three sides cut to size.

The patient who presents with an anterior tear-drop fracture associated with a compression fracture and posterior displacement, a subluxation or a posterior tear-drop fracture, will certainly produce a hard ridge as the years go by. Prophylactic fusion may preclude a transverse myelopathy if no deficit has occurred with the initial injury.

A posterior decompressive laminectomy may not provide relief from root pain. Patient No. 22, a 22-year-old female, gained relief from left arm pain only after an anterior fusion. Her decompressive laminectomy did not help. She had a compression fracture of C6 with an anterior tear drop.

Skeletal traction and cast immobilization for the usual three-to-four-month period does not guarantee stability. After Patient No. 23, a 34-year-old male with a compression fracture of C5, had been in skeletal traction for six weeks, he was placed in a Minerva jacket for three months. One year later his neurological deficit had increased and he was noted to be subluxed; a myelogram confirmed the C5/6 defect. Realignment was gained with a fusion.

Patient No. 28, a 28-year-old male, presented with a lower extremity paraparesis and weak hand intrinsics. The C7 comminuted fracture was unstable, and at operation the posterior longitudinal ligament was noted to be ruptured. A large free central fragment was lying adjacent to the dura.

Posterior tear-drop fractures are potentially serious hazards. Patient No. 40, with a comminuted C5 body, had a free piece of bone extending 13 mm back into the canal. The resistance of the spinal cord to such abuse is

amazing at times; the patient had no neurologic deficit.

The best method of management for fracture dislocations is: (1) initial skeletal traction, (2) myelography, (3) anterior fusion, (4) maintenance of skeletal traction for four weeks, and finally, (5) immobilization in plaster or in a rigid cervical collar for three months.

The anterior approach is ideal for the patient with an acute central cord injury. Patients treated during the later period not covered in this report were found to have large central free disc fragments, and they presented the characteristic syndrome of weak arms and good legs. Cervical bodies that are badly smashed and malaligned can be removed. Actual reconstruction of the neck can be done with strut grafts (Table 4, Figures 9 through 13).

Long Tract Myelopathy

Patients with long tract signs regardless of symptomatology and with x-ray evidence of osteoarthritic cervical spurring are discussed in the myelopathy category. Twenty-three pa-

tients, consisting of 22 males and one female, were seen with long tract signs. Their age range was from 22 to 57 years; the average age was 40 years.

Trauma that occurred considerably earlier or recently was a causative or an incidental factor in four patients. One other patient, a 47-year-old male, had proven hypoxia of traumatic origin. Five years previously he had had an anaphylactic reaction to pentothal and had become apneic. After a tracheostomy he had awakened with a left-sided weakness and hyperreflexia that cleared in 24 hours. There were no cranial signs or symptoms, but five years later he began to have gradually progressive weakness of the arm and leg.

Single Catastrophic Incident

Some patients presented with a single catastrophic symptom, of considerable interest because of its uniqueness. One patient had complete numbness of all extremities for 20 minutes after a skiing fall; one had his legs buckle while dancing; one had from 50 to 100 electric shocks in the arms while playing handball, i.e., a Lhermitte sign; one fell down while running because of leg incoordination; one was unable to run for cover during an air attack because of leg incoordination; one was unable to move his arms or legs for two hours after a fall; one jumped into a swimming pool during survival training (with marked weakness of arms and legs); one was taken off the baseball team because of stumbling too often while running bases; and one noted the ascent of the sensory level from the feet to the nipple line in one week.

Pain

The symptoms in the upper extremities of patients with myelopathy were variable. Half of them had radiating arm pain, neck pain, paresthesias, and weakness as basic complaints. Eighteen had clonus of the lower extremities that was detected at the knee, the ankle or both; nineteen had hyperactive reflexes; fourteen had spastic gaits, and four had a Lhermitte sign. Incoordination of an arm or leg or both legs was a notable complaint in more than one half of the patients.[13] Eleven (almost half) had a sensory level to pin, and ten of these 11

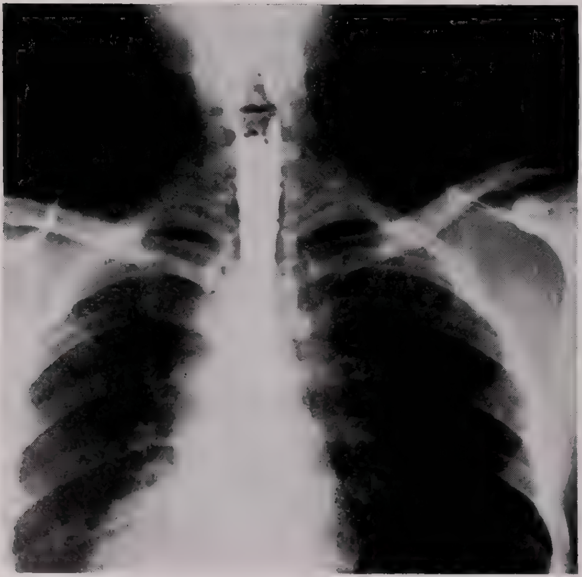

Fig. 15—Spondylosis—long tract signs, myelogram.

were between T4 and T8. It is presumed that a compromised blood supply was the cause. Three patients were classified as Brown-Sequard types.

Radiographic Findings

Radiographs of the neck disclosed hypertrophic spurring, interspace narrowing, and foraminal encroachment in the 23 patients. Myelographic defects of a severe nature were also observed in all patients. A block was found in nine, single-level defects in six, and multiple level defects in the remaining eight. Cerebrospinal fluid protein levels failed to correlate with the severity of disease.

Fusions were done at one level in 11 patients (C3/4 in three, C4/5 in two, and C5/6 in six); at two levels in nine patients (C4/5/6 in four, C5/6/7 in four and C6/7/1 in one patient), and three levels in three patients (C4/5/6/7). The operative findings were of interest. A free central disc fragment was removed from two patients; a calcified central disc indenting the dura was found in two; eleven had a single-level significant ridge, and the remaining eight had multiple ridges.

The degree of long tract involvement is directly related to the result. Admittedly, it is difficult to evaluate results. A patient is better or he is not; but the yardstick of values is variable. A sincere effort was made to note the disappearance of signs, or at least their reduction; some are negligible, but they are present nevertheless.

Hyperactive reflexes diminished in only four of 19 patients. Clonus diminished in five of 18 patients; one patient who had 4+ clonus before surgery had none thereafter. The Babinski sign was reversed in three of four patients. Seven (50 percent of the patients with a spastic gait) had significantly improved ambulation. Pain was alleviated completely in the 11 patients in whom the symptom was disturbing.

Clinical Classification

Patients have been placed arbitrarily into four grades on the basis of the severity of the neurologic deficit:

Grade I. Minimal (3 cases)

Exaggerated reflexes.

Unsustained clonus at knee or ankle.

Grade II. Mild (2 cases)

Signs of Grade I, and weakness of one or both upper extremities.

A sensory deficit, other than of the trunk.

Grade III. Moderate (17 cases)

Signs of Grades I and II, and weakness of one or both lower extremities.

Gait difficulties.

A sensory deficit including the trunk.

Grade IV. Severe (1 case)

Signs of Grades I, II, and III, and inability to ambulate.

For placement in a group, a patient was not required to have all the signs in any group to qualify.

A complete neurological evaluation was done at the end of one month in all but two patients. Twelve were considered improved on the basis of the lessening of reflex hyperactivity, diminution of clonus, increased strength, reversal or lessening of Hoffmann or Babinski signs, lowering of sensory level, or improved gait. One claimed subjective improvement, but no changes in signs were noted. Seven were unchanged and one patient was worse.

Thirteen patients (56 percent) were reexamined from six months to three years after surgery. The one patient who worsened had shown no improvement by the end of two years. Another maintained his subjective improvement. No change occurred in five who originally were unchanged one month after surgery. Seven of the original group (25 percent) were improved; five of these were felt to be significantly improved.

A comparison of these results with those of Stoops and King[1] or those of Clarke and Robinson[2] is not of significant value because of the small number of cases. However, it seems logical to conduct the operative approach from the side where the basic pathology exists if any attempt is to be made at alleviating or at least halting signs and symptoms (Figures 14 through 17).

Complications

The management of the complications of the anterior cervical fusion operation presents a challenge, but experience has demonstrated that they merely delay recovery.

Complications occurred in 74 patients, including ten who had two complications each and one who had three in this series of 213 patients. No deaths occurred immediately. One patient died of pulmonary cancer 18 months after surgery. The complications, which were of 23 types, were grouped into five categories (Table 5).

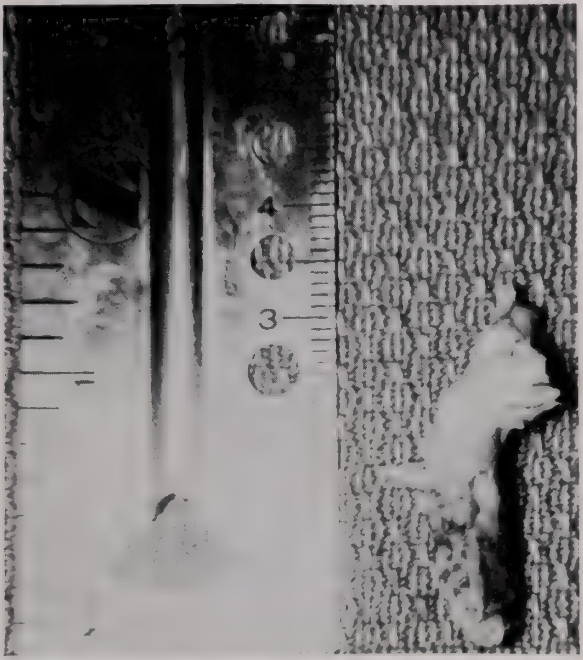

Fig. 16—Large central fragment.

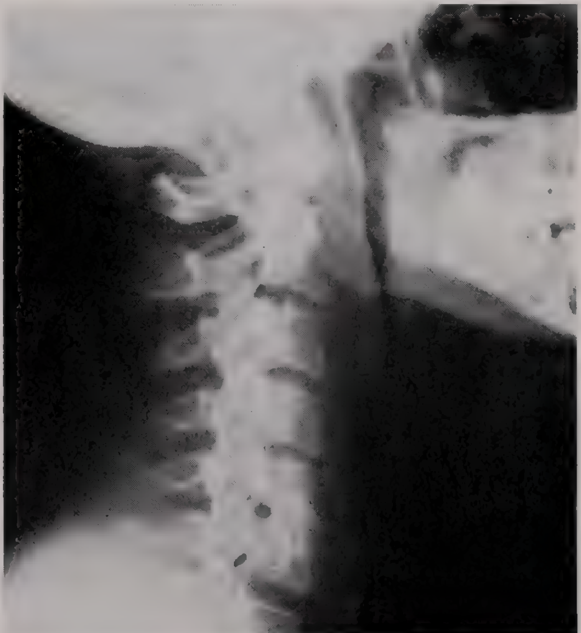

Fig. 17—Spondylosis—long tract signs, postoperative x-ray.

Group I. Complications of Wound Sites

There were 36 complications of wound sites: 12 in the neck and 24 at the donor site. These included 11 patients with superficial infections (eight of the neck and three of the hip); 19 with hematomas (one of the neck and 18 of the graft site); and six with deep wound infections. Three were deep abscesses of the neck with the graft involved, and three were deep infections of the donor site. The latter included two patients with osteomyelitis of the ilium and one patient with a sterile abscess at the donor site six months after surgery as a consequence of a retained sponge.

Superficial wound infections were managed locally, and all healed. Hematoma management varied with the severity, and all cultures were negative. The single hematoma of the neck drained spontaneously on the ninth postoperative day, but healed subsequently. In the hip, a hematoma resolved spontaneously in one patient, required Varidase® in another patient, and cleared with a single needle aspiration in four patients. Multiple aspirations and pressure dressings were required in nine patients, incision and drainage in two, and portable suction as well as multiple aspirations in one patient.

Deep wound infections posed the most serious problem in Group I, as illustrated by the following cases:

Case Report

Case 1

The first patient, a 45-year-old man, had an uneventful C6/7 fusion for spondylosis. Postoperatively a low-grade temperature elevation persisted for two weeks, but finally resolved by lysis. A non-tender, firm mass was seen in the neck wound two weeks after surgery. X-rays disclosed that a retro-esophageal mass had displaced the tracheal air shadow slightly to the left. Three weeks after surgery spontaneous drainage of seropurulent material occurred, and coagulase-positive Staphylococcus aureus sensitive to penicillin was cultured. At that time the wound was treated locally, and no systemic antibiotics were given. However, x-ray of the neck one month after surgery showed collapse of the C6 vertebral body. Then skeletal traction was applied, and the wound was reopened, irrigated and drained. The graft appeared intact and was not removed. The wound was then drained and closed with wire. After skeletal traction for six weeks, a cervical collar was worn for the next three months. Penicillin and chloramphenicol were administered for two weeks. Three months after surgery, x-rays indicated a solid fusion and good alignment. The patient was asymptomatic when he was seen five months later.

Case 2

The second patient was similar to the first. A two-level fusion was performed at C5/6 and C6/7 for cervical spondylosis. On the ninth postoperative day the patient had a temperature elevation to 102 degrees C and an indurated, warm, erythematous neck wound. After heat was applied, the fever and the neck mass subsided. The patient continued to complain of mild difficulty in swallowing and of neck discomfort. Two months after surgery, cervical spine x-rays showed early destructive changes of the C5, C6, and C7 vertebral bodies with bony sequestra and a retropharyngeal mass (Figure 18). Vinke tong traction was instituted, and exploration of the wound revealed that the C6 body and both grafts were infected. The C5 and C7 bodies were curetted to good bone, and both the C6 body and the grafts were removed. The wound was closed with wire and drained. Coagulase-positive Staphylococcus aureus sensitive to lincomycin grew on culture. Skeletal traction was applied for six weeks, and lincomycin was given. A four-poster collar was substituted for the next four weeks. X-ray five months postoperatively indicated a solid fusion (Figure 19). The patient was asymptomatic at follow-up six months after surgery.

Case 3

The third patient had a C6/7 fusion for cervical spondylosis with no relief of his symptoms. Myelography, repeated two weeks after surgery, disclosed a residual C6/7 defect and a smaller defect at C5/6. Three weeks after the first procedure a second was done at C6/7 and C5/6. Two weeks later spontaneous drainage of purulent material from the neck wound ensued. Coagulase-positive Staphylococcus aureus sensitive to penicillin was recovered. X-rays disclosed osteomyelitis of the inferior body of C5 and of the superior body of C6 as well as resorption of the C5/6 graft.

At re-operation one month after the second procedure the graft was necrotic and the adjacent surfaces of the C5 and C6 vertebral bodies were infected. The C5/6 graft was removed, and the infected bodies were curetted to good bone. The C6/7 graft, which appeared to be solidly fused, was left intact. Cultures taken at surgery yielded coagulase-positive Staphylococcus aureus sensitive to lincomycin and resistant to penicillin. The wound was closed with wire and drained with through-and-through catheters for continuous postsurgical irrigation. The patient was kept in bed for one week before being allowed to be up and about with a plastic cervical collar. Postoperatively, the wound was irrigated with neomycin solution continuously for one week, and the patient was given lincomycin for four weeks. One month after surgery there was x-ray evidence of progressive fusion and he was discharged asymptomatic. No follow-up was available.

Case 4

Osteomyelitis of the ilium occurred at the site of a bone dowel removal in one patient. One week after surgery heat and erythema of the wound were treated with moist heat applications, after which the wound drained spontaneously. Pseudomonas species and beta hemolytic Streptococcus grew on culture. He was treated with chloramphenicol for three weeks. At that time x-rays of the hip disclosed osteomyelitis of the ilium and formation of bony sequestra (Figure 20). The wound was opened and a sequestrectomy was done. The wound was then packed open and allowed to heal by secondary intention. Culture at surgery disclosed Pseudomonas species sensitive to colistin, which had been administered for one month postoperatively. The wound healed after six weeks (Figure 21).

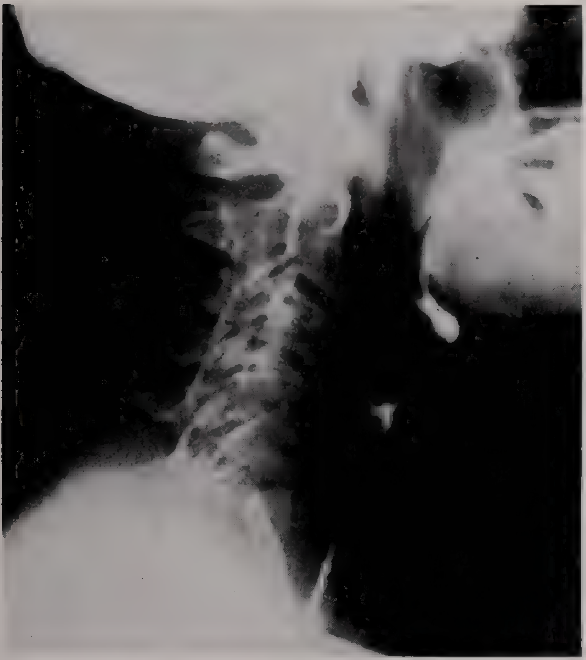

Fig. 18—(Case 2) Before debridement.

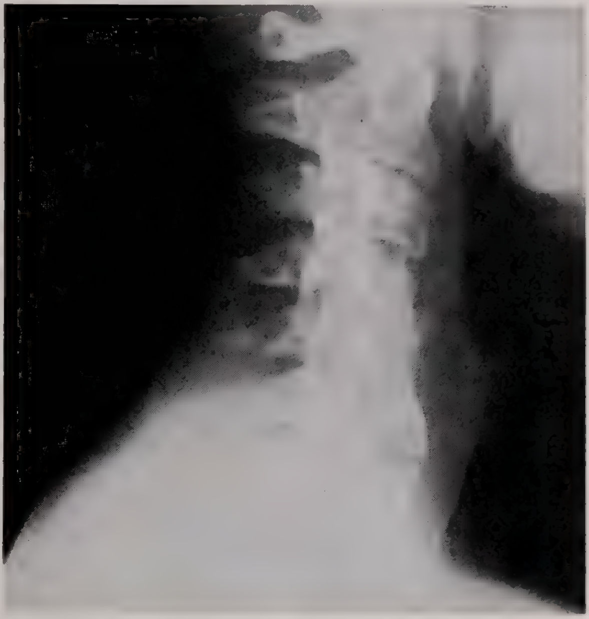

Fig. 19 (Case 2) After debridement.

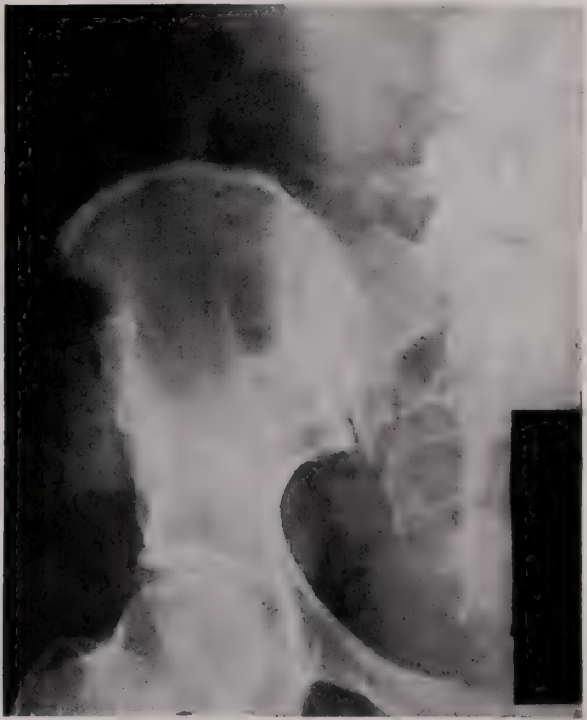

Fig. 20—Osteomyelitis of hip before debridement.

Case 5

One patient returned six months after surgery and complained of a tender mass at the site of the dowel removal. X-rays of the hip showed soft tissue swelling and no evidence of osteomyelitis. When the wound was excised, purulent material escaped; exploration disclosed a sponge. The wound was packed open and allowed to heal by secondary intention.

Group II. Neurologic Complications

Group II consisted of neurologic complications that occurred in eight patients: one had a transverse myelopathy; two had C7 root trauma; two had a peculiar "shawl" hypalgesia; one had causalgia*-like arm pain; unusual flapping extremity movements developed in one patient; and one had left arm paresthesia and upper trunk hypalgesia still present and unchanged eight months after discography. Examples of cases follow.

Case 6

A 47-year-old man had a C5 to C7 block graft for cervical spondylosis. On the second postoperative day he complained of radicular pain and progressive left upper extremity weakness. Lateral cervical spine x-ray disclosed that the graft had been displaced anteriorly, with resultant angulation at C5/6. The patient was returned to the operating room, where the graft was removed, repositioned and reimpacted. A Minerva jacket was applied. On the first postoperative day follow-up cervical spine x-ray again showed anterior displacement of the graft. Skeletal traction was instituted with a 10-pound weight, but progressive displacement of the graft persisted.

Again on the seventh postoperative day the patient was taken to the operating room, where the graft was revised and replaced. Skeletal traction was continued, and the patient seemed to do well for seven days postoperatively. Then urinary retention developed. Bethanecol, 10 mg, was given subcutaneously and 15 minutes later the patient was found unresponsive and in shock. After a quick response to resuscitation, he was found to be quadriplegic. Over the next 20 minutes he moved the four extremities progressively, but remained quadriparetic. Sensation was intact and reflexes were equally diminished bilaterally in the upper extremities, but hyperactive in the lower extremities. He had no pathologic reflexes. On lateral x-ray of the cervical spine, the graft appeared to be tilted. The superior end was displaced anteriorly, the inferior end posteriorly, and the graft was impinging on the spinal canal. The graft was quickly removed and the patient maintained in skeletal traction. Quadriparesis improved progressively; skeletal traction was discontinued after eight weeks and the patient was ambulated.

Twelve weeks after the last surgery he was ambulatory and had no evidence of spasticity; however, mild distal paresis of the upper extremities persisted. The reflexes remained hypoactive in the upper extremities and hyperactive in the lower extremities. Bilateral upturned toes were present.

Case 7

Injury to the left C7 nerve root had occurred. Preoperatively he presented with pain and paresthesias in a C7 distribution in the left upper extremity. Examination disclosed moderately weak triceps C6 and C7 hypalgesia, and an absent triceps reflex, all on the left side. Cervical spine x-rays showed minimal anterior lipping at C5/6 and C6/7, and a cervical myelogram disclosed a large irregular lateral defect at C6/7 on the left. At operation, a large disc fragment was found superior to the root, which was tightly compromised at the neuroforamina. The fragment was grasped with a pituitary rongeur, but during removal the dura was torn. Cerebrospinal fluid filled the wound, and brisk bleeding from the epidural venous plexus followed immediately. Repeated applications of Gelfoam(R) controlled bleeding, and the small dural tear was not repaired. A stamp made of Gelfoam(R) was placed over the dural opening.

Postoperatively there was no cerebrospinal fluid leak, and the wounds healed well. However, the patient had a stormy postoperative course with severe bilateral upper extremity radicular pain, subjective bilateral glove anesthesia, and bilateral weak grip. His condition improved gradually during the next two weeks. At follow-up five months later the patient was free of pain but unable to use the left hand. Examination showed marked weakness of the interossei and lumbricales with weak grip and inability to extend, abduct, or adduct the fingers fully. Atrophy of the dorsal interossei was seen. Anesthesia was present in the left C7 root distribution. Reflexes in the upper extremities were markedly hypoactive, but equal bilaterally.

Case 8

One patient with fusions at C3/4, C4/5, C5/6 and C6/7 for severe spondylosis had protracted radicular pain in the left upper extremity that persisted for four months and then gradually subsided. Another cervical myelogram three months after surgery showed no signif-

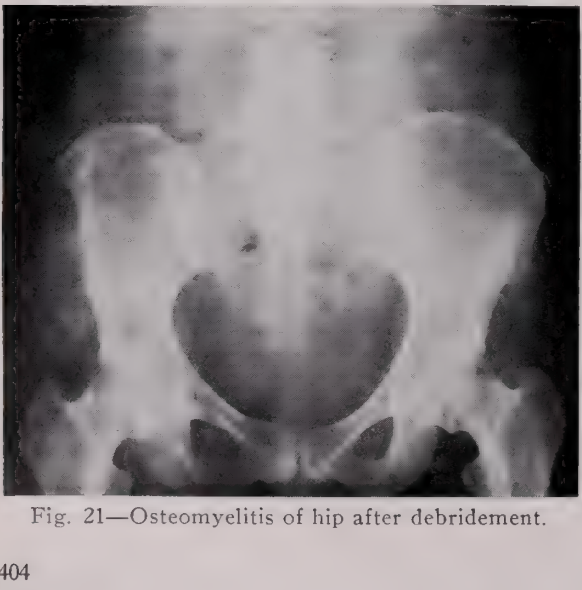

Fig. 21—Osteomyelitis of hip after debridement.

---

*See Test Your Word Score Page 457.

icant defect. The pain was managed with analgesics and physical therapy after a two-week trial of steroid therapy failed to alter the symptoms.

Case 9

This patient complained of shawl distribution numbness on the first postoperative day after a C5/6 and C6/7 anterior fusion. Bilateral C4 hypalgesia and hypesthesia were demonstrated, but cleared gradually after persisting for six weeks.

Case 10

The patient complained of pain in the left shoulder and arm. He had decreased pin sensation of the thumb and index finger. The triceps jerk was diminished. Myelography disclosed a left C6/7 defect. Two extruded fragments were removed by the posterior approach on March 19, 1964. He returned three months later complaining of pain in the right shoulder and arm. Cervical spine x-rays were taken again, and a large lateral inferior spur of C6 and spurring at C5/6 were seen. The repeat myelogram disclosed defects at C5/6 and C6/7. An anterior two-level fusion was done on August 9, 1964, and the spurs were removed. Three days after surgery he was noted to have unusual flapping movements of the arms and legs. No hypotension was noted during surgery. Then a jerking movement of the head developed, and a conversion reaction was suspected.

He returned to work and was next seen two years later, when he had only an irregular non-rhythmic tremor of the left thumb and occasional jerking of the left arm and leg. He complained also of numbness of the left side of the body, including the head and face. Reflexes were symmetrical and intact. A recording of the tremor was done using a transducer and an electroencephalograph amplifier. The tremor was irregular in amplitude and frequency. He probably still had some conversion phenomena, although an extrapyramidal cause could not be excluded. He was retired as disabled.

Group III. Problems with Accessory Structures

The complications in Group III involved 23 patients. Seven had recurrent laryngeal nerve damage; three had Horner's syndrome, including one with postoperative apnea requiring tracheostomy; six had injury of the lateral femoral cutaneous nerve; four had dural tears; and three had intermittent dysphagia.

The laryngeal nerve was damaged in seven patients; five of them had a single level C6/7 fusion, one a single level C5/6 fusion, and one a two-level fusion at C5/6/7. All patients had their neck wounds on the right side. Direct laryngoscopy disclosed right vocal paralysis in six patients; the seventh patient did not have laryngoscopy. Two of the seven patients had persistent cord paresis at last follow-up one month and five years, respectively. Of the other five patients one cleared in eight months, one after six months, and two after two or three months, whereas the last patient had persistent hoarseness for ten weeks and then suddenly regained his normal voice, although subsequent laryngoscopy showed persistent mild weakness of the right vocal cord.

Horner's syndrome was present postoperatively on the right in two patients and on the left in one patient. On the right side it was associated with a C6/7 fusion in one patient and with C5/6 and C6/7 fusions in another patient. On the left side the syndrome was associated with C4/5, C5/6 and C6/7 fusions in a third patient (Case 10). At the last follow-up, i.e., eight months, one year, and five years, respectively, after surgery the syndrome was still present.

Case 11

A 52-year-old man presented with a two-month history of pain and paresthesias in the left upper extremity that failed to respond to conservative measures. Examination disclosed left C8 hypalgesia, moderately weak infraspinatus and grip on the left, and absent left triceps reflex. X-rays indicated narrowing and foraminal encroachment by osteophytic spurs bilaterally at C5/6 and C6/7. A preoperative chest x-ray exhibited a slightly widened mediastinum that was interpreted as normal. Myelographic defects were seen at C4/5, C5/6 and C6/7. At surgery, the patient was found to have a soft disc at C6/7 with a free fragment impinging on the left C7 root and hard, degenerative discs at C4/5 and C5/6. Anterior fusion was performed at these levels, using iliac bone dowels. Surgery proceeded uneventfully, and no evidence of excessive trauma was seen at intubation or extubation.

However, eight hours postoperatively the patient complained of a muscle spasm in the left upper extremity that was not relieved by meperidine. An intravenous infusion of 5 per cent dextrose in water (250 cc) with methocarbamol (1 gm) was given over a 30-minute period. Shortly thereafter, the patient suddenly complained of difficulty in breathing, had stridor, and became apneic and cyanotic. Emergency tracheostomy was performed and mouth-to-trachea resuscitation was begun, to which the patient responded immediately and resumed normal respirations. The total time of apnea was estimated to be 90 seconds. A left Horner's syndrome, not present previously, was noted immediately after this episode. The patient recovered quickly and the tracheostomy was removed in four days; he was discharged two weeks after surgery. Shortly after discharge he began to complain of burning pain in the left upper extremity; and when he was seen one month later, he had a pronounced reflex sympathetic dystrophy on the left. He was followed closely at three-month intervals. The Horner's syndrome persisted, and one year postoperatively the patient had a severe coughing bout, after which paraparesis suddenly developed. On admission, a chest x-ray again disclosed a widened mediastinum; spine x-rays showed a destructive lesion of the T3 pedicle, and myelography revealed a complete block at T2. When decompressive laminectomy of C7, T1, T2 and T3 was performed, extradural metastatic adenocarcinoma consistent with a primary lung focus was found. Postoperatively the patient was given palliative cobalt^{60} therapy. He died 18 months after surgery.

Six patients complained of parethesias to the anterolateral thigh after surgery. At the last follow-up, from one to 12 months postoperatively, the symptoms were still present.

Dural tears occurred during surgery in four patients, including one already discussed. A second occurred in curetting an osteophyte that was embarrassing the left C7 nerve root. The small tear was closed with a single 4-0 black silk suture and the patient recovered uneventfully.

Case 12

A third dural tear occurred in a 35-year-old woman who presented with a marked deformity of the neck that was associated with a 15-year history of slowly progressive paraparesis after a C5/6 fracture-dislocation that was sustained at the time of a sudden hyperextension injury. A posterior fusion that was attempted 15 years prior to admission had failed. After a second posterior fusion three years later, the patient noted the gradual development of a neck deformity that was characterized by an immobile neck and flexion of 90 degrees with an exceedingly tender midline, bony prominence at C4. Examination revealed the deformity and moderate spastic quadriparesis. A sensory level to pinprick was present at T2. All reflexes were hyperactive with unsustained ankle clonus and bilateral upgoing toes. Cervical spine x-rays disclosed that C5 was tilted a full 90 degrees on C6. The neck appeared to be solidly fused posteriorly. Cervical myelograms showed marked anterior encroachment of the dye column at C5/6.

Because of the progressive neurologic defect, it was elected to take down the old fusion and to perform an anterior fusion from C3 to C7 using staged procedures. Skeletal traction was instituted, and the patient had the posterior fusion taken down, followed by formal laminectomies from C1 to T2. Three weeks later, the central bodies of C4, C5, and C6 and the intervening discs were removed through the anterior approach, and a block graft of iliac bone was placed from C3 to C7. At surgery it was noted that the cord was greatly compressed anteriorly and that the dura appeared quite attenuated. Postoperatively, the patient had persistent cerebrospinal fluid leakage from the wound and was returned to surgery three days later. The dural tear was identified and closed by suturing a muscle patch graft; no more leakage occurred. The patient was kept in skeletal traction for ten weeks after surgery; at that time she had x-ray evidence of excellent fusion. Neurologically, she was essentially unchanged from the preoperative status.

Case 13

One patient had prolonged dysphagia for one year after anterior cervical fusion. Esophagoscopy and barium swallow were normal. No specific treatment was given, but the symptoms gradually subsided. The other two patients also had normal barium swallows.

Group IV. Surgical Complications

The complications in Group IV, which were observed in nine patients, were not related specifically to anterior cervical fusion. Five had postoperative episodes of atelectasis, manifested by fever, chest pain and x-ray evidence of lung infiltrate. All responded properly to intermittent positive pressure breathing, but two were given penicillin empirically. Left superficial saphenous thrombophlebitis developed postoperatively in one patient, but it was managed successfully with heat and elevation. A localized osteomyelitis of the skull occurred in another patient who was maintained in skeletal traction. Replacement of the tongs and curettement of the involved area led to complete healing.

Fusion was performed at the wrong level in one patient. The patient who required the tracheostomy has been discussed.

Group V. Primary Graft Problems

Primary problems arising from the graft constituted Group V and affected nine patients. Three patients had mobilization of the graft, five had graft collapse, and one patient had failure to fuse with resultant pseudoarthrosis. The last patient is the only one who had a fibular graft. All other patients in the entire series were grafted with autogenous iliac bone. Case examples follow:

Case 14

The second patient had mobilization of the graft after fusion of C4/5 for subluxation, with resultant instability of that joint. Two days after surgery a cervical spine x-ray disclosed a 6-mm forward displacement of C4 on C5. The patient was placed in a plaster Minerva jacket and the displacement reduced to 3 mm which was considered satisfactory. X-rays indicated a good fusion after he was maintained in the plaster jacket for six weeks. Then he was placed in a plastic cervical collar. No more follow-up information was available.

Case 15

One patient who had an anterior fusion at C7/T1 had a collapse of the graft, with resultant subluxation. This man had had bilateral cervical laminectomies at C5/6 and C7 with foraminotomies at C5/6, C6/7 and C7/T1 for cervical spondylosis. At follow-up three months later he was found to have subluxation of C7 on T1. When cinefluoroscopy disclosed motion, an anterior fusion was performed at that level. The patient did well until two months postoperatively, when radicular pain and paresthesias developed in the C7 distribution. Cervical spine x-rays again showed subluxation of C7 on T1 and collapse of the graft. The patient was returned to surgery; a block graft from the iliac crest was applied from C6 to T1, and C5/6 was fused. Postoperatively he was placed in a Minerva jacket for two months and then in a four-poster cervical brace for six weeks. Three months after surgery the patient had a solid fusion and a good alignment, and was asymptomatic.

Case 16

A 19-year-old man who had sustained a compression fracture of C5 with subluxation of C4 on C5 as a consequence of a tumbling accident was immobilized in skeletal traction for four weeks. He had no neurologic deficit. The subluxation reduced initially, but at four weeks he had minimal slip. An anterior fusion was accomplished at C4/5 and C5/6 using iliac bone dowels. He was kept in skeletal traction for one week after surgery and then placed in a cervical collar. X-rays six weeks after surgery disclosed that C4 was subluxed on C5 with 20 degrees of angulation; the C5 body had collapsed anteriorly. He was again placed in skeletal traction and returned to surgery for removal of the old C4/5 and C5/6 grafts and the C5 body, and a block graft in the iliac crest was applied from C3 to C6. For six weeks after surgery the patient was kept in skeletal traction and then ambulated in a four-poster neck brace for three months. X-rays six weeks after the last surgery indicated solid fusion. On follow-up at one year he had an excellent fusion without angulation and was asymptomatic.

Case 17

The one patient with a graft that failed to fuse had a C6/7 fusion using a fibular graft: the only graft of this type. At surgery, only a pencil-lead thickness of cancellous bone was used as a graft. Postoperatively the patient was asymptomatic, but x-rays four months later disclosed a pseudoarthrosis at the C6/7 interspace. However, the patient received no more treatment because he was thought to have no instability in the neck.

Case 18

One patient had the incorrect level fused. At surgery, the C6/7 interspace was mistakenly identified as C5/6 and fused, but this was not known until follow-up cervical spine x-rays were taken. The patient had no more radicular pain and remained asymptomatic for five years after surgery, when right upper extremity pain developed again. Then a C5/6 fusion was performed.

Summary

There were 85 complications in 74 of the 213 patients, making the complication rate 38 per cent. Wound site complications accounted for 16 per cent, neurologic complications for 4 per cent, accessory structure problems for 10 per cent; general complications for 4 per cent, and graft problems for another 4 per cent.

Charles Nicolle 1928

For His Work on Typhus

"The center of my observations was the native hospital of Tunis. When I visited this hospital I often stepped over the bodies of typhus patients who had come to be admitted and had fallen down from exhaustion at the door. Now there was a singular event taking place in this hospital, the significance of which no one had understood, and which impressed me. The typhus patients were lodged at this time in the common medical wards. As far as the doors of these rooms they scattered the contagion. Typhus developed on contact with them in the families where they were received, and the doctors required to visit them became infected on contact. Moreover the contagion struck the personnel of the admitting offices of the hospital, the employees whose duty it was to collect the clothes and linen, and the laundresses who washed them. And for all this, a typhus patient once admitted to the common ward did not contaminate a single one of his ward neighbors, not an attendant, not a doctor.

"This observation was my guide. I asked myself what happened between the hospital door and the sickroom. What happened was this: the typhus patient was relieved of his clothes and linen, and was shaved and washed. The agent of the contagion was therefore something attached to his skin, to his linen, and something of which soap and water rid him. This could only be the louse."

Nicolle convicted the louse; Paul Miller, of DDT fame, discovered the means to kill it.*

The Midwife

The midwife occupied a position of great importance in the Colonial community; in fact, she was a community institution. New Amsterdam gave its first midwife, Lysbert Dircken, a house built at public expense, and one of her successors, Hellezond Jaris, was paid a yearly salary of 100 guilders.

Some of the midwives made for themselves records of which they might justly be proud. On her tombstone in the Phillip Street burying ground at Charleston, you find it recorded of Mrs. Elizabeth Phillips (and we have no way of disputing the good lady's mortuary boast) that she assisted at the delivery of some 3000 children. Mrs. Lydia Robinson, of New London, Connecticut, claimed to have helped deliver 1200 in thirty-five years of practice—and never lost a case!

The transition from midwife to male physician was gradual. Dr. James Floyd of Boston returned from London in 1752 equipped to handle obstetrics, and had the temerity to offer himself as a "man midwife." Further South, Drs. Atwood and Tennent, in New York, Dr. Shippen in Philadelphia, and Dr. Moultrie of Charleston, all began the same practice. Many, however, deemed the employment of a male accoucheur scandalous, and for years the old Granny midwife—whose fees ranged from $3 to $8—was still the favourite. The change came about, it is said, because on the Continent fashionable women began to employ men doctors for such cases, and American women of those times (as now) followed whatever Continental styles dictated.*

Artery Shunt for Cyanotic Heart Disease

Intrapericardial Ascending Aorta-Right Pulmonary Artery Anastomosis

BYRON N. DOOLEY, Lt. Colonel, USAF MC
RAYMOND G. ARMSTRONG, Lt. Colonel, USAF, MC
WILLIAM STANFORD, Lt. Colonel, USAF, MC

SINCE THE INTRODUCTION of palliative subclavian pulmonary artery anastomosis in the early 1940s by Blalock and Taussig,[1] thousands of children with cyanotic heart disease have been effectively palliated by these procedures. However, during the intervening years, with the development of cardiopulmonary bypass and surgical techniques for correction of cyanotic congenital heart anomalies, the need for palliative operations has lessened. In newborn infants and young children, where the risk of open heart surgery is high, there is still a definite place in the surgeon's armamentarium for shunt procedures. A great variety of systemic pulmonary anastomoses have been employed, and the principal disadvantages have been with their take-down and closure at the time of open heart procedures.

Because of the difficulty involved in repairing Potts' and subclavian-pulmonary artery shunts at the time of open heart surgery, as well as the difficulty of performing such procedures in small infants, we began to use intrapericardial aorticopulmonary artery shunts in 1965 and have been pleased with the results. This report deals with our clinical experience with the intrapericardial ascending aorta-right pulmonary artery anastomosis in 21 cases and our experience with the closure of this shunt in three children who later came to open repair of their congenital anomalies.

Surgical Technique

All patients were operated upon by the technique described by Hallman and Cooley.[2] With the patient in the left semilateral position, a right anterolateral thoracotomy incision was made and the pleural cavity entered through the 4th intercostal space (Figure 1). The pericardium was opened anterior to the right phrenic nerve and traction sutures placed on the pericardial edges to facilitate exposure.

From the Thoracic Surgery Service, Wilford Hall USAF Hospital, Lackland Air Force Base, Texas.

The posterior parietal pericardium overlying the right pulmonary artery was incised and the right pulmonary artery fully mobilized intrapericardially. A double loop ligature was then placed around the distal pulmonary artery just beneath the superior vena cava. Utilizing a partial occlusion clamp, both the right pulmonary artery and the undersurface of the ascending aorta were secured and parallel incisions made in both the ascending aorta and the pulmonary artery (Figure 2). These incisions are made 3 mm in size for infants under one year of age and 4 to 4.5 mm in size for children in older age groups. Utilizing a continuous suture technique, a side-to-side anastomosis between the two incisions was completed and all clamps released. A continuous thrill should be immediately palpable over the anastomosis after release of the clamps, assuring a patent anastomosis. The pericardium was closed loosely to facilitate drainage and the chest closed in a routine manner.

The shunt was closed in three patients subjected to total correction by placing interrupted sutures through a superimposed longitudinal aortotomy after the patient was placed on extracorporeal bypass with the aorta cross-clamped (Figure 3). This exposure has been excellent and no difficulties have been encountered in closing the shunt. After repair of the ascending aorta, total correction of the cardiac anomaly was accomplished in the usual manner.

Clinical Experience

Since November 1964, the cardiac surgical team at Wilford Hall USAF Hospital has operated upon 21 patients with cyanotic heart disease, utilizing an ascending aorta-pulmonary artery shunt. Other procedures utilized during this period include subclavian artery-pulmonary artery shunt and vena cava-pulmonary artery shunt; however, those patients thought to be candidates for future total correction have preferably undergone ascending aorta-pulmonary artery shunts.

Clinical Indications

The ages of the 21 patients undergoing this

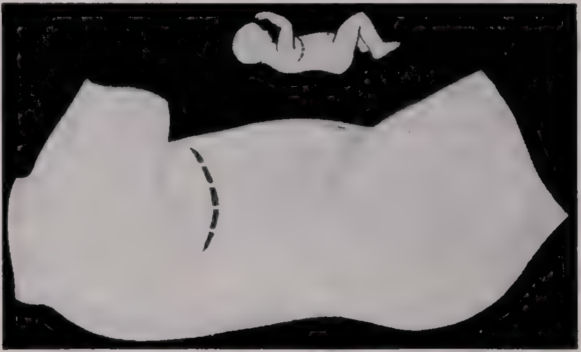

Fig. 1—Standard left lateral thoracotomy position.

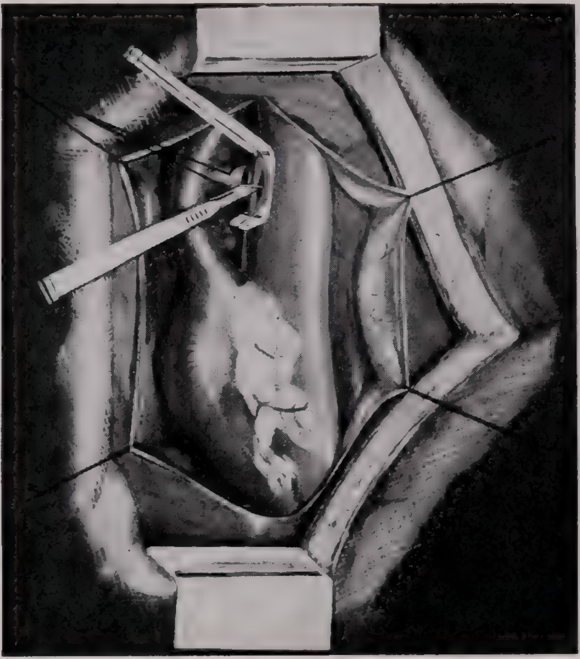

Fig. 2—Parallel incisions for side-to-side ascending aorta-right pulmonary artery shunt.

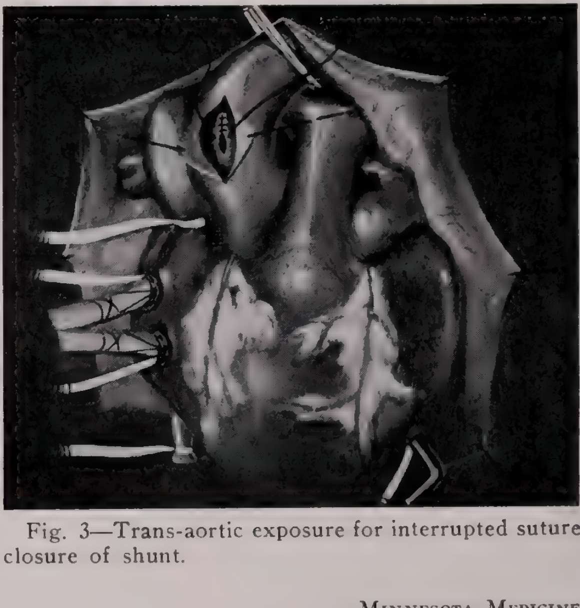

Fig. 3—Trans-aortic exposure for interrupted suture closure of shunt.

type of shunt have varied from six weeks to 21 years, with an average age of less than one year. The operation was performed as a first stage in smaller infants with severe hypoxemia in order to increase oxygenation and survival in infancy prior to total correction at a later date. However, in older patients with uncorrectable lesions, such as pseudotruncus and tricuspid atresia, the shunt was performed because of the small size of the pulmonary artery or anomalies of the aortic arch which did not seem well suited for use of the subclavian artery as a means of creating a systemic shunt. In all patients the main indications for this procedure were severe cyanotic spells, the possibility of strokes, decreased exercise tolerance, fatigue or growth retardation.

Morbidity-Mortality

Among the 21 patients, there were four hospital deaths, giving an overall mortality rate of 19 per cent (Table 1.) Tetralogy of Fallot (16 patients) made up the largest group with two deaths. One patient died of hemorrhage in the postoperative period from a leak at the anastomotic site, the other of a cerebrovascular accident which occurred, possibly, as a result of air embolism or thrombosis during the surgical procedure. Of the four patients with tricuspid atresia, there was one death in the postoperative period due to heart failure from too large a shunt. The other three patients in this group did well.

TABLE I
Hospital Mortality.

Tetralogy of Fallot	16 Pts.	2 Deaths
Tricuspid Atresia	4 Pts.	I Death
Pseudo-Truncus	I Pt.	I Death
19% Mortality	21 Pts.	4 Deaths

All infants with tricuspid atresia operated upon were extremely ill and all were less than three months of age. Although their postoperative courses were much stormier than those of patients with tetralogy of Fallot, all survivors were significantly palliated by the procedure. One 21-year-old patient with a pseudotruncus arteriosus was severely hypoxemic, with extremely small peripheral pulmonary arteries and no main pulmonary artery. A shunt was attempted, but the patient died two days postoperatively of pneumonia and pulmonary insufficiency.

Of the 17 patients who have survived the procedure, all have been effectively palliated and have been followed carefully. Three have come to total correction and closure of the shunt at a later date. In this group, the shunt has very effectively reduced hypoxemia and has successfully afforded a good means of palliation.

We have observed certain complications with this procedure. One patient required reoperation in the postoperative period to narrow the shunt because of heart failure, and another who had thrombosis of the shunt required reoperation one week later. In this case it was technically easy to re-explore the shunt, remove the occluding clot, and re-do the anastomosis.

Discussion

Since 1945 many types of systemic pulmonary artery shunts have been proposed and performed, giving effective palliation to thousands of children with cyanotic heart disease. The original procedure proposed and performed by Blalock in 1945 involved the use of subclavian-pulmonary artery shunt,[1] and that by Potts[3] proposed a shunt between the descending thoracic aorta and the left pulmonary artery. With the advent of extracorporeal circulation for open heart procedures and total repair of tetralogy of Fallot, the situation became somewhat more complicated. The closure and repair of these previously performed shunts is a difficult procedure and is attended with increased morbidity and mortality. Several authors have described various ways of obviating these problems.[4,5] These have included dacron grafts between the ascending aorta and pulmonary artery, as well as the aorticopulmonary artery shunt as originally described by Waterston,[6] which has now become widespread in its use.[7,8,9]

The simplicity and ease of performance of the ascending aorta-pulmonary artery shunt, as well as the fact that it can always be performed through a right thoracotomy incision regardless of the size of the aortic arch, requires little or no mediastinal dissection around the hilum of the right lung and can be closed simply at the time of open heart surgery at a later date, make this type of shunt most appealing.

There are several important factors in the performance of the operation which enhance its successful outcome (Table 2). First is the size of the shunt. Since infants may easily go into heart failure, the shunt should be approximately 3 mm in diameter if the infant is less than one year of age, or 4 mm if older. Older children can tolerate a 4-mm shunt quite nicely without difficulties in most cases. An immediate thrill should be palpable after the performance of the operation; if not, then immediate reoperation should ensue. In our experience, all shunts which have not had immediate thrills or a machine-type murmur over the area have not been open.

TABLE 2

Important Factors for Successful Outcome.

1. Size of Shunt
    - A. 3 mm. Infants under one year.
    - B. 4 mm Children over one year.
2. Immediate Thrill
3. Early Re-operation for Failure
4. Avoid Emboli

Another important consideration is the advisability of early re-operation for cardiac failure, as an infant who develops heart failure after a shunting procedure will not survive. Immediate narrowing of the orifice of the shunt by simple suturing will decrease the size of the shunt and prevent further failure, thus enhancing survival. During the creation of the shunt, air may become trapped in the ascending aorta. Therefore, it is very important to first fill the anastomotic area in retrograde fashion from the pulmonary artery prior to releasing the aortic clamp.

Closure of the shunt in the three patients who have come to open repair has been done through an aortotomy with interrupted suture closure of the shunt from within the aorta. This approach has worked well and we have encountered no difficulties. Closure has been satisfactory and certainly much simpler than taking down a Potts' or Blalock anastomosis. It is possible, however, to cause excessive narrowing of the right pulmonary artery during closure of this anastomosis from within the aorta.[10] Therefore the interrupted sutures should be placed very carefully in order not to produce an acquired pulmonary artery stenosis. We feel that this operation can be easily performed with an acceptably low mortality rate and can provide effective palliation of critically ill, small infants who might otherwise be unable to survive until corrective surgery can be carried out at a later date.

Summary

Twenty-one patients have undergone shunting procedures from the intrapericardial ascending aorta to the right pulmonary artery for severe cyanotic heart disease. Most of these patients have been hypoxemic infants who have had shunts performed in preparation for definitive open repair of the underlying cardiac defects along with simultaneous closure of the shunt. This type of shunt has worked well, has been easy to repair at the time of open heart surgery, and is therefore recommended as a standardized preliminary procedure for any patient, especially small infants who would otherwise have a prohibitive risk for early open heart surgery.

Addendum

The ascending aorta—right pulmonary artery shunt has been performed on six additional patients including one with transposition and tricuspid atresia and one with transposition and pulmonic atresia. There were no deaths among these additional patients giving a mortality rate of 15 percent for the 27 patients treated thus far.

Radioisotope Dilution Assay for Vitamin B_{12}

Experiences

GUILFORD M. DUDLEY III, Captain, USAF, MC*
CHARLES A. COLTMAN, Jr., Lt. Col., USAF, MC

FOUR COMPONENTS are required for an isotope dilution assay system. The first requirement is that the substance being assayed must be available with a radioactive label. Secondly, a binder must be available which is capable of distinguishing the non-radioactive substance from its radioactive counterpart. Thirdly, the affinity of the binder for the substance being assayed should be independent of the concentration of the substance being assayed. Lastly, there is the requirement for a means of separating the bound substance from the unbound (free), such that the dilution of radioactive substance by the unlabeled counterpart may be measured; i.e., the specific activity of the bound substance changes according to its dilution with the non-radioactive material. If these conditions exist, the principle of radioisotope dilution applies and the substance in question may be assayed without the necessity of repeating a standard curve.[1]

In the measurement of vitamin B_{12} by radioisotope dilution, a labeled form of vitamin B_{12} is available. There are, in addition, two natural binders: Intrinsic Factor, obtained from gastric juice, and normally occurring serum B_{12} binders, Transcobalamine I and II. Both of these binders have been used for the vitamin B_{12} assay.[2,3,4] Intrinsic Factor has been found to adhere to the principle of isotope dilution when using the physiologic amounts of vitamin B_{12} which appear in the serums being assayed.[2] However, Intrinsic Factor has been found to be unstable upon thawing and refreezing and its binding capacity may change in the presence of the serum extract which is to be analyzed.[2,4,6] The transcobalamines have been used, both from normal serum[3] and from patients with chronic myelocytic leukemia who have a high Transcobalamine I and Trancobalamine II ratio.[4] We have used sera from chronic myelocytic leukemia patients with high Transcobalamine I: Transcobalamine II ratios,

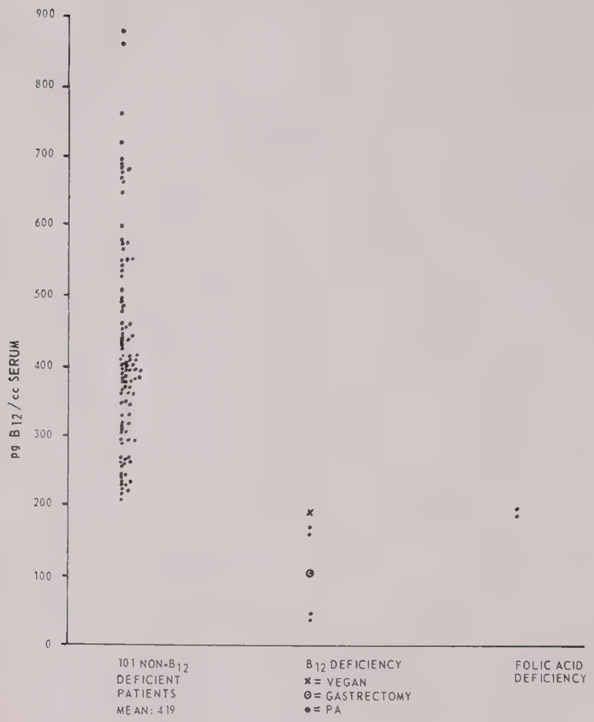

Fig. 1—Plot of 109 serum vitamin B_{12} assays.

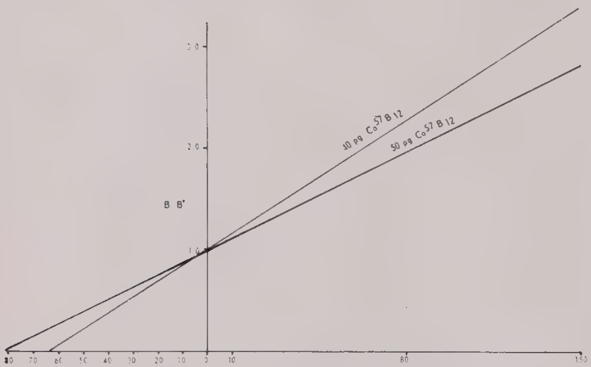

Fig. 2—The principle of isotope dilution is applied where B = C.P.M. bound in the presence of 40 or 50 pg of isotope and B′ = C.P.M. bound following dilution by the addition of 0-150 pg of the unlabeled B_{12}. Extrapolation of lines A & B are found to overestimate the actual amount of isotope by a factor of 1.6.

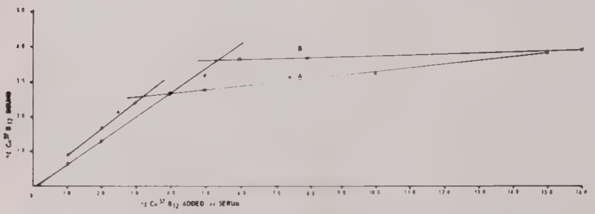

Fig. 3—A plot of the amount of B_{12} bound/cc of serum as a function of the amount of B_{12} added. Line A represents a serum with a Transcobalamine I: Transcobalamine II ratio of 44.3:55.7; line B, 73.6:26.4.

as described by Rothenberg,[4] to determine if this method in our laboratory will: (1) distinguish between normal and low serum vitamin B_{12}, (2) adhere to the principle of isotope dilution, and (3) require a standard curve with each batch assay.

Methods and Materials

$Co^{57}B_{12}$ with a specific activity ranging from 12 c/ gm to 100 c/ gm was used as the isotopically labeled vitamin. Radioactivity was determined with a Picker Nuclear Autowell #2 scintillation counter.

The serum used for the binder was obtained from patients with chronic myelocytic leukemia whose Transcobalamine I: Transcobalamine II ratio was greater than 70:30 as determined by using either the "Baby Column Technique" or starch gel electrophoresis.[7,4]

The assay procedure for vitamin B_{12} was that of Rothenberg[4] who uses two 15-minute boiling periods to extract vitamin B_{12} from its serum binders. One with equal volumes of buffered sodium acetate .68M, PH 4.3, and NaCN, 10 mg/1, followed by an equal volume of .3N NaOH. A dilution of the binder with saline was used such that 70-80% of 40-60 picograms (pg) of isotope was bound. The addition of $ZnSO_4$ followed by $Ba(OH)_2$ is used to precipitate the binders, thus separating the bound from the free vitamin.[4] If Ba $(OH)_2$ is added prior to $ZnSO_4$ it will dissociate the B_{12} protein complex.

The non-labeled vitamin B_{12} used in the standard curve for dilution of the isotope may be stored in concentrations of 1000 pg/cc at 5° C for at least three months, as dilutions of this in our laboratory have given a consistent standard curve from batch to batch (Figure 4).

The unsaturated vitamin B_{12} binding capacity curves were determined by the addition of increasing amounts of radioactive vitamin B_{12} to 0.5 cc serum, followed by a 30-minute incubation at 37°C. The free vitamin B_{12} was then removed by hemoglobin-coated charcoal dialysis according to Gottlieb et al.[8]

Results

The results from 109 serums analyzed for vitamin B_{12} are seen in Figure 1. Of these, 101 have values greater than 200 pg/cc, the mean of these is 419 pg. There were eight sera that had values below 200 pg.

Using the principle of isotope dilution and plotting ratios of B/B′ (Figure 2) against unlabeled vitamin B_{12} shows that the principle of isotope dilution is not obeyed, as the amount of isotope is overestimated by a factor of 1.6.

Figure 3 shows the unsaturated binding capacity curves done with two sera from patients with chronic myelocytic leukemia. One has a Transcobalamine I: Transcobalamine II ratio of 73.6:26.4 and the other 44.3:55.7. The one with the high Transcobalamine I: Transcobalamine II ratio showed little change in its binding capacity once saturation was reached.

Figure 4 represents the mean of three standard curves done in duplicate. The regression line was plotted considering the mean of the duplicate determinations at each level of isotope dilution by 10, 40, 80, and 150 pg of unlabeled vitamin B_{12} for each curve. The binder used in this case was from a patient with chronic myelocytic leukemia whose Transcobalamine I: Transcobalamine II ratio was 72.6:26.4. The greatest variation of any point from the mean of the three standard curves shown as the regression line is 7 pg at levels of dilution from 0 to 80 pg. This value is multiplied by a factor of four when converted to pg of vitamin B_{12} per cc serum because of dilution of the serum during extraction. Therefore, if a mean standard curve is used, the greatest variation to expect would be 28 pg per cc in the range of 0-320 pg per cc. In order to test the precision of the method, four assays were done over a several-month period of time on the same sample of serum obtained from one patient with PA and another with chronic myelocytic leukemia. The mean of the four determinations was 56.5 ± 4.9 (S.E.) pg/ml for the PA patient and 1988.0 ± 28.8 (S.E.) pg/ml for the chronic myelocytic leukemia patient. The chronic myelocytic leukemia serum was diluted so as to fall within the standard curve.

Discussion

Analysis of eight sera gave vitamin B_{12} levels of below 200 pg. Four of these patients had pernicious anemia, one patient was a vegetarian, and another had B_{12} lack, secondary to gastrectomy. There were two patients with folic acid deficiency. There are previous reports of low serum vitamin B_{12} levels in patients with folic acid deficiency.[9] Two of our patients, as indicated in Figure 1, with pernicious anemia had serum values which were in the same range as the values

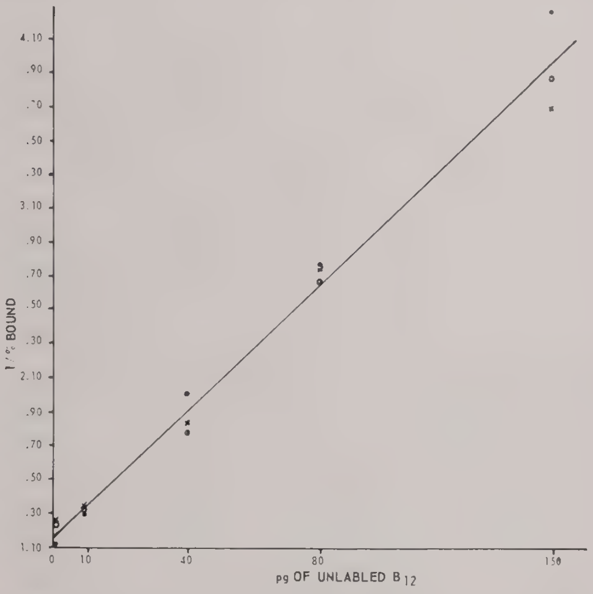

Fig. 4—A mean of three standard curves done over a three-month period of time. Each point represents the mean of duplicate determinations for each of the three curves. The regression line was plotted by the method of least squares.

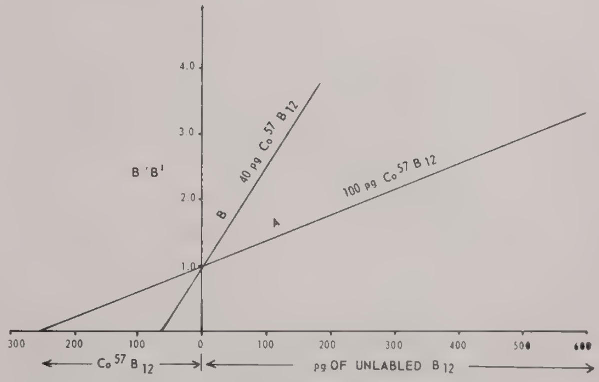

Fig. 5—A plot of B/B′ as a function of isotope dilution by non-labeled B_{12}, where line A represents pooled normal serum used as a binder and B is a serum with a high Transcobalamine I:Transcobalamine II ratio. 100 pg of isotope were used with the normal pooled serum and 40 pg with the high Transcobalamine I serum. Extrapolation reveals a greater over-estimate of the isotope with the normal serum binder.

seen in the two patients with folic acid deficiency. It would appear that a random serum level of vitamin B_{12} could be misleading unless one further investigates the etiology of the "vitamin B_{12} deficiency" as determined by serum levels. However, values below 200 pg/cc should be considered as being low and indicate either B_{12} or folic acid deficiency or both.

Serum containing a high ratio of unsaturated Transcobalamine I: Transcobalamine II as a binder does not obey the principle of isotope dilution as indicated by the overestimation of the isotope by a factor of 1.6 when plotted as B/B′ as a function of unlabeled vitamin B_{12} (Figure 2). This plot allows one, by extrapolation of the curve, to measure the concentration of the labeled vitamin, if the specific activity of the labeled substance is reduced in direct ratio to the total amount of material present with addition of unlabeled substance, i.e., if the principle of isotope dilution is obeyed. There is apparently closer adherence to this principle than is obtained with the use of normal serum as the binder, which has an average Transcobalamine I: Transcobalamine II ratio of 18.8:81.2.[7] Frenkel,[3] using such normal pooled sera as the binder, found that the amount of isotope was overestimated by a factor of 2.5. Figure 5 shows the comparison of Frenkel's data with normal serum as a binder and our data using a binder with a Transcobalamine I: Transcobalamine II ratio of 73.6:26.4 from a patient with chronic myelocytic leukemia. The 100 pg is estimated to be 260 pg by normal serum, while 40 pg is estimated to be 65 pg by chronic myelocytic leukemia serum. This suggests that increasing the concentration of Transcobalamine I as the binder results in closer adherence to isotope dilution kinetics.

Figure 3 shows two binding curves for chronic myelocytic leukemia sera with differing ratios of Transcobalamine I: Transcobalamine II. It should be noted that in the sample with higher Transcobalamine I there is relatively little additional binding with large increases of vitamin B_{12} after saturation is reached. Such is not the case when Transcobalamine I and Transcobalamine II are present in roughly equal amounts. Rothenberg similarly showed a larger increase in the binding capacity of normal serum than Transcobalamine I serum with the addition of increasing amounts of vitamin B_{12}.[4] This may account for the closer adherence to isotope dilution kinetics when using sera with high Transcobalamine I: Transcobalamine II ratio. One could predict that the best binder for the analysis would be the serum fraction containing Transcobalamine I alone.

Because of the lack of adherence to radioisotope dilution kinetics, it is necessary to refer to a standard curve. Our experience with standard curves, using the same binder with a high Transcobalamine I: Transcobalamine II ratio at intervals separated by several months, indicates very close reproducibility (Figure 4). We would support Rothenberg's proposal for using a zero dilution of the isotope with each batch as a check to insure that not only the binder but the isotope remain in the same proportions from batch to batch.[4] Serum values may be determined from the mean standard curve or, as suggested by Rothenberg, they may be calculated from the formula for the straight line where the slope and intercept are known. Using our standard curve, the formula would be pg B_{12} per ml serum = [54 (1/FB)—94] x dilution.

Summary

Serum with high unsaturated Transcobalamine I: Transcobalamine II ratios from patients with chronic myelocytic leukemia has been used, as described by Rothenberg, as the binder for a radioactive dilution assay of serum vitamin B_{12}. With this binder, values of below 200 pg should be considered abnormal and may represent vitamin B_{12} and/or folic acid deficiencies. The assay does not adhere to the principle of isotope dilution kinetics and thus requires a standard curve. Due to the stability of the binder, the standard curve is reproducible from month to month and thus does not require repeating with each batch assay.

Subtalar Inflammatory Response to Stress

A Cause of Foot Pain

GEORGE H. CHAMBERS, Colonel, USAF, MC*
RICHARD F. PREATOR, Major, USAF, MC†

PATIENTS WITH PAINFUL FEET present from all walks of life with myriads of symptoms and etiologic factors.[1,2] The knowledge that feet become sore when stressed with unaccustomed walking is a personal observation familiar to all. The label of "tenderfoot" placed on the newly arrived traveler by the western mountaineer is legend. The painful foot of the basic trainee in the Armed Forces sends him to sick call with complaints that vary in number and intensity relevant to the amount of stress from the marching and standing required by the duty schedule.

Symptoms

One group of patients described pain in the foot below the ankle that became worse on standing and marching, but was eased by rest. Acute pain was reproduced when the rotary stress of the subtalar joint caused movement of the os calcis with the ankle stabilized; and frequently there was associated pain over the peroneal or posterior tibial tendons and acute pain on pressure over the sinus tarsi. If the duration was long enough there was spasm and tenosynovitis of these tendons. Most patients gave a history of a sedentary occupation prior to entry into the Air Force.

These observations suggested an acute inflammatory response in the subtalar joint caused by repetitive stress to the subtalar joints as an etiology for foot pain.

Anatomy and Function of the Subtalar Joint

Lapidus[3,4] emphasizes the subtalar joint as having two compartments, the anterior talonavicular and the posterior talocalcaneal, separated by an intra-articular ligament known as the interosseous talocalcaneal ligament. This ligament begins as a portion of the united capsules of the talonavicular and talocalcaneal

---

†Present address: USAF/RAF Exchange Program (Ely), A.P.O. New York 09218.

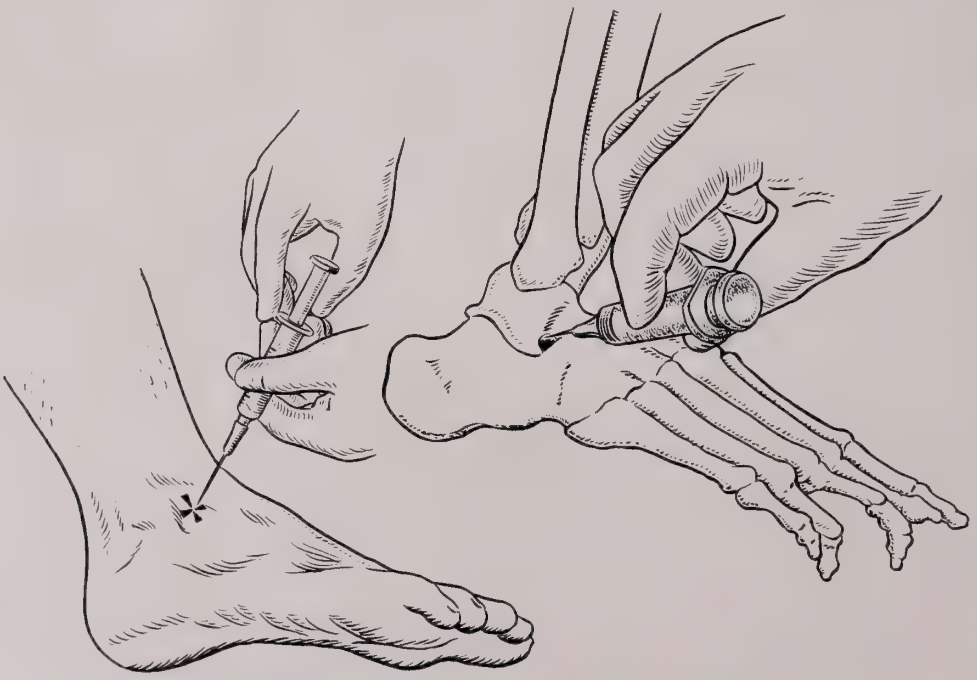
joints in the depths of the sinus tarsi, and passes obliquely from an anterolateral to a posteromedial direction across the subtalar joint attaching to grooves in the talus and calcaneus to form the strongest bond between these bones. The axis of motion of the subtalar joint is not the longitudinal axis of the foot, but runs obliquely from superior-medial-distal to plantar-lateral-posterior.[4-9] This axis crosses the interosseous talocalcaneal ligament and, since subtalar movement is in a compound arc, the ligament must absorb repetitive twisting stress at the extremes of motion, thereby becoming tense on inversion and relaxing on eversion.

Since no muscles insert on the talus, it can only follow passively the movement of associated bones. Because of the oblique subtalar axis of movement, the gastrocnemius-soleus tendon inserting medially on the os calcis probably always acts as an invertor of the foot. With the heel in valgus position during weight-bearing, each push-off places a strong varus pull on the os calcis and produces a rotary subtalar motion. This muscle group also provides the greatest amount of inversion to the foot.[10] Therefore, walking, jogging and running are direct stretches of the interosseous talocalcaneal ligament. The protective device of the foot is the contraction of the peronei, which neutralizes the inversion force.

Material and Methods

With these anatomical concepts in mind, it was thought that some of the painful foot problems seen might be due to acute inflammation of the subtalar joint and the intra-articular talocalcaneal ligament, and that resolution of this inflammatory response would resolve the painful foot. A short trial of injecting the subtalar with varying amounts of local anesthetic and steroids produced encouraging short-term results and a clinical study was entered upon.

Basic airmen who presented to the Orthopaedic Clinic with painful feet, pain on passive subtalar motion, and tenderness over the sinus tarsi were treated. Many of these airmen had tenderness over the peroneal and/or posterior tibial tendons, and limped with the foot everted and peroneal muscles in spasm. X-rays were made on all patients to exclude tarsal coalition anomalies and to rule out recent or remote trauma. All were questioned as to motivation for a career in the Air Force, and those who appeared to be manipulating in order to escape duty or obtain a medical discharge were excluded. Twenty airmen were selected for



Figure—Technique of injection of subtalar joint.

therapy.

Treatment

Treatment consisted of aseptic injection of the subtalar joint with a mixture of 3 cc of 1 per cent lidocaine, 1 cc prednisolene tertiary butyl acetate, and 1 cc dexamethasone. Usually 3 cc of the solution were injected.

The technique of injection was to pass a No. 21 needle across the sinus tarsi into the posterior portion of the subtalar joint (Figure). To enter the joint initially could prove difficult; but it was accomplished by "walking" the needle across the substance of the os calcis until penetration of the joint was felt. After injection the airmen were returned to duty with the advice that they might have some post-injection pain and the request that they remain off their feet as much as possible for the remainder of that day, but resume full duty the next day. Six airmen had both feet injected and 14 had one foot injected.

Results of Treatment

Of the 20 airmen treated, 19 had good results and completed basic training without enough loss of duty time to require that they be set back in their training schedule. One airman did poorly and was treated subsequently with molded arch supports, repeat injections, and prolonged rest, without improvement. He was separated from the Service.

Follow-up was from one to three weeks. The airmen proceeded to their duty assignments and were lost to long-term follow-up.

Discussion and Summary

Many aspects of the painful foot are unsolved. The sinus tarsi syndrome reported by O'Connor,[11] and later by Brown,[12] is one example. The role of the subtalar joint in relation to the peroneal spastic flat foot has been studied[13-15] and seems to be implicated as an etiological factor in the painful foot.

This paper has attempted to introduce a concept of the role of the subtalar joint in the acute painful foot syndrome seen in young adults and precipitated by prolonged foot activity. Basic anatomical considerations have been discussed and a program for symptomatic relief of the painful foot has been based on the concept of an acute inflammation of the subtalar joint, secondary to repetitive stress, as an etiological factor.

Twenty patients with an acutely inflamed subtalar joint and painful foot have been treated by injections of a local anesthesia and steroids to the subtalar joint with good results in nineteen. This experience strongly suggests that an inflammatory process of the subtalar joint and the intra-articular talocalcaneal ligament is the etiology.

The results of the study on a short-term basis have been gratifying, and the authors have been sufficiently encouraged to extend the treatment beyond this limited clinical study.

It requires a very unusual mind to undertake the analysis of the obvious.—Alfred Whitehead

The Bigger They Come, the Harder They Fall

The ancient version of "the bigger they come, the harder they fall," was written by Herodotus (484-424 B.C.) and is concerned chiefly with obesity. "You may have observed how the thunderbolt of heaven chastises the insolence of the more enormous animals, whilst it passes over without injury the weak and insignificant: before these weapons of the gods you must have seen how the proudest palaces and the loftiest trees fall and perish."

Ptolemy VII was one of the fattest men of antiquity who was so obese that he could not walk unless supported from both sides. Another tiny tot of antiquity was Denys of Heraclea, who was so fat that he hardly dared to go to sleep for fear of suffocation.

Obesity has been found in all parts of the world from the Eskimos and their whale blubber, to the South Africans and their vegetable oils and human steaks. The civilized, the aborigines, no peoples have escaped the glutton with his physical handicaps and retardation. Socrates writes, "Bad men live that they may eat and drink, whereas good men eat and drink that they may live." Saint Jerome (345-420 A.D.) echoes: "A fat paunch never breeds fine thoughts." A young lad of Philadelphia is said to have become so fat that he was unable to get out of his house for at least five years. A man from North Carolina attained a round thousand pounds and a woman from Baltimore is reported as blossoming 850 pounds. Daniel Lambert of Leicester at twenty-three years of age weighed 448 pounds, at 39 years of age he weighed 779 pounds, measured three yards around the body and one yard around the leg.

Probably more jokes are directed at the obese individual than to any other type of human being. Whenever the cartoonist or the joke writer runs out of good material, it is always easy to fall back on the cushion of obesity, for the fat sufferer is the natural butt of the joke-smiths. The movies, the radio, the journalist, everybody takes advantage of Fatso.*

Acute Abdominal Syndrome

Goldstone and Le Marquand described a syndrome observed in 13 European servicemen on duty in West Africa that simulated acute abdominal disease. The condition was characterized by fever, right upper abdominal pain, and muscular rigidity. Symptoms appeared gradually, reaching a peak within a few hours. The pain sometimes spread to the entire right side of the abdomen and loin. Considerable rigidity was present with relatively less tenderness in the painful areas. Usually there was diminished movement of the right side of the chest and diaphragm, occasionally accompanied by shoulder pain. The prognosis was good with a rapid, spontaneous improvement in most cases. Goldstone and Le Marquand concluded that these patients most likely had an abortive form of perinephric staphylococcal infection. They also suggested that cases which simulate a perforated peptic ulcer with negative findings at operation may be similar to those described here.

Significance of Late-Developing Reactions in Allergy Skin-Testing

Clinical Correlations

MAX I. MICHELS, LT. Colonel, USAF, MC*
ROBERT E. SMITH, Colonel, USAF, MC*

THE ALLERGY SKIN TEST has been of inestimable value in the identification of specific antigens to which an atopic† person may be sensitive. Many investigators have discussed at length the interpretation of the immediate wheal and flare reaction which occurs within 15 to 30 minutes, and general agreement exists with respect to the positive significance of these reactions.[1-11] However, many physicians who perform these tests occasionally find that several hours may elapse before the skin tests become positive.[3] It has not been common practice to have patients look for, or report, such reactions.

This paper presents an attempt to evaluate the significance of skin tests that were negative at 30 minutes but positive a few hours later. Interest in this investigation was stimulated by the return of a middle-aged woman with classical evidence of allergy by history, physical examination and laboratory data, but entirely nonreactive intradermal skin tests even one hour after testing. When the need for retesting was mentioned, she asked whether it was essential and stated that her arms had been sore, swollen and itching for several days after the first tests.

Material and Methods

All new patients referred to the Wilford Hall USAF Hospital Allergy Clinic must give a complete history and undergo a complete physical examination. Patients who have a probable diagnosis of inhalant allergy and reside in the local area are skin-tested to the 24 antigens most significant for this geographical area.

The Tested Antigens

These antigens are: cottonwood, American elm, white ash, hackberry, oak, pecan, mesquite, mountain cedar, grass mix (Bermuda, Johnson and Timothy), privit, franseria, pigweed, Russian thistle, ragweed mix, scrub elm, house dust, hormodendrum, alternaria, spondylocladium,* helminthosporium, fusarium,* aspergillus* mix, penicillium mix and phoma*. In addition, all patients receive scratch tests to cat dander, dog dander, feathers, kapok,* cattle hair and wool.

*From the Allergy Section, Department of Medicine, Wilford Hall USAF Hospital, Lackland Air Force Base, Texas.

†See Test Your Word Score Page 457.

Beginning with the present study, these patients were asked to observe the skin test sites hourly until bedtime on the day tested and twice a day on the next two days, and to report all reactions. A standard pattern of applying the skin tests was used, and the patient was informed about how to accurately report the reaction to a particular antigen. When any question arose as to the identity of the specific antigen, the tests were repeated.

Patients who reported late reactions were given another appointment for a review of the history with respect to the antigens in question, repeat skin testing if necessary, nasal provocative tests, and nasal smears for eosinophils.

Nasal Challenge

Prior to the nasal challenge the nose and throat were inspected; and the condition of the nasal mucosa, the size of the airway and the amount of mucus in both nares were noted. Mucus from each nostril was taken and placed on separate microscopic slides for staining with Hansel's stain. Then the nasal challenge was performed by spraying 0.15 cc of the suspected antigen directly on the nasal mucosa of one nostril and 0.15 cc normal saline on the nasal mucosa of the other nostril. The patients were not told which nostril received the saline control and which received the challenge. They were observed for 30 minutes and their symptoms recorded. A repeat nose-and-throat examination was performed and the nasal smears for eosinophils were repeated.

Whenever possible, the nasal smears were prepared by having the patient blow each nostril separately onto wax paper. If this procedure did not produce enough material for study, cotton applicators that had been moistened with normal saline were inserted into each nostril for one minute, removed and

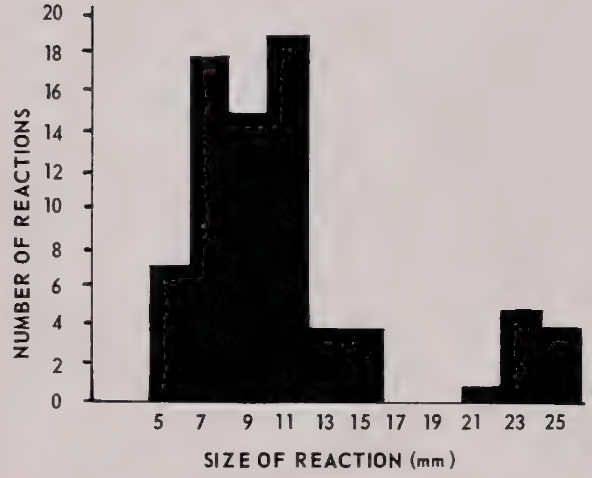

Fig. 1—Size of late reactions in 23 patients.

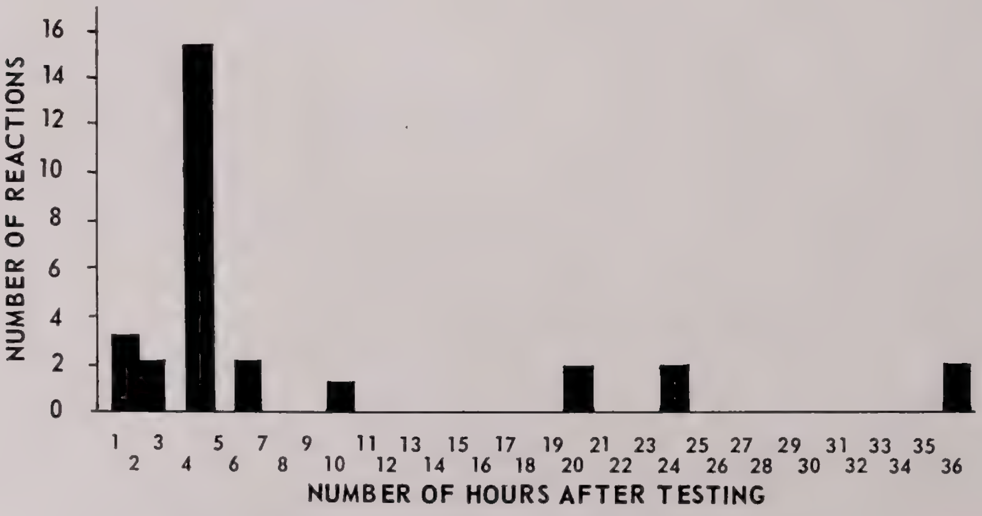

Fig. 2—Number of late reactions by number of hours since onset.

smeared onto microscopic slides. They were then air-dried and stained with Hansel's stain. The patients also prepared slides in a similar manner at home eight and 24 hours, respectively, after the test. Aqueous extracts of pollen and molds were used in a 1:500 dilution and house dust in a 1:10,000 dilution for both the testing and the challenge.

Results

Percentage

The 23 patients who reported late reactions constituted 2 to 3 percent of the group tested during the study interval. The reactions were erythematous papules on an erythematous base; they were moderately pruritic and varied in size from 5 to 25 mm (Figure 1). Of the 77 late reactions in these 23 patients, 52 were in the 6 to 12 mm range. The 23 patients ranged in age from 11 months to 58 years. Six patients were in the first decade, seven in the third, and two each in the second, fourth, fifth and sixth decades. The age distribution of the 10 males and 13 females appeared to be typical of the patients seen in the Allergy Clinic.

Diagnosis

Allergic rhinitis was the primary diagnosis in 18 patients, including two children who were referred because of recurrent otitis media, an apparent complication of the allergic rhinitis. Asthma was the primary diagnosis in the other five patients, although they also had varying degrees of allergic rhinitis. The three to one ratio of allergic rhinitis to asthma was slightly higher than the average in this clinic.

Period of Delay

In 15 patients the late reactions began between the fourth and sixth hours, in three patients between the first and second, in two patients between the second and fourth, and in two patients between the sixth and eighth hours (Figure 2). Other patients had reactions that began at approximately the 10th, 20th, 24th and 36th hours. Three patients had reactions that started at two different times. Ten patients had late reactions only, whereas 12 had both immediate and late reactions (but to different antigens). Several patients showed multiple late reactions, including as many as 15 for some. When the antigens were considered by groups, i.e., pollens, molds, house dust and epithelials, 12 patients reacted to only one group (including five to a single antigen), seven to two groups, and four to three groups (Figure 3). No patients reacted to the four groups. Patients with a single reaction demonstrated no discernible difference by antigen, basic diagnosis and sex from those with multiple reactions. Eighteen patients reacted to molds and, for 11 of them, it was the largest reaction (Figure 4). Twelve reacted to house dust; likewise for five this was the largest. Similarly, seven reacted to pollens and, for four, it was the largest. One patient reacted to cat dander and one to kapok.

The antigens that produced the late reactions corresponded exceedingly well to the clinical history in 13 patients (Figure 5a). In

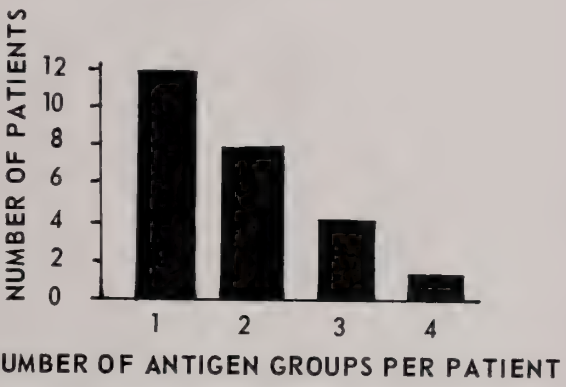

Fig. 3—Number of patients with reactions by numbers of antigen groups.

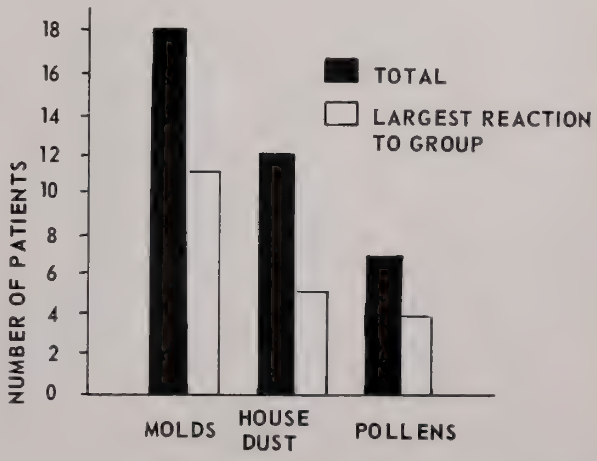

Fig. 4—Number of patients with reactions to various antigen groups.

four other patients, the history was only suggestive. In six the perennial symptoms and the lack of acute observation (usually by the father) made a definite judgment impossible.

Within five to 30 minutes after the nasal challenge, 14 patients complained of significant nasal itching, congestion and/or obstruction and an increase in seromucous rhinorrhea on the challenge side, but not on the control side (Figure 5b). The reactions persisted one to four hours for most patients, whereas they continued 24 to 36 hours for four patients. A few complained of increased itching and tearing of the eyes on the challenge side and/or itching of the palate. No clearcut pulmonary symptoms developed. Those with persistent symptoms did not differ from the rest with respect to antigens, diagnosis, length or course of illness, sex or age.

The symptoms increased in two patients after the challenge, but the effect was almost the same on the control side. One had no change in symptoms, whereas two others had such severe symptoms prior to the challenge that it was impossible to be certain that there was a definite change.

Nasal Eosinophilia

Although the presence of nasal eosinophilia was a consistent finding among these patients, attempts to quantitate the nasal smears were unsuccessful. In those who were asymptomatic prior to the challenge, it was a good index of significant increases in symptoms from the time of the challenge. The smears were positive whenever profuse rhinorrhea was present, but often small increases in counts were difficult to interpret, especially in those with a high percentage prior to challenge or with lower counts that varied from one area of the slide to another. Seven patients had a marked increase in eosinophilia after challenge on the challenge side only (Figure 5c). An increase in eosinophilia in four other patients could not be considered significant. Nine patients were classified as having negative reactions. Three of them had a slight increase in eosinophilia on the challenge side and a similar increase on the control side. Three others who had less than 2 percent eosinophilia before the challenge had a marked increase in the number of lymphocytes and macrophages afterwards, as well as moderate increase in symptoms and rhinorrhea. The remaining three patients were children one, three and five years of age, respectively, with no discernible reaction of any kind to the challenge.

The late reaction of the three-year-old child was entirely different, for it consisted of a 50 to 60 ml patch of eczema beginning approximately 36 hours after the scratch test to Bermuda grass. He had an immediate 18 to 20-ml wheal that lasted three to four hours. The mother reported that during the two previous summers the child had had eczema on the legs and that it was relieved by wearing long pants. Bermuda grass was the only antigen to which the patient reacted, and his allergic rhinitis and asthma attacks were clearly related to ex-

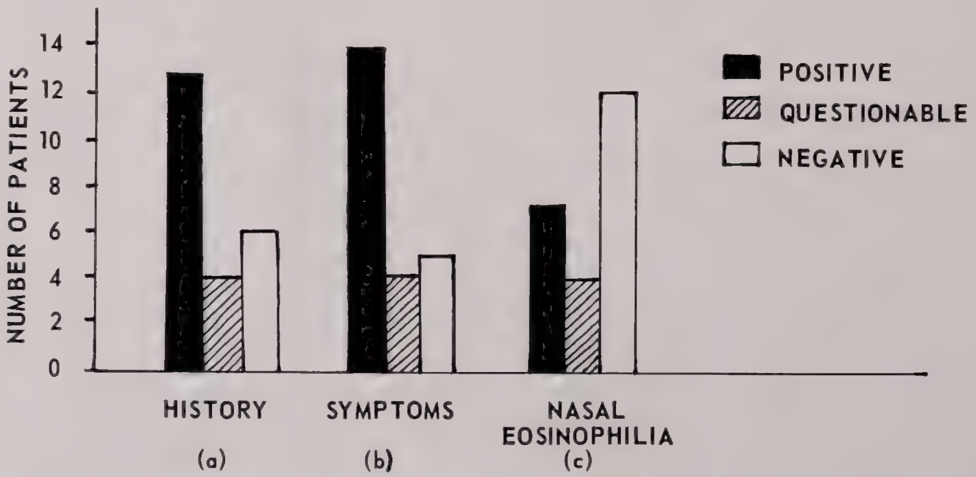

Fig. 5—Positive, questionable and negative correlation of late reactions with history, and with symptoms and eosinophilia after challenge.

posure to that pollen. This child was the only patient who had an immediate and a late reaction to the same antigen.

Physical examination of the patient generally agreed with the symptoms. No patient with a significant increase in symptoms failed to show readily apparent changes on inspection. Two patients with an equivocal increase in symptoms had a marked increase in pallor and edema on the challenge side.

Eighteen of the 23 patients demonstrated excellent correlation between the antigens producing late reactions and *one* of the following: signs, symptoms, eosinophilia after challenge, and history. Two other patients showed highly probable correlations between their antigens and *two* of the four parameters considered. Molds and house dust were the antigens most frequently responsible for late reactions, which usually began from four to six hours after testing.

Discussion

The implication from the results of this study is that the late-occurring reactions are clinically significant. It is now the policy to have all patients who are skin tested at the Allergy Clinic report late reactions. These are considered in the same light as the immediate reaction tests for the treatment of the patient.

Care has been taken to call the reactions late instead of delayed, because in general they appear similar to the immediate wheal and flare responses, and not like the classical tuberculin response, which usually is referred to as delayed. Calling these reactions delayed would add confusion to an already confused terminology and would infer a mechanism that has not been elucidated by this study. One wonders if these reactions might not be mild arthus reactions, but immunologic studies that would confirm or reject this speculation have not been done. It is not known whether the mechanisms for these late reactions are similar to the immediate wheal and flare reactions, in what immunoglobulin fraction the antibody involved in these reactions resides, and how these lesions compare with the classic immediate and delayed reactions.

Conclusions

In a small, but sizable, percentage of allergic patients, local reactions to some or all of the antigens fail to develop until a few hours after intradermal testing. The antigens that produce the late reactions may be highly important to those patients. Therefore, this type of reaction should be looked for actively and given appropriate consideration in evaluations and treatment.

Maternity is a matter of fact; paternity always a matter of opinion.—Ridpath: History of the U.S.

Shakespeare: Diseases

Scrofula (Macbeth)

That "a crew of wretched souls" was delaying the King was the court doctor's reply to Malcolm's inquiry whether Duncan would soon be emerging from the palace.

Those "wretched souls" were scrofulitics suing for the laying on of hands. For centuries English and French kings were supposedly endowed with the divine and hereditary power, "the royal touch," to cure scrofula.* What the doctor himself thought of the ceremonial abracadabra can only be conjectured; monarchs' physicians were too discreet to editorialize on court matters.

When Malcolm asked what disease the doctor was referring to, Macduff explained:

" 'Tis called the evil:†

A most miraculous work in this good king;
Which often, since my here-remain in England,
I have seen him do. How he solicits Heaven,
Himself best knows; but strangely-visited people,
All swollen and ulcerous, pitiful to the eye,
The mere despair of surgery, he cures.
Hanging a golden stamp about their necks,
Put on with holy prayers." Macbeth IV, III

The ritual of the royal touch flourished for centuries, probably initiated by Edward the Confessor early in the eleventh century. Whether or not patients were cured; whether or not they even had scrofula; whether or not they sought the touch for exhibitionism or for the golden disc that was hung around their necks after completion of the rite—all are moot questions.

The royal touch has long been defunct in practice; but under Shakespeare's "magic touch" it survives to contribute literary excellence to Macbeth by way of local color, human interest, and historic validity.

Treatment of Dog-Bite Wounds

GEORGE H. CHAMBERS, Colonel, USAF, MC*
JOHN F. PAYNE, Major, USAF, MC

IN THE UNITED STATES the problem of dog bite is common. Public health officials estimate that approximately 500,000 to one million persons are bitten each year. Annually since 1957, 50,000 to 60,000 people have received prophylactic anti-rabies injections, averaging 14 injections each.[1]

Wilford Hall USAF Hospital, Lackland Air Force Base, Texas, has a unique source of dog bites because of the presence on the same base of the United States Air Force Sentry Dog School, which uses German shepherd dogs. Physical examinations, isolation of dogs before training, and inoculations eliminate the problem of rabies. However, wounds resulting from bites have been problems, for a dog's mouth is often faster than a trainee's hand.

The inexperienced handler is "wedded" to his dog initially, and they experience a getting-acquainted period. Obedience training follows; similar to the basic training of the human recruit, the dog receives obedience training until his response to commands is virtually automatic. Then the team advances to agitation training in order to develop the aggressiveness that is mandatory for a sentry dog. The person who does the agitating wears padded clothing for protection from the attacking dog. Beyond a certain point of aggressiveness, the handler cannot control the dog, and he may be attached to a stake by a line during such training. Most bites occur during the early period of training, but occasionally also by an over-excited dog in the latter stages.

The characteristics of a dog-bite wound are somewhat involved. Studies by veterinarians at Lackland Air Force Base indicate that the bite power is 150 to 200 pounds per square inch and as much as 400 to 450 pounds per square inch by the end of training. This bite power is adequate at times to perforate the

sheet metal gauntlet that is worn as a protective device.

The bacterial contamination of the dog-bite wound has been debated. According to some, the saying, "as clean as a hound's tooth," has some validity.[2] Therefore it has been generally taught that these wounds may be cleansed, debrided if necessary, and closed primarily. However, according to the veterinary literature, the nares and tonsils of a dog are a constant source of many organisms. Staphylococcus albus, alpha streptococcus, and Escherichia coli are extremely common,[3] and Staphylococcus aureus, beta streptococcus and Pasteurella septica are also present in significant numbers. Recent studies from the United States Air Force Epidemiological Laboratory at Lackland Air Force Base have shown that the carrier rate of Staphylococcus aureus, as determined monthly among dogs under controlled conditions, ranges from 16 to 71 percent with an average of 32 percent.[4] Penicillin-resistant Staphylococcus aureus ranges from 10 to 16 percent. Because of this source of infection and the force with which these animals attack, the dog bite must be considered as a potential infected crush injury, and not a simple laceration.

Material

Since 1961, 74 dog bites of the extremities were serious enough to require transfer to the Orthopaedic Clinic at Wilford Hall USAF Hospital, the majority having occurred during the past two years, commensurate with the increase in the number of dogs being trained for service in Vietnam. During these two years there was an average of four bites each month; but only patients who had more severe bites were referred to the hospital. Fifty patients were hospitalized; of these 45 had upper extremities involved and five lower extremities. The 24 patients not hospitalized had involvement of the hand or forearm.

Results

One of the most serious problems in handling these wounds arose with the patients initially treated in the emergency room or the outlying dispensary. Thirty patients were hospitalized after receiving initial treatment three or more hours earlier; 14 had wounds that were described at first as puncture wounds of the hands or fingers. Their wounds were cleansed in the emergency room with Phisohex and covered with a simple bandage. From three to 72 hours later, these patients returned for hospitalization, with massively swollen hands or fingers, as well as limitation of motion. On no occasion was an organism isolated from these patients, although three had epitrochlear and one, axillary nodes. All of these patients responded well to simple splinting, ice, elevation, and soaks.

Debridement and Closure

Ten patients with wounds of the hand or forearm were treated according to the precepts of debridement and primary closure. Of these, eight had positive cultures, including three with Staphylococcus aureus, two penicillin-resistant, two with Escherichia coli, one with beta streptococcus, one with Aerobacter, and one with erysipelothrix, Staphylococcus aureus and Escherichia coli. The wounds of the two patients with cultures reported as showing "no growth" were described as erythematous; swelling and drainage also were present. In addition, serious complications occurred in this group. A mid-palmar space infection developed in one patient and required incision and drainage; the flexor tendon sheaths of the fourth and fifth fingers were necrotic. Another patient required suturing of laceration over the left fourth metacarpophalangeal joint. On incision and drainage one week later, the metacarpophalangeal joint was found to be completely destroyed; Staphylococcus aureus was the responsible organism.

Secondary Closure

The remaining 20 patients who were hospitalized had wounds that were allowed to heal by secondary intention; but sometimes they required secondary closure or split-thickness skin grafting. Positive cultures were obtained from six of these patients; Staphylococcus aureus was responsible in three, Aerobactor klebsiella in two, and beta streptococcus in one; none of these patients had complications.

Antibiotics

Those who recommend treating dog bites

as lacerations also advise the use of a broad-spectrum antibiotic or of penicillin. Only nine patients in the present series received antibiotics; eight of these were among the ten patients who had had their wounds closed primarily but had returned later with the wounds infected. Only then were these patients started on antibiotics. The one patient with beta streptococcus was treated with penicillin; only one patient who had a puncture wound was treated with antibiotics, and a comparison with experience in treating similar wounds gave no indication that the antibiotics shortened the period of healing.

The 24 patients who had upper extremity involvement and were treated on an outpatient basis had wounds comparable to the 42 treated as inpatients. Therapy consisted of thorough cleansing, splinting, bulky compressive dressings (Figure), and elevation for two to four days. Then soaks were started, if needed. Although none of these patients received antibiotics, they had no complications.

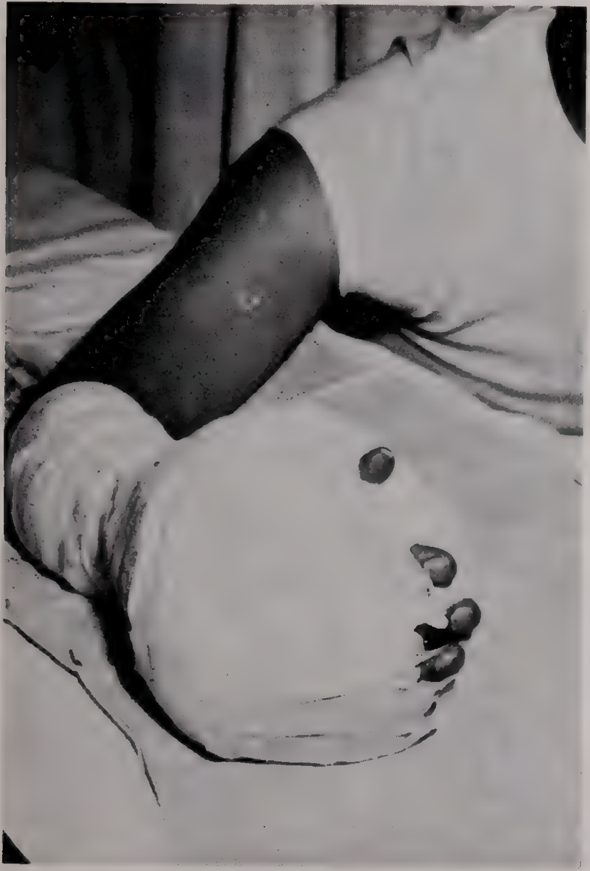

Figure 1—Application of bulky dressing.

Discussion

Dog bites constitute a more serious problem in the United States than is generally realized. It is estimated that from 500,000 to one million people are bitten each year.[1] According to three studies, the extremities have been involved in approximately 75 percent of all bites.[5-7] Actually, the rate of infection in dog bites is unknown. In the epidemiological study of Parrish and associates,[1] the rate of infection has not been determined. Lee and Buhr have investigated 69 dog bites bacteriologically[7] and found an overall infection rate of 29 percent. They report that of the 30 dog bites closed primarily, 47 percent became infected, the most commonly isolated organism being Pasteurella septica. This observation corresponds to the findings of other investigators[8-10] who report complications, such as septicemia and osteomyelitis due to Pasteurella septica. In contrast, 80 percent of the wounds closed primarily in the present series became infected, but no single organism predominates as in Lee and Buhr's series.

Birt[11] reports on 175 dog bites in Great Britain. He states that the most common complication in that country is the development of pyogenic infection; but he includes no percentages in his report. In the United States most authors have dismissed the dog bite as a laceration and advised that the "usual surgical principles" be followed.[2,12,13] However, the present experience demonstrates that the wound must be recognized as an infected crush wound.

Summary

During the past five years 50 patients with dog bites were hospitalized and 24 treated as outpatients at Wilford Hall USAF Hospital. In contrast to treating dog bites as lacerations, as recommended in the current textbooks and journal articles, present experience has dictated the necessity for considering these wounds as infected crush wounds. All patients hospitalized had clinically infected wounds, and the cultures were positive in 20 percent of the patients and became positive in 80 percent of the patients with wounds closed primarily. Two complications resulted in permanent disability in the latter group.

Patients who were treated by thorough cleansing, splinting, bulky dressing, elevation, and soaks had no serious complications. The treatment of this group of wounds was completed by secondary closure and split-thickness skin grafting, or by permitting the wound to close by secondary intention. Antibiotics were not found necessary to the successful treatment of these patients.

Of The Epidemics—Case XV

In Thasus, the wife of Dealces, who was lodged upon the Plain, from sorrow was seized with an acute fever, attended with chills. From first to last she wrapped herself up in her bedclothes; still silent, she fumbled, picked, bored, and gathered hairs (from them); tears, and again laughter; no sleep; bowels irritable, but passed nothing; when directed, drank a little; urine thin and scanty; to the touch of the hand the fever was slight; coldness of the extremities. On the ninth, talked much incoherently, and again became composed and silent. On the fourteenth, breathing rare, large, at intervals; and again hurried respiration. On the sixteenth, looseness of the bowels from a stimulant clyster; afterwards she passed her drink, nor could retain anything, for she was completely insensible; skin parched and tense. On the twentieth, much talk, and again became composed; loss of speech; respiration hurried. On the twenty-first she died. Her respiration throughout was rare and large; she was totally insensible; always wrapped up in her bedclothes; either much talk or complete silence throughout. Phrenitis.*

The Management of Rh ISO-Immunization

by Amniotic Fluid Analysis

DALE R. DUNNIHOO, Lt. Colonel, USAF, MC*

SINCE THE DISCOVERY of the Rh_0(D) blood factor in 1940,[1] significant advances in the diagnosis, management and prevention of Rh sensitization in pregnancy have occurred. The primary method of diagnosis is based on the early studies of Bevis,[2,3] who showed a direct relationship between the amount of bilirubin in the amniotic fluid and the severity of the fetal hemolytic process. The subsequent use of amniotic fluid analysis in the management of Rh iso-immunization in pregnancy has resulted in a decrease of the perinatal mortality from approximately 25 to 9 percent.[4,5]

Although a method of prevention[6] is available currently, the present group of sensitized patients in the childbearing ages will continue to provide a challenge to the obstetrician for approximately the next 10 years. During this period, further refinements in diagnostic and therapeutic technics will be necessary if a continued reduction in perinatal mortality is to be realized.

The four factors essential for an accurate assessment of the fetal state are: (1) the individual delta optical density value, (2) the trend of serial delta optical density values, (3) the changes in the bilirubin peak on the spectrophotometric scan, and (4) the changes in the slope angle of the baselines on serial scans.[7,8] The present study is an attempt to define the usefulness of these four factors in determining the condition of the fetus in an Rh sensitized pregnancy.

Material and Method

Wilford Hall USAF Hospital functioned in its capacity as a consultation center for 51 per cent of the patients in this series. Primary management was accomplished at other Air Force installations except for patients with severe involvement who were referred to this hospital. Inasmuch as patients who underwent intrauterine transfusion procedures will be

the subject of a later report, they were excluded from the present study.

There were 265 amniotic fluid specimens available for evaluation in 85 patients. Amniocentesis was performed from once to 11 times in each patient between 23 and 40 weeks of gestation. The amniotic fluid specimen was placed in a brown bottle immediately after collection and sent to the laboratory, where it was centrifuged for 10 minutes at 2500 rpm and filtered through a No. 48 millipore filter in order to assure removal of all particulate matter. Then the fluid was scanned on a Beckman DK-2A® automatic scanning spectrophotometer from 700 mμ to 350 mμ. The values obtained at 12.5 mμ intervals were plotted on semilogarithmic paper after the method of Liley.[9] The baseline was drawn arbitrarily from 375 mμ to 525 mμ on all graphs, as recommended by Freda.[4] To obtain the delta optical density value (△ O. D.), which represented the amount of bilirubin in the amniotic fluid, the baseline value was subtracted from the peak value at 450 mμ (Figure 1). Then this value was plotted on a modified Liley gestation graph, and the level of involvement ascertained according to the week of gestation. Serial determinations of the delta optical density values plotted at one to two-week intervals were necessary to establish the trend of involvement.

In order to evaluate critically the degree of fetal involvement in the patients studied, the last delta optical density value obtained prior to delivery was plotted on a modified Liley gestation graph, which was subdivided arbitrarily into eight subzones, as follows: the minimal-to-no involvement zone represented by subzones 1 and 2; the moderate involvement zone represented by subzones 3, 4 and 5; and the severe involvement zone represented by subzones 6, 7 and 8 (Figure 2). By use of these subdivisions it was hoped that a clearer definition of the degree of fetal involvement could be obtained from the data.

Results

Three primary types of trends in serial delta optical density values were identified during this study. They were an increasing trend (A), a parallel trend (B), and a decreasing trend (C) (Figure 3). As anticipated, these trends had a tendency to reflect the three basic

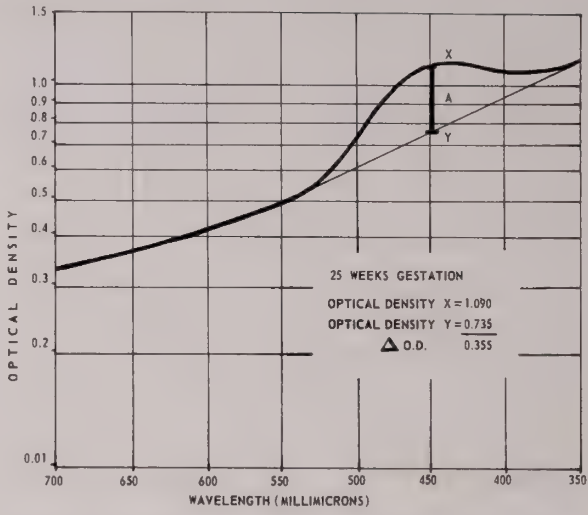

Fig. 1—Semilogarithmic graph showing the method of obtaining the delta optical density value.

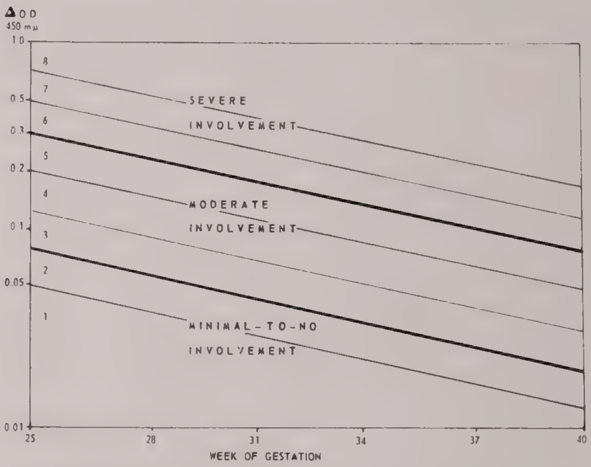

Fig. 2—Modified Liley gestation graph showing the arbitrary division into subzones 1 through 8.

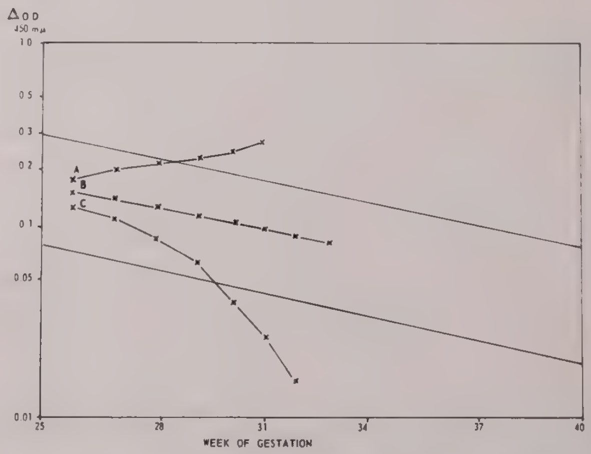

Fig. 3—Three primary delta optical density trends: A, increasing trend; B, parallel trend; and C, decreasing trend.

zones of Liley (Table 1). With the exclusion of the single isolated values, decreasing trends were noted in 88 per cent of the patients in the minimal-to-no involvement zone, parallel trends in 61 per cent of the patients in the moderate involvement zone, and increasing trends in 75 per cent of the patients in the severe involvement zone.

TABLE 1

Types of Trends in Patients in Each Zone of Liley

Zone	Trend		
	Increasing	Parallel	Decreasing
Minimal-to-no involvement	1	2	22 (88%)
Moderate involvement	10	19 (61%)	2
Severe involvement	6 (75%)	2	0
Total	17	23	24

The division of the modified Liley gestation graph into eight subzones revealed a sharp separation of the data with regard to the degree of fetal involvement (Table 2). The average cord hemoglobin value decreased abruptly between subzones 4 and 5. In addition, with the exception of one fetal death in subzone 2 associated with technical difficulties during a neonatal exchange transfusion, no fetal losses occurred below subzone 5. Of the 18 fetal deaths in this series, seven (39 per cent) occurred in subzone 5, the high moderate zone of Liley.

Examination of changes in the spectrophotometric scan that might have prognostic significance revealed that two changes in the bilirubin curve pattern were associated with severe fetal involvement. These changes, previously described by Queenan and Goetschel,[8] consisted of a gradual shift of the bilirubin peak into the shorter wavelengths as the hemolytic process became more severe. The initial shift of the peak to the 420 mμ area produced a double peak at 450 mμ and 420 mμ. Later, immediately prior to fetal death, another shift into the 410 mμ area occurred (Figure 4). A similar shift of the bilirubin peak into the shorter wavelengths may occur in the presence of blood contamination of the amniotic fluid. Oxyhemoglobin produces a major peak at 412 mμ and two minor peaks at 540 mμ and 575 mμ.[7] If blood contamination is minimal, the minor hemoglobin peaks may be difficult to identify and the major peak can be mistaken for the 410 mμ peak of methemalbumin. When methemalbumin is present, a major peak occurs at 410 mμ and a minor peak at 623-630 mμ.[7]

The present series included 11 patients with a bilirubin peak shift into the 410 mμ area that was not associated with fetal death. Only five of these patients had a confirmatory minor peak at 630 mμ, and only two of them had cord hemoglobin values of 8.0 gm per 100 ml or less. For seven of the 11 patients, the cord hemoglobin was less than 11.0 gm per 100 ml.

TABLE 2

Distribution of Patients with Rh Iso-immunization by Zone, Subzone and Outcome of Pregnancy

Zone	Sub-zone	No. patients	Average cord hemo-globin gms%	No. neonatal deaths	No. still-births	Salvage %
Minimal-to-no involvement	1	20	13.7	0	0	100

	8	4	—‡	0	3†	25
Total		85		9	9	80

*Includes 1 hydrops fetalis.

†Includes 2 hydrops fetalis.

‡Insufficient data.

In this series there were 18 fetal deaths, nine neonatal deaths and nine stillbirths. Of the 18 deaths, three were not associated with changes in the bilirubin peak, although the delta optical density values for the three were in the severe zone of Liley. In 12 of the 15 remaining fetal deaths there was a definite 410 mμ shift; in nine of the 12 there was also a confirmatory 630 mμ peak, whereas in three, contamination with blood made evaluation of the peak shift impossible. In two of the three with blood contamination a 630 mμ peak was present. Thus, 12 of the 15 patients with scans suitable for evaluation demonstrated a 410 mμ peak in association with fetal death.

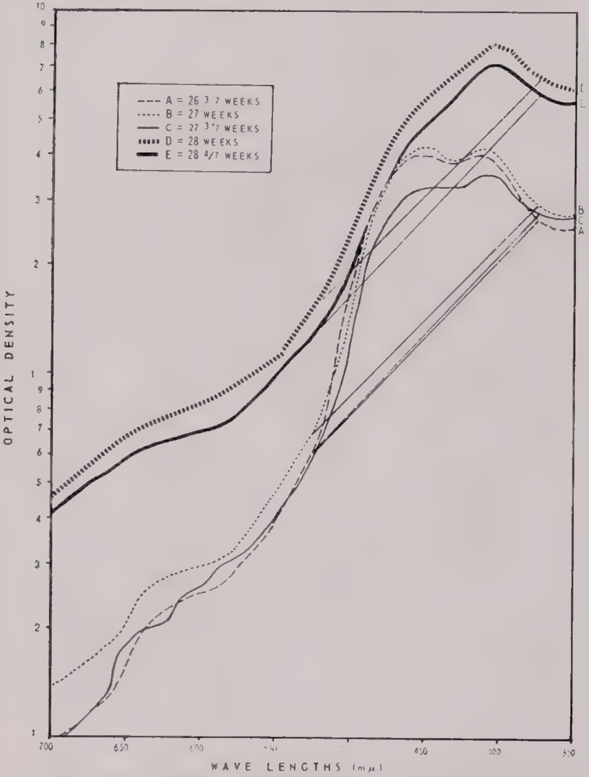

Fig. 4—Serial spectrophotometric scans showing the 420 mμ and 410 mμ shifts in the bilirubin peak. Note the minor peak at 630 mμ on scans A, B, D, and E.

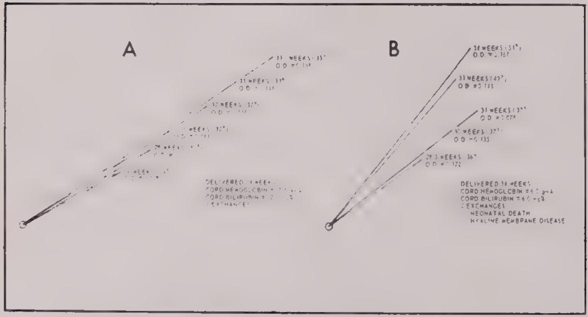

Fig. 5—Comparison of the baseline slope angles in serial delta optical density (ΔO.D.) values of two patients. Patient A had no bilirubin peak shift into the 410 mμ area, whereas patient B had a 410 mμ peak shift.

Another change pointed out by Queenan and Goetschel[8] is that of increased angulation of the baseline on serial scans when the peak has shifted into the shorter wavelengths. When an uninvolved scan was compared to that of a severely involved scan with a peak shift, the baseline was found to have increased as much as 50 degrees from the horizontal. The resultant delta optical density values remained almost constant, even though the hemolytic process became more severe. A comparison of the data in two patients served to illustrate this change (Figure 5). Although the delta optical density values remained about the same in both patients, the slopes of the serial baselines differed markedly. In patient A, with no 410 mμ shift, the slope of the baselines changed little. However, in patient B, with a 410 mμ shift, the baselines increased to 51 degrees from the horizontal. This change in slope of the baselines in patient B masked the severity of the hemolytic process. Therefore, both patients appeared to be similarly involved on the basis of the delta optical density values, whereas patient B was much more severely involved. When the patients were delivered at 34 weeks of gestation, the cord hemoglobin in patient A was 11.6 gm per 100 ml, but the cord hemoglobin of patient B was 6.0 gm per 100 ml.

Discussion

The purpose of this study was to evaluate four prognostic factors in amniotic fluid analysis in 85 patients with Rh sensitization. These factors were: (1) the individual delta optical density value, (2) the trend of serial delta optical density values, (3) the changes in the bilirubin peak on the spectrophotometric scan, and (4) the changes in the slope angle of the baselines on serial scans.

Individual Delta Optical Density

The individual delta optical density value was important in establishing the level of involvement beyond 36 weeks gestation, but prior to this time a single value was of little benefit. Since the magnitude of the curve deviation from normal at 450 mμ decreases progressively as gestation advances in uninvolved pregnancies, it would be essential for a single value to be considerably elevated before it could be considered significant.

Trend of Serial Optical Density

Only after a trend was established could a more accurate prognosis be considered. The trend of serial optical density values was determined by obtaining amniotic fluid specimens at one to two-week intervals and plotting the values on the modified Liley gestation graph. A minimum of three values was necessary to establish a definite trend. If the trend was decreasing, the fetus almost always survived. If the trend was increasing, the fetus was involved to the extent indicated by the zone of involvement, unless there were changes in the scan pattern. Parallel trends were more difficult to evaluate, for they tended to increase or decrease abruptly and assume the prognosis of the subsequent trend. Occasionally, an increasing or decreasing trend would level out and assume a parallel trend.

Change in the Bilirubin Peak

The shift of the bilirubin peak from 450 mμ into the shorter wavelengths was an additional factor in determining prognosis. Although this finding was not limited to a single zone of involvement, the majority of patients with this finding were in the moderate and severe zones of Liley. The significant features of the bilirubin peak shift were the presence of a major peak at 410 mμ, usually associated with a confirmatory minor peak at 630 mμ, and a progressive increase of both peaks on subsequent serial scans. When this occurred, 75 per cent of the infants were significantly involved and 50 per cent did not survive. Considerable caution should be observed in interpreting scans of amniotic fluid contaminated with blood because of the similarity of the 412 mμ peak secondary to oxyhemoglobin.

Freda[4] suggested that the bilirubin peak shift into the shorter wavelengths was caused by fetal acidosis, for the addition of acid to the amniotic fluid produced the same effect. Queenan[7] stated that methemalbumin would produce a major peak at 410 mμ and a minor peak at 623-630 mμ. Abelson and Boggs[10] studied the plasma pigments of infants with erythroblastosis fetalis by spectrophotometric analysis and noted that heme pigments with maximum absorption at 410 mμ or less occurred in infants that usually were severely affected. It would be interesting to speculate that the fetal reticuloendothelial system was overwhelmed by the hemolytic process and that free heme pigment somehow escaped into the amniotic fluid and appeared on the scan as methemalbumin. However, no reliable evidence to support this concept is available at the present time.

Change in the Slope

The change in slope angle of the baseline on serial scans seemed to be significant in its effect on the delta optical density value. Decreasing trends were characterized by a decrease in the slope angle on serial scans from 30 to 40 degrees down to 15 to 20 degrees from the horizontal. Increasing trends had a reverse pattern. Although these changes occurred to some extent with, or without, a shift in the bilirubin peak, the amount of increase appeared to be more marked when there was a concomitant shift of the bilirubin peak into the shorter wavelengths. Only when there was a shift in the bilirubin peak and an increase in the slope of the baseline did the delta optical density value cease to reflect the true state of the fetus.

Summary

Management of Rh sensitization in pregnancy by spectrophotometric analysis of bilirubin in the amniotic fluid has proven valuable and relatively accurate in the majority of patients. Correlation of the bilirubin peak pattern and the baseline slope changes with the trend of delta optical density values should make it possible to increase accuracy.

The incidence of fetal deaths in patients with delta optical density values in the high moderate zone of Liley (subzone 5) was much higher than anticipated. The data suggested that changes in the bilirubin peak pattern and in the baseline slope angles could serve as additional indicators of the degree of fetal involvement. When these changes occurred,

75 per cent of the infants were significantly involved and 50 per cent did not survive.

It's the Law

Involuntary Blood Sample Admissible*

The Supreme Court of Arkansas ruled that a blood sample, taken from the driver of an automobile without his permission, was admissible as evidence of his intoxication. The laboratory technician took the blood sample without asking the driver for permission and tested the blood for alcohol. The pathologist who analyzed the blood testified that it contained .140 per cent of alcohol when taken and that the percentage would probably have been higher one hour earlier. The driver of the car had been involved in an accident where a pedestrian was killed. He was convicted of involuntary manslaughter partly on the basis of the blood alcohol determination.

Walker v. State, 429 S.W. 2d 121 (Ark., June 3, 1968; rehearing denied July 15, 1968).
The Citation 17:12, October, 1968.

I Chose Medicine

My sister and I decided that we must train ourselves to earn our living, for the family finances were rapidly diminishing and our only hope of a wide and full life, of going out into the big world, lay in our own efforts. There seemed only a few careers open to us—teaching, nursing, the practice of medicine. I chose medicine, not because I was scientifically-minded, for I was deeply ignorant of science. I chose it because as a doctor I could go anywhere I pleased—to far-off lands or to city slums—and be quite sure that I could be of use anywhere.*

War

Older men declare war. But it is youth that must fight and die. And it is youth who must inherit the tribulation, the sorrow, and the triumphs that are the aftermath of war.—Herbert Hoover

Let's be specific about Campbell's Soups...
and *reducing diets*

Calorie content of Campbell's Soups

There are more than 30 million people in America who are overweight. During the next year, you probably will see more than 1,000 of them in your own practice.

One good way to help these patients is to give them a reducing diet based on ordinary eating patterns.

Campbell has prepared a sensible plan for weight control based on ordinary eating patterns. The plan consists of a patient instruction booklet and a set of menus which provide approximately 1,200 calories daily. The menus are balanced to provide the minimum daily requirements of nutrients.

To obtain a supply for your office write to:
Campbell Soup Company, Box 265, Camden, N. J. 08101

Campbell's
SOUP

No two women are quite alike...

Ovulen-21 Com
Directions

and no other oral contraceptive is quite like Ovulen-*21*®

Each tablet contains ethynodiol diacetate 1 mg., mestranol 0.1 mg.

The progestin is distinctive, and for some women this may mean a different clinical response. The Compack® tablet dispenser is distinctive; its functional simplicity makes it virtually patient-proof. The acceptance of Ovulen-21 is distinctive... together with Ovulen®, it is more often prescribed than any other individual contraceptive product currently available.

Indication—Oral contraception.

Contraindications—Thrombophlebitis, thromboembolic disorders, cerebral apoplexy or a past history of these conditions, markedly impaired liver function, known or suspected carcinoma of the breast, known or suspected estrogen-dependent neoplasia, undiagnosed abnormal genital bleeding.

Warnings—Watch for the earliest manifestations of thrombotic disorders (thrombophlebitis, cerebrovascular disorders, pulmonary embolism, retinal thrombosis); if present or suspected discontinue the drug immediately.

British studies reported in April 1968[1,2] estimate there is a seven- to tenfold increase in mortality and morbidity due to thromboembolic diseases in women taking oral contraceptives. In these controlled retrospective studies, involving 36 reported deaths and 58 hospitalizations due to "idiopathic" thromboembolism, statistical evaluation indicated that the differences observed between users and non-users were highly significant. The conclusions reached in the studies are summarized in the table below:

Comparison of Mortality and Hospitalization Rates Due to Thromboembolic Disease in Users and Non-Users of Oral Contraceptives in Britain.

Category	Mortality Rates		Hospitalization Rates (Morbidity)
	Age 20-34	Age 35-44	Age 20-44
Users of Oral Contraceptives	1.5/100,000	3.9/100,000	47/100,000
Non-Users	0.2/100,000	0.5/100,000	5/100,000

No comparable studies are yet available in the United States. The British data, especially as they indicate the magnitude of the increased risk to the individual patient, cannot be applied directly to women in other countries in which the incidences of spontaneously occurring thromboembolic disease may differ.

Discontinue medication pending examination if there is sudden partial or complete loss of vision, or sudden onset of proptosis, diplopia or migraine. Withdraw medication if papilledema or retinal vascular lesions are found.

Since the safety of Ovulen in pregnancy has not been demonstrated, it is recommended that pregnancy be ruled out for any patient who has missed two consecutive periods before continuing the contraceptive regimen. If the patient has not adhered to the prescribed schedule the possibility of pregnancy should be considered at the first missed period.

A small fraction of the hormone agents in oral contraceptives has been identified in the milk of mothers receiving these drugs. The long-range effect to the nursing infant cannot be determined at this time.

Precautions—Pretreatment physical examination should include special reference to the breasts and pelvic organs, and a Papanicolaou smear.

Endocrine and possibly liver function tests may be affected by Ovulen. Therefore, it is recommended that such tests if abnormal be repeated after the drug has been withdrawn for two months.

Pre-existing uterine fibromyomas may increase in size under the influence of progestogen-estrogen preparations.

Because these agents may cause some degree of fluid retention, conditions which might be influenced by this factor, such as epilepsy, migraine, asthma, cardiac or renal dysfunction, require careful observation.

In breakthrough bleeding, and all irregular vaginal bleeding, consider nonfunctional causes. Adequate diagnostic measures are indicated in undiagnosed vaginal bleeding.

Carefully observe patients with a history of psychic depression and discontinue the drug if severe depression recurs.

Any possible influence of prolonged Ovulen therapy on pituitary, ovarian, adrenal, hepatic or uterine function awaits further study.

A decrease in glucose tolerance has occurred in a significant percentage of patients on oral contraceptives. The mechanism of this decrease is obscure. For this reason, diabetic patients should be observed carefully while receiving Ovulen.

Because of the effects of estrogens on epiphyseal closure Ovulen should be used judiciously in young patients in whom bone growth is not complete.

The age of the patient constitutes no absolute limiting factor, although Ovulen therapy may mask the onset of the climacteric.

The pathologist should be informed of Ovulen therapy when relevant specimens are submitted.

Adverse Reactions—A statistically significant association has been shown between use of oral contraceptives and the following serious adverse reactions: thrombophlebitis, pulmonary embolism.

Although available evidence is suggestive of an association, such a relationship has been neither confirmed nor refuted for the following serious adverse reactions: cerebrovascular accidents, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.

The following adverse reactions are known to occur in patients receiving oral contraceptives: nausea, vomiting, gastrointestinal symptoms (such as abdominal cramps and bloating), breakthrough bleeding, spotting, change in menstrual flow, amenorrhea during and after treatment, edema, chloasma or melasma, breast changes (tenderness, enlargement, secretion), change in weight, changes in cervical erosion and cervical secretions, suppression of lactation when given immediately post partum, cholestatic jaundice, migraine, allergic rash, rise in blood pressure in susceptible individuals, mental depression.

Although the following adverse reactions have been reported in users of oral contraceptives, an association has been neither confirmed nor refuted: anovulation post treatment, premenstrual-like syndrome, changes in libido, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, fatigue, backache, hirsutism, loss of scalp hair, erythema multiforme and nodosum, hemorrhagic eruption, itching.

The following laboratory results may be altered by oral contraceptives: hepatic function: increased sulfobromophthalein and other tests; coagulation tests: increase in prothrombin, Factors VII, VIII, IX and X; thyroid function: increase in PBI and butanol extractable protein bound iodine, and decrease in T^3 uptake values; metyrapone test; pregnanediol determination.

Editorials

Wilford Hall USAF Hospital

THE EDITORS of MINNESOTA MEDICINE are pleased to present this issue from the Wilford Hall USAF Hospital. Elsewhere in this issue* an account of the development of this huge medical installation is given. General Thomas Crouch assumed command of Wilford Hall Hospital on June 1, 1965; however command changed hands November 1, 1968, and Wilford Hall Hospital is currently supervised by Brigadier General Edgar Harrison Underwood, Jr. General Underwood, in addition to being a flight surgeon, is a member of the Aerospace Medical Association, Society of Air Force Flight Surgeons, and is a Fellow of the American College of Surgeons. Through General Underwood we extend our thanks to the Medical Staff at Wilford Hall Hospital and particularly to the physicians who contributed to this issue of MINNESOTA MEDICINE.

Many members of the Minnesota State Medical Association have pleasant memories of duty at Kelly Field, the site of Wilford Hall Hospital, during World War II. This member of the Board of Editors served as the first medical director of the San Antonio Aviation Cadet Center when it was opened for Cadet Reception in the Fall of 1941. I recall those gruelling days when 300 cadets traipsed through the wooden barracks building assigned to the Medical Department every day, five days a week, for an Air Force physical examination. Those days, of course, the cadets were members of the Army Air Corps, the Air Force not yet in being. Dr. E. G. Benjamin was one of the early physicians in charge of these examinations. The high point of our service together at Kelly Field was a trip we two medical officers took to Ft. Sill, Oklahoma, in the rear seats of two AT-6's. This was a training flight for the pilots and the flight surgeons, and incidentally Ft. Sill was the training location at that time of the Minnesota Hospital Unit.

It is important that the advances in medicine being made currently in military hospitals be made available to civilian physicians. We are pleased to take part in such dissemination of important information.

Reuben Berman, M.D.

...you have a lot going for you in the wide range of bacterial infections.

PRESCRIBING INFORMATION. For complete information consult Official Package Circular. **Indications:** Infections due to susceptible strains of Gram-negative bacteria (including Shigellae, *S. typhosa* and other Salmonellae, *E. coli, H. influenzae, P. mirabilis, N. gonorrhoeae* and *N. meningitidis*) and Gram-positive bacteria (including streptococci, pneumococci and nonpenicillinase-producing staphylococci). **Contraindications:** A history of allergic reactions to penicillins or cephalosporins and infections due to penicillinase-producing organisms. **Precautions.** Typical penicillin-allergic reactions may occur, especially in hypersensitive patients. Mycotic or bacterial superinfections may occur. Experience in newborn and premature infants is limited and caution should be used in treatment, with frequent organ function evaluations. Safety for use in pregnancy is not established. In gonorrheal therapy, serologic tests for syphilis should be performed initially and monthly for 4 months. Assess renal, hepatic and hematopoietic function intermittently during long-term therapy. **Adverse Reactions:** Skin rash, pruritus, urticaria, nausea, vomiting, diarrhea and anaphylactic reactions. Mild transient elevations of SGOT or SGPT have been noted. Black tongue has been noted in some patients receiving the Chewable Tablets. **Usual Dosage:** Adults—250 or 500 mg. q. 6 h. (according to infection site and offending organisms). Children—50-100 mg./Kg./day in 3 to 4 divided doses (depending on infection site and offending organisms). Bacterial menir —150-200 mg./Kg./day in 6 to 8 divided d Children weighing more than 20 Kg. shoul given an adult dose when prescribing o In parenteral administration, children weig more than 40 Kg. should be given an adult Beta-hemolytic streptococcal infections sh be treated for at least 10 days. **Supplied:** Capsules—250 mg. in bottles of 2 100. 500 mg. in bottles of 16 and 100. For Suspension—125 mg./5 ml. in 60, 80 anc ml. bottles. 250 mg./5 ml. in 80 and 15 bottles. Chewable Tablets—125 mg. in b of 40. Injectable—for I.M./I.V. use—via 125 mg., 250 mg., 500 mg., and 1 Gm. Ped Drops—100 mg./ml. in 20 ml. bottles.

Cardiac Catheterization in the Management of the Acutely Ill Patient

THE TRADITIONAL ROLE of the Cardiac Catheterization Laboratory was to serve as an elective tool to establish an anatomic diagnosis in patients with heart disease. Pathophysiologic measurements were not available. The acutely ill patients were considered too sick for catheterization. Image intensification fluoroscopic equipment, rapid methods of pressure and cardiac output measurements, continuous monitoring, techniques for the control of arrhythmias, and advances in resuscitation have expanded the role of the laboratory by enabling the safe and successful catheterization of critically ill patients and have provided pathophysiologic data which may assist in their management. The laboratory may be employed in one of three ways: as a diagnostic tool; to assess and follow pathologic physiology; and as a means of therapy.

The diagnostic catheterization of critically ill patients carries a higher risk[1] than the usual diagnostic study. This fivefold increase is warranted where adequate therapy, e.g., surgery, depends upon a precise anatomical or physiologic diagnosis, for the risk of deferred or improper therapy is greater than that of catheterization. Pulmonary embolism, for example, is a disease where selective pulmonary angiography can establish the diagnosis in patients with obscure clinical pictures or can show the exact localization of the lesions for emergency surgery such as the Trendelenberg procedure. The less hazardous, less time-consuming, but not specific chest films or radioisotope scans can be used to follow the patient once the diagnosis is established.

In the patient with a dissecting aneurysm, aortography will establish the diagnosis and outline the anatomy of the lesion so that the surgeon may be properly prepared to deal with the specific vascular lesion. In the cyanotic infant, conditions such as transposition where prompt surgery may be lifesaving can be differentiated from tetralogy where careful medical management will enable survival so that the defect may be repaired later at lower risk. The postoperative heart surgery patient may benefit from catheterization since defective function of prosthetic valves or grafts, intracardiac clots, faulty repairs, etc., may be demonstrated, enabling prompt surgical correction.

The value of assessing the pathophysiologic changes is best exemplified by the patient in shock. Though presenting a well defined clinical syndrome, these patients may suffer from a diversity of pathologic alterations in cardiovascular physiology, including cardiac output, peripheral vascular resistance and central filling pressure. Catheterization, with measurement of these variables, provides a better understanding of the "shock syndrome" and enables therapy to be directed at the specific alteration. Already a number of shock units have been established to enable physicians to rapidly insert right and left heart catheters and make repeated measurements of these fundamental derangements in patients in shock.

The introduction of catheter pacemakers has demonstrated the importance of the cardiac laboratory in treating certain conditions. The prompt placement of an emergency pacemaker catheter may be lifesaving in a patient with myocardial infarction who develops heart block or in the patient with Stokes-Adams attacks. Pacing is more practicable than drug therapy and produces fewer complications. The laboratory later may be the source of definitive therapy with insertion of a permanent transvenous pacemaker if required.

The introduction by Rashkind[2] of ballooning the atrial septum in patients with transposition of the great vessels to provide better mixing may significantly improve survival in these critically ill infants without the risk of a thoracotomy, another therapeutic use of catheterization. A still newer therapeutic application is the use of pulsed balloon catheters[3] to support the circulation in patients with myocardial failure due to acute infarction, a procedure whose value needs to be further explored.

The value of the Catheterization Laboratory

Dear Doctor,
You made me
what I am today
a whole lot
slimmer!

TEPANIL —the right start in support of the weight-control program *you* recommend. It reduces the appetite. Doesn't kill it. Weight loss is significant—gradual—yet there is a relatively low incidence of CNS stimulation. Because TEPANIL works on the appetite, not on the "nerves."

Contraindications: Contraindicated concurrently with MAO inhibitors, in patients hypersensitive to diethylpropion hydrochloride, and in emotionally unstable patients known to be susceptible to drug abuse.

Warning: Although generally safer than the amphetamines, use great caution when prescribing for patients with severe hypertension or severe cardiovascular disease. Should not be used during the first trimester of pregnancy unless potential benefits outweigh potential risks.

Side Effects: While rarely causing therapy to be withdrawn, side effects may occur occasionally; CNS effects (such as insomnia, nervousness, jitteriness), dryness of mouth, thirst, nausea, abdominal distress, constipation, headache, allergic response including urticaria or other dermatitis; rarely associated with tachycardia, cardiac arrhythmia or ECG changes.

Convenience of two dosage forms: TEPANIL Ten-tab tablets: One 75 mg. tablet daily, swallowed whole, in midmorning (10 a.m.); TEPANIL: One 25 mg. tablet three times daily, one hour before meals. If desired, an additional tablet may be given in midevening to overcome night hunger.

Use in children under 12 years of age is not recommended.

THE NATIONAL DRUG COMPANY
DIVISION OF RICHARDSON-MERRELL INC.

T817A U.S. PATENT NO. 3,001,910 1/69

in the management of the critically ill patient is already apparent. Its more widespread use depends on the development of techniques which enable the safe, rapid and simple acquisition of data with minimal trauma to the patient, the widespread use of portable image intensifiers so that the laboratory can be brought to the acutely ill patient rather than vice versa, and the use of computer techniques so that the multiple variables present can be rapidly analyzed and the data made immediately available.

The United States Air Force Central Tumor Registry

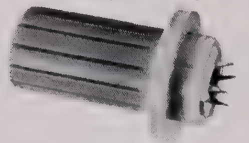
MAJOR AIR FORCE HOSPITALS throughout the United States have had tumor registries for the past seventeen years. Eleven such registries had been functioning, but several inevitable problems had developed from this situation. With the mobile population of Air Force personnel, many patients were followed by three or four tumor registries for the same tumor. In other instances, a patient might move to a new station and be lost to follow-up. Clinical investigation of a particular tumor Air-Force-wide was impossible. Records from each registry were kept locally with the result that an investigator either had access to only a single registry's experience, or would have to make trips to each of the eleven registries to accumulate all of the Air Force data.

In June 1967 a USAF Central Tumor Registry was established to avoid duplication of patient follow-up and loss of patients to follow-up, to assess a quality control of treatment of malignancies in various Air Force hospitals, and to allow physicians access to Air-Force-wide experience. This registry collates the records of the prior registries and incorporates subsequent Air Force records. To accomplish these aims, a new Air Force directive was written requiring all hospital registrars to send copies of pertinent patient material to the Central Tumor Registry each time a patient is admitted to a hospital. Registrars receiving records of patients with malignancy at the time of transfer to a new station are required to register the name and address of such patients with the Central Tumor Registry. All Air Force pathologists, pathology centers and the Armed Forces Institute of Pathology send duplicates of pathology reports of malignant conditions occurring in active-duty, dependent, or retired Air Force personnel. Radiation treatment centers and tumor boards submit duplicates of treatment records and recommendations to the Central Tumor Registry. Physicians caring for patients in the Outpatient Clinic are contacted for their evaluation of the status of patients periodically. By means of these multifaceted checking procedures, almost 100 percent follow-up of patients with malignant diseases is possible.

The functional format of the Central Tumor Registry has been developed to store and code information in a mode that allows total ac-

TB is still around.

In 1967 almost 45,000 new active cases were reported. Isn't that a good reason to make tuberculin testing with the white LEDERTINE™ Applicator a routine part of your physical examinations?



TUBERCULIN TINE TEST
(Rosenthal) with Old Tuberculin

Precautions: With a positive reaction, consider further diagnostic procedures. Use with caution in persons with active tuberculosis or known allergy to acacia. Vesiculation, ulceration, or necrosis may occur at the test site in highly sensitive persons.

cessibility and rapid retrieval to all contributing physicians and hospitals. To accumulate information without using it, or to serve merely as a repository of patient records is a useless and wasteful exercise, too often indulged in by tumor registries.

The information in the Central Tumor Registry is accessible to rapid retrieval in two major forms. All records are microfilmed and filed according to tumor type and site. Review of Air-Force-wide experience with a specific tumor may be accomplished readily through diazo duplication ("microfiche") of the contents of the original jacket. Thus a particular hospital's experience can be evaluated, for the microfilm records are filed and accessible in this manner. Specific information about a particular patient or type of tumor, a tumor treated in a certain manner, results of chemotherapy or radiation therapy on longevity and quality of survival, and gross survival statistics are instantly available through a code system using punch-card data sorting or a magnetic tape computer retrieval. Presently, the Central Tumor Registry is collaborating with a non-profit research computer organization (MITRE) to determine the feasibility of computerizing patient data in malignant diseases. The Central Tumor Registry has an "on-line" remote teletype linked to a computer in Massachusetts that allows local program development and nearly instant readout of information from the magnetic tape 2,000 miles away. Information about any of the problems mentioned previously can be obtained, analyzed, calculated statistically and typed in any desired format in five minutes.

At the present time, a physician who wants to use Central Tumor Registry information has access to complete records of any type of tumor or hospital information that he would like to have within 24 hours. If specific information is desired, such as that available on punch cards or magnetic tape, it is retrievable within a few hours. It is hoped that this rapid accessibility will encourage physicians and hospitals to use the tumor registry data rather than consider the register a one-way street on which all information comes into the Central Tumor Registry, only to lie dormant and unused.

Future plans include further development and refinement of the punch-card data, magnetic tape input-accessibility, and further definition of the exact type of computer best suited to registry requirements. It is envisioned that within two years a Phase II computer will be rented for the tumor files. At that time "on-line" teletypes should be available to each major Air Force hospital tied in with the computer in order to allow these hospitals identical accessibility to all Air Force records without having to query the Central Tumor Registry for feedback of information. This registry is only in its first year of development, but the number of patient records available, the refinement of data accessibility and the potential for improvement of patient management have made this hospital most enthusiastic about its future.

Fred G. Conrad, Lt. Colonel, USAF, MC
Chairman, USAF Central Tumor Registry

Changes in Vietnam Casualty Management

ALTHOUGH MUCH of the surgical management of war wounds in Vietnam is patterned after the lessons learned during World War II and especially during the Korean War, some changes are in evidence. These changes are due to medical advances and to certain aspects of the tactical situation. Helicopter evacuation from the field to definitive treatment centers had its inception during the Korean War. In Vietnam it has become commonplace and, as a result, patients frequently are operated upon within an hour after wounding.[1] Many more patients are thus salvaged, whereas formerly they would have succumbed during the longer interval between injury and treatment required for surface vehicle evacuation.

As a consequence of this expeditious treatment, the postoperative management of many patients who survive with multiple, extensive injuries has assumed more complexity. Therefore, even a slight improvement in the mortality rate among treated Vietnam casualties, compared to that of the Korean War,[1] is a tribute to not only the effectiveness of the helicopter evacuation system, but also, notably, the medical advances in techniques of resuscitation and management of shock.

The cause of missile injury in Vietnam has changed significantly compared to World War II and the Korean War.[1,2] In the latter conflicts, 75 percent of the battle casualties resulted from fragmentation injury and 25 percent from gunshot wounds. However, in Vietnam the incidence of high velocity small arms fire has been close to 50 percent, the difference probably due to the increased number of search and destroy missions during which the individual is more exposed to sniper fire. The significance of a high velocity bullet wound in terms of morbidity has been brought out by a study of 621 Vietnam casualties with penetrating wounds of the abdomen admitted for interval care to the United States Air Force Hospital at Clark Air Base between July 1965 and December 1966.[2] The injury was caused by bullets in 310 patients and by fragments in 311 patients. An abdominal re-operation has been required in 41.3 percent of those with bullet wounds, whereas such intervention was needed in only 13.2 percent of those with fragment wounds. Moreover, 70 percent of the 415 significant complications recorded for the entire group occurred in patients with bullet wounds.

The incidence of arterial wounds in Vietnam is essentially the same as in the Korean War and World War II; however, the management of these injuries has undergone significant changes with each conflict. In World War II the vast majority of arterial wounds were ligated. In Korea, direct arterial suture was introduced and the technique refined. When primary anastomosis was impossible, arterial homografts were used sparingly. Eventually experience was gained in the insertion of a limited number of autogenous vein grafts, which comprised less than 15 percent of repairs in any of the series reported. In Vietnam, vascular repair has been attempted in all patients when there is a potential for salvage of the limb. However, a notable difference in management has been indicated by the significant increase in use of autogenous vein grafts, which constitute approximately 42 percent.[1,2,3]

In general, the more extensive arterial wounds will require vein grafts for reestablishing continuity; however, this correlation has not always been clearly defined. It is possible that the current increased incidence of high velocity small arms fire, with its greater destructive potential, is an apparent explanation for the increased use of vein grafts in Vietnam. However, no correlation has been found between the selection of a vein graft and the wounding agent in 171 major arterial wounds of the extremity.[2] Although it has not been substantiated, it is presumed that, in some cases at least, the selection of vein grafts in Vietnam has reflected a familiarity with this technique gained in recent years during the management of peripheral vascular occlusive disease. The final chapter on vascular injury in Vietnam awaits the results of comprehensive

WHEN YOU WANT COUNSEL—
YOU WANT THE BEST!

That's why we're proud to publicize our twenty-four years of experience working exclusively with the Medical and Dental Professions. Consider also the 50 Consultants and 2000 Clients involved and you know that within the framework of our organization must lie the answer to your problems, whatever they may be. We offer you wide experience, vast statistical data, and expert counsel on all phases of practice management and personal financial planning—RECORDS, ROUTINES, TAXES, INVESTMENTS, INSURANCE, CREDIT AND COLLECTIONS, FEES, PERSONNEL, PARTNERSHIP PROBLEMS, AND MORE.

Our representative in your area will be pleased to explain to you—without obligation—how you, too, may have at your disposal all that the past twenty-four years have taught us. Surely it's worth your time to investigate!

and exhaustive studies by Rich and Hughes, who have established a Vietnam vascular registry at Walter Reed Army Hospital.[4] Currently, there are more than 850 registered casualties.

The most notable change in the management of thoracic wounds in Vietnam is the use of a chest tube in the treatment of hemothorax and hemopneumothorax.[5] In 77 percent of 476 patients with penetrating wounds of the thorax, insertion of a chest tube was the initial treatment. In marked contrast, thoracentesis was used initially in 80 to 90 percent of patients during the Korean War. Moreover, the incidence of empyema was significantly less in the Vietnam series than in Korea.

An ingenious innovation that combines simplicity with safety is the one-way flutter valve developed by Heimlich,[6] a device which eliminates the need for underwater seal drainage in many patients, often allows earlier ambulation, and permits safer and easier management of patients who must be evacuated to rear echelon treatment centers while a chest tube is in place.

These examples highlight some of the major changes in treatment and management currently practiced in Vietnam. The majority of the principles of casualty care are well established and applied in one conflict after another. However, the overall management can be expected to undergo useful modifications in keeping with advancements in medicine.

Clinical Research at Wilford Hall USAF Hospital

A NECESSARY COMPONENT to any teaching hospital or teaching program is a research laboratory. The need for an experimental surgical/anatomy unit for the surgical specialties is obvious. An anatomy laboratory is strongly recommended for all surgical residency programs to develop new surgical techniques or to acquire skills in accepted, but difficult procedures which should be practiced on experimental animals to develop speed, assurance and technique. Non-surgical specialties should also have access to a research laboratory as an incentive in acquiring and maintaining the interest of outstanding attending physicians and to induce a high caliber of trainees to select a residency through the assurance that the teaching staff is current in knowledge, active in the forefronts of medical specialties and expert in specific facets of their specialty. If members of the staff have published a great deal and are recognized authorities, young men will be attracted to seek further training under such mentors.

The staff physicians assigned to Wilford Hall USAF Hospital are selected because of their interest in teaching and in clinical investigation. A research laboratory which is able to support these interests and make avail-

able equipment, supplies, space, technical and professional assistance required for research is a major inducement for a highly trained research physician to become career military. This hospital has a full staff of research-trained veterinarians, veterinarian technicians and surgical technicians to allow residents to develop technical skill in complicated established surgical procedures and to undertake the development of experimental surgical techniques to correct medical problems refractory to satisfactory surgical treatment.

Some of the more notable achievements accomplished in this laboratory over the past several years have included *pressor assay determinations* as a means of selecting patients with correctible unilateral renal hypertension. McPhaul[1] and his associates with the collaboration of Dr. Arthur Grollman developed and evaluated pressor substance obtained from renal vein plasma in an attempt to correlate the presence or absence of pressor substance with other functional and morphologic parameters of unilateral renal disease and with response following surgical correction of a vascular abnormality or extirpation of a diseased kidney.

In the field of hematology, Conrad and Grisham modified the thromboplastin generation test and thereby detected large numbers of patients with plasma thromboplastin antecedent deficiency (Factor XI).[2] Their publication defined the inheritance, incidence and diagnostic laboratory parameters of this disorder. Cooper's[3] studies on exercise physiology and physical conditioning has revitalized the entire health program of middle-aged Americans.

The publication "Aerobics",[4] which arose from these studies in exercise physiology conducted in the clinical research laboratory, has placed exercise and physical conditioning on a firm scientific basis and will be the standard for Air Force physical conditioning tests.

Most recently, interest has been centered in the area of organ transplantation. Renal homotransplantations, first experimentally perfected in the laboratory, have been performed clinically for the past four and one-half years at Wilford Hall USAF Hospital with notable success.[5] The development of *immuno-suppression techniques,* including thoracic duct fistulae, antilymphocyte globulins, and extensive histocompatibility typing, is being actively investigated. Surgical techniques for cardiac and liver transplantation are currently being perfected by the surgical staff.

The concept of research physicians available to support and to complement clinical specialists as exemplified in the Aerospace Medical Laboratory (Clinical) has proven a successful means for each physician to contribute toward continual improvement in patient care.

Fred C. Conrad, Lt. Colonel, USAF, MC
Director
Aerospace Research Laboratory (Clinical)

You May Be Right

Abortion or Compulsory Pregnancy?

"The dogmas of the quiet past are inadequate for the stormy present"—Abraham Lincoln

MINNESOTA'S ANTIQUATED abortion law should be repealed or liberalized. The present law, last changed in 1886, was established at a time when women played a far more subservient role in society and had little or no influence on law-making—even that having to do with their own bodies. If *men,* being the law-givers, were the child-bearers and child-tenders in our society, all proscriptions on abortion would undoubtedly have been removed centuries ago.

The question whether abortion is moral or immoral has been strongly colored by generations of philosophers and theologians (all men) indoctrinated in the ancient role of male dominance, and it is their sonorous voices that have established our present punitive abortion laws. Our present law impresses the philosophy of a minority upon all our women. Now that the battle for women's rights has been joined by both men and women, the existing laws relating to abortion are gradually being modified. Recent polls disclose a desire on the part of both the general public and the medical profession for a more humane and liberal law.[1,2,3,4,5] Hopefully, the day will come when a decision regarding abortion will be left to the pregnant woman.

We must ask ourselves who is best qualified to decide whether a pregnant woman should be allowed an abortion? Should the physician alone make this decision? Or the patient's minister, lawyer, or (perish the thought) the pregnant woman herself? An increasing number of countries have answered this question by accepting the premise that the pregnant woman be granted this prerogative.

The unfairness of the present situation is also reason for change. It is unjust that one woman, because she is *poor,* be denied an abortion, while a *wealthy* woman flies to Tokyo, has her abortion performed by a Harvard-trained gynecologist, and is back in Minneapolis within the week. It is unfair that one woman, because she doesn't know the right doctor, be denied an abortion, while another more knowledgeable woman finds a sympathetic physician, here or in a neighboring state, to perform her abortion. It is not only unjust but cruel to hear of a district attorney who commanded a rape victim, under threat of criminal prosecution, to bear the child of her degenerate attacker,[6] when we know, law or no law, that an influential woman could easily obtain an abortion in such a situation.

Should the law be liberalized, medical developments will provide physicians with further indications for abortion; amniocentesis is now being used to determine the presence of a fetus with chromosome abnormalities. This method, in conjunction with a liberal abortion law, would allow us to decrease the percentage of children born with congenital anomalies.

There has been an unnatural concern of many over the "rights of the fetus." The author, while respecting the right to hold such a view, feels that there has been *too little* concern for the pregnant woman. At our own feet must lie some of the responsibility for women who have died following

New drugs take exams, too.

Today, virtually every medical school in the United States cooperates with pharmaceutical manufacturers in the clinical evaluation of new and promising drugs. Just as you might find it significantly more difficult to practice medicine without the useful new compounds made available through original pharmaceutical research in the past twenty years—prescription-drug manufacturers would find it equally difficult to obtain extensive, long-term, dependable evaluations of new therapeutic agents without the close cooperation of medical staffs and clinical facilities of medical schools and teaching hospitals. Such cooperation leads toward more effective care of more patients—the common goal of medical and pharmaceutical research—toward reduction in the cost of disease, toward increase in useful longevity.

This message is brought to you as a courtesy of this publication on behalf of the producers of prescription drugs.

criminal abortions. We cannot be proud of conforming to a law that has produced so much heartache. If we as physicians were truthful regarding our own foibles, we would admit, I think, to a tendency to be *judgmental* in regard to many of the decisions we make. As one woman so aptly stated, "Physician, heal thyself; your deity complex is showing."[7]

In an enlightened society we should, so far as possible, provide conditions that ensure that every child is a wanted child. Unloved, unwanted children are an expensive social burden, for they are unhappy individuals frequently involved in delinquency. Those who snivel about the "rights of the fetus" might better be concerned about the right of every child to a home where he is wanted and loved. Single women who decide to raise an unwanted illegitimate child usually must work; the child is frequently neglected and sometimes even rejected by the mother. Bringing into the world an unwanted child should be recognized for what it is: a crime against the child and society.

Finally, one of the strongest arguments for a more liberal law is the increasing disregard of the present law by so many physicians. Abortions performed to interrupt conception following rape, incest, and German measles are all criminal under the present law. Likewise, abortions performed to help preserve the emotional health of the mother or the stability of the family are also illegal. When it becomes necessary to break the law in order to practice good medicine, then it is time to change the law.

Letter to the Editor

Isoteric

Dear Editor: Though a non-hunter myself, I found your article in Minnesota Medicine* on "Headaches in the Hunting Season in Kandiyohi County" challenging and informative. Particularly fascinating was the description of the double blind experiment. Though the METHOD was not completely explained, I assume in this case the double blind faced a slough or bog or lake and contained two hunters. Is this not a dangerous experiment in a double blind, both hunters having guns? Please give us more particulars.

Rabbi ben Jacob

Editor's Note: Dear Rabbi ben Jacob, You are so right! You, being a non-hunter, I marvel at your insight in having been able to so accurately decipher the literary implications in my time-consuming scientific venture. As one of the participants in the double blind, I must admit that I had to duck a few times, but fortunately my assailants were amateurs, poor shots, and inadequately equipped; they made my head ache, occipitally, though, and that's what tipped the balance so overwhelmingly in favor of—.

Associate Editor's Note: Now go back and read 'em all. R.B.

*Minnesota Med 51:1759, 1968.

Dear Colleague Rice!

Through your kindness and open-mindedness, which we gratefully acknowledge, it has become possible to publish in Minnesota Medicine a first, albeit short, cross-section of scientific endeavors in a German University, i.e., in the Department of Surgery of the University of Bonn.

My co-workers and I are grateful for your cooperation in publishing these scientific contributions in Minnesota Medicine at this time and for others in the future. This will broaden the common basis for continuing scientific research and publications; it will deepen our personal and scientific contacts, extend the stream of intellectual exchange, and thus help our mutual scientific endeavors.

The special issue* devoted to the Rheinischen Friedrich-Wilhelms-University in Bonn depicted on its cover a superb picture of our new building of the Surgical Hospitals and Policlinic. For this distinction I would like to add the expression of grateful appreciation of the Dean of my faculty as well as of the Rector of the Rheinischen Friedrich-Wilhelms University in Bonn.

You may be assured that my co-workers and I at the Surgical University Hospitals in Bonn will continue to submit to Minnesota Medicine contributions of our own as well as papers of value as they originate in Germany at large.

My special appreciation goes also to all those responsible for the superb translations as well as for the excellent printing and the layout of the format.

With all my good wishes, also for the New Year, and my best greetings as a colleague, I remain

Director o. Prof. Alfred Gütgemann, M.D.

The Editor's Soliloquy

Honorable Men

THE "ABSOLUTE FREEDOM" promulgated and practiced by some of our brash and vociferous minorities today should rather be termed absolute license: the prerogative to enjoy the rights of a democratic society without assuming the responsibilities that must morally complement those rights. Destructive criticism of our social order without the implementation of constructive alternatives constitutes nihilism: the demolition of institutions and values not only for the revolutionaries themselves but for the total society.

Individuals who coalesce into mobs are rarely responsible citizens—either singly or socially. Their mass ideology fosters the delusion that government must generously provide for its people instead of expecting them to provide for themselves: a fallacy that breeds militant intolerance and hostility toward others who neither share nor condone their ideology.

Of course we must listen and try to understand the minority malcontents our social system has unwittingly produced; we must encourage and educate individuals and groups to improve their economic status and elevate their social standards. But we need not identify with them or promote their ideologies. A healthy society encourages the symbiotic, not the parasitic role in its members.

Within some segments of our society a few of the finest terms in the English language are growing obsolete: personal integrity, self-reliance, social-mindedness, and nobility of spirit. Also becoming anachronistic is the word honor—about which Marlowe said:

"Honour is purchased by the deeds we do;
* * * honour is not won,
Until some honourable deed be done."

On very rare occasions there may have been minor violations of our ethical code of honor by some of us members of the medical profession, when we were young, over-articulate, idealistic, and perhaps a bit rebellious against authority and intolerant of institutionalization; nevertheless, we outgrew our crusaders complex and matured into the realization that we must share and thereby communalize our knowledge for the benefit of all—to the exclusion of none.

To expand our horizons and sharpen our perspective this issue of MINNESOTA MEDICINE, like some of the other Special Issues, is endeavoring to explore beyond the confines of our local society: to benefit from experience and instruction available from other sources.

The United States Air Force can be justly proud of its young members who have in this issue shared with us their research and achievement—each in his own vineyard. We can one and all profit from their valuable contributions.

We herewith salute these men, their dedication to their profession and their service to humanity. They are honorable men, indeed!

Carl O. Rice, M.D.

Old Doc Hess Says: If you endeavor to think in accordance with the mind of the masses instead of with your own excellent brain, your thoughts may originate from an inferior and unworthy source. COR

They serve God well, Who serve his creatures.—CAROLINE NORTON

Bygone Gout "Cures"

For the antiquarian interested in ancient and obsolete materia medica, literature provides some quaint and preposterous cures for age-old diseases afflicting man.*

The simplest and most disarmingly naive treatment for gout was that advocated and employed by Hippocrates in 300 B.C., which persisted for some 800 centuries thereafter: namely, the burning of flax adjacent to the gouty body area. Presumably the disease was allergic to flax smoke.

Apocryphal as it may now sound, the medical advice of Aetius of Mesopotamia about 500 A.D. consisted of the following 12-month program:

"In January: take a glass of pure wine every morning! February, eat not beets; March: mix sweets with eatables and drinkables; April: refrain from horse radish; May: eat no polypus fishes; June: take cold water every morning; July: abstain from venery; August: eat no mallows; September: drink only milk; October: garlic must be eaten; November: bathing is prohibited; December: eat freely of cabbage."

Around 550 A.D. Aetius' unique recommendation was superseded by Alexander of Tralles' repellent prescription of:

"A mixture of caraway seeds, anise, rhubarb, wolf's milk, vinegar, honey, dill, pepper, ginger, aloes, and—, pretty much by choice—colchicum."

In the seventeenth century a Dr. Daniel Sennart of Prussia proffered this bizarre combination:

"A poultice composed of marsh-mallow leaves, cabbage, barley, and frog sperm."

Also at the same time a Dr. John Loselous of Germany presented his gout patients with the following startling directions:

"Shave with a razor the hair off both legs, and at the same time cut the nails of hands and feet. This should be in the spring when sap is flowing, and the day before new moon. Make a hole right into the heartwood of a poplar or oak tree and insert the hair and nails. Stop it tight with a plug made of a branch of the tree, and the transplantation is perfect. Cut off close to the tree that part of plug that sticks out, and the next day plaster the place well with cow dung. If the patient does not in the next three months feel the *malum* again, he can credit it to the tree."

The year 1735 produced one mind-over-matter practitioner, Sir Richard Blackmore, who loftily and authoritatively asserted: "Fright can cause and cure an attack." Obviously, in his opinion gout was psychosomatic.

Of all the above fantastic specifics only one, colchicum, again saw the light after long eclipse. Its use was revived in 1763, reportedly by Baron von Strenck of Vienna, and was later introduced into the United States by Benjamin Franklin, himself a gout sufferer.

Ironically, colchicum was the one effective ingredient in Aetius' formula, but included as a purgative only, and later omitted, thereby markedly diminishing the efficacy of his prescription.

Curbstone Consultation

Burns

QUESTION: What is the current status of the topical treatment of burns?

ANSWER: At the present time there are five compounds that appear promising in the control of surface infection in burns. Two of these, 0.5% Silver Nitrate Solution and Gentamycin are commercially available; Mafenide or Sulfamylon is expected to be released at any time; and 0.5% Silver Acetate Cream and Silver Sulfadiazine (CF-100) Ointment are still investigational drugs.

Since the advent of 0.5% Silver Nitrate Solution as advocated by Moyer,[5] many reports have shown control of surface bacteria and progressive epithelialization. However, problems with linen staining, the need to keep dressings continuously wet, chloride depletion, and methemoglobinemia[8] have detracted from its usefulness.

Gentamycin, as advocated by Stone, has shown good control of surface bacteria, especially Pseudomonas, and does not appear to interfere with epithelialization. Ototoxicity and nephrotoxicity have been reported as side effects.[6]

Sulfamylon, as advocated by Moncrief and the Brooke Army Hospital group,[4] has prevented Pseudomonas colonization while not interfering with epithelialization. Problems with carbonic anhydrase inhibition, acidosis, pain on application and, recently, a report by Burke et al. concerning the development of hyaline membrane disease in guinea pigs[3] treated with Sulfamylon have encouraged investigators to search for better agents.

Two new compounds have recently been reported. Butcher et al. in St. Louis have been using a 0.5% Silver Acetate Cream which appears to give fewer problems with chloride depletion, linen staining, and methemoglobinemia; but only a few patients have been so treated.[1] The action is similar to Silver Nitrate Solution.

The other new compound as reported by Fox and Stanford is Silver Sulfadiazine or CF-100.[2,7] Its use in over 280 patients has shown elimination of Pseudomonas on surface cultures and no interference with wound healing. There is no pain on application, no staining of linens and no carbonic anhydrase or electrolyte problems. Application of this insoluble compound is by gloved hand one time per day after washing. Radioactive silver studies have shown the silver to combine with the DNA of sulfhydryl groups of the bacteria; hence one receives the bactericidal effects of silver combined with the bacteriostatic effect of sulfadiazine. As such, the drug is lethal to many organisms, especially Pseudomonas. Early clinical trials look extremely promising.

William Stanford, Lt. Colonel, USAF, MC
Assistant Chief, Thoracic Surgery Service

Breast Mass after Mastectomy

QUESTION: What do I do with an anterior chest mass in a patient who has had a bilateral subcutaneous mastectomy and breast implant reconstruction?

ANSWER: Treat the mass as any other dominant breast mass. After no longer than one to two months of observation, do an excisional biopsy for small or medium size masses, or an incisional biopsy for larger masses. Even though a subcutaneous near total mastectomy has been performed to prevent carcinoma, existing breast may remain unless the nipple is removed and unless all subcutaneous tissue and fascia are removed, (1) superiorly to the clavicles, (2) medially to past the midline of the chest, (3) inferiorly well below the costal margin onto the rectus abdominus muscle, (4) laterally past the border of the latissimus dorsi, and (5) well into the axilla to remove the tail of the breast.

Residual tissue can develop carcinoma just as any other breast tissue can. There is no evidence to even suggest that silastic implant material has caused cancer, and in the two cases in our series the cancer was medial to the implant and not in contact with the silastic or its dacron mesh. Subcutaneous mastectomy and silastic implant reconstruction constitute a very good prophylactic procedure in certain clinical situations, a common example being the patient with numerous cysts and breast masses and numerous previous biopsies, with the expectation of numerous future biopsies. Even though less than 100% of breast parenchyma is removed, more than 99% is removed; therefore 99% of the cancer-developing tissue is eliminated. The remaining tissue, if it develops carcinoma, is relatively easy to examine, and if it is realized that cancer can still develop in this situation, small early lesions can be discovered and treated early.

If the lesion is not cancer, a meticulous two or three-layer closure under strict aseptic operating room technique is necessary to prevent infection and/or rejection of the implant.

The cancer surgery itself requires removal of the pectoral muscles since some of the breast implants are placed beneath the pectoral muscles, sometimes intentionally and sometimes accidentally. When the pectorals are removed, most surgeons will elect to perform the axillary dissection and complete the standard radical mastectomy. If any bilateral breast surgery has been performed in the previous two to five years, bilateral breast cancer cell seeding may have occurred and bilateral breast cancer surgery is required.

It may be that a bilateral mastectomy is required in all cases, regardless of the time interval. The initial subcutaneous mastectomy and implant reconstruction are usually performed after several previous breast biopsies; and, in that instance, we recommend a four to eight-centimeter normal tissue margin removal of skin scars with the mastectomy specimen. One of our patients had her cancer develop in a scar through which three previous biopsies had been performed over a six-year period. Skin grafts will be necessary when such wide skin removal is required.

David G. Bowers, Jr., Lt. Colonel, USAF, MC
Chief, Plastic Surgery Service

Spontaneous Pneumothorax

QUESTION: Is a chest tube necessary in the management of spontaneous pneumothorax?

ANSWER: Yes, The principle to be followed in the treatment of pneumothorax is full expansion of the lung with obliteration of any pleural air space. Insertion of a large-bore intercostal catheter seems to be the most expeditious method of accomplishing this with very little morbidity. Prolonged periods of bedrest waiting for a collapsed lung to re-expand are not only risky to the patient but can result in prolonged hospitalization with no assurance that a chest tube will not be necessary at a later date.

Thoracentesis is not always satisfactory because it may require multiple taps and the patient is left with the possibility of recurrence of a pneumothorax. Small-bore tubes or "intra-caths" likewise are not satisfactory because they may become sealed off; and they produce no intrapleural reaction that may help prevent future pneumothoraces.

I recommend insertion of a (30-36 French) rubber catheter in the 2nd anterior interspace, and connection of the catheter to an underwater seal trap with suction applied to the system. The tube is removed 24 hours after all air leaks have stopped and the lung has fully expanded. If the air leak persists for seven days or full lung expansion cannot be achieved, then open thoracotomy with suture of the bronchial leak and decortication, if necessary, should be accomplished.

Bryon N. Dooley, Lt. Colonel, USAF, MC
Chief, Thoracic Surgery Service

God made everything out of nothing. But the nothingness shows through.—Paul Valery

Some men are born great, some achieve greatness, and others just keep still. —Kin Hubbard

Teach thy tongue to say, "I do not know."—Talmud

The Fortunate One.

Her urinary tract infection reveals itself through pain and discomfort.

While the pain and discomfort of a G.U. infection are anything but pleasant, the patient may be luckier than she realizes. That burning sensation (and/or frequency, urgency, dysuria) is a usually reliable sign of a urinary tract infection. And it's her good fortune that her infection won't go undetected...or untreated.

Azo Gantanol® therapy usually provides analgesic action within one-half hour, while control of the infection begins within two hours. Azo, a specific urinary analgesic, soothes inflamed mucosa to give symptomatic relief. At the same time, the antibacterial component, Gantanol (sulfamethoxazole), achieves therapeutic levels in the blood and urine, with diffusion into interstitial fluids. Azo Gantanol—a good choice when urinary tract infection reveals itself through symptomatic distress.

Before prescribing, please consult complete product information, a summary of which appears on opposite page.

Azo Gantanol®

(Each tablet contains 0.5 Gm sulfamethoxazole and 100 mg phenazopyridine HCl.)

Azo for the pain
Gantanol®
(sulfamethoxazole)
for the pathogens

Before prescribing, please consult complete product information, a summary of which follows:

Indications: Urinary tract infections with associated pain or discomfort when due to susceptible organisms; prophylactically in urologic surgery, catheterization and instrumentation.

Contraindicated in sulfonamide-sensitive patients, pregnant females at term, premature infants, newborn infants during the first three months of life, glomerular nephritis, severe hepatitis, uremia and pyelonephritis of pregnancy with gastrointestinal disturbances.

Warnings: Use only after critical appraisal in patients with liver damage, renal damage, urinary obstruction or blood dyscrasias. If toxic or hypersensitivity reactions or blood dyscrasias occur, discontinue therapy. In closely intermittent or prolonged therapy, blood counts and liver and kidney function tests should be performed.

Precautions: Observe usual sulfonamide therapy precautions including maintenance of an adequate fluid intake. Use with caution in patients with histories of allergies and/or asthma. Patients with impaired renal function should be followed closely since renal impairment may cause excessive drug accumulation. Occasional failures may occur due to resistant microorganisms. Not effective in virus and rickettsial infections.

Adverse Reactions: Headache, nausea, vomiting, urticaria, diarrhea, hepatitis, pancreatitis, blood dyscrasias, neuropathy, drug fever, skin rash, Stevens-Johnson syndrome, injection of the conjunctiva and sclera, petechiae, purpura, hematuria or crystalluria may occur, in which case the dosage should be decreased or the drug withdrawn.

Dosage: Adults—4 tablets initially, then 2 tablets morning and evening.

How Supplied: Tablets, bottles of 50.

RHEUMATIC FEVER

Here are two ways:

1. If your child has a bad sore throat, don't wait – it might be "strep." Call your doctor. Treatment of "strep" infections usually can prevent rheumatic fever and the heart damage it sometimes causes.

2. Give to your Heart Fund. Your Heart Fund dollars support research and community service programs which can wipe out rheumatic fever and save thousands of young lives.

so more will live
HEART FUND

Bad Health and Big Shots

Ill health is supposedly much pleasanter nowadays than it was in the past but, as far as I can see, people of all epochs have had little trouble putting up with it. Some months ago when I was re-fighting the War Between the States, assisted by Douglas Southall Freeman and Carl Sandburg, I asked myself over and over again how men whose health was at best indifferent could play such important roles in this titanic struggle. Of the Union administrative big shots, Honest Abe alone seemed to have a physique commensurate with the demands made upon it. Stanton was dyspeptic as an over-age sow and Seward was very delicate. At the start of the war, General Winfield Scott ran the Union Army from a sofa.

Ill health was just as prevalent among the Confederates. Jeff Davis was pure courage and passion prodding along a semi-invalid body. Alexander Stephens was one of the frailest statesmen that ever lived. General Lee was by no means an invalid, but his heart was in perilous condition before the war was half over. Stonewall Jackson couldn't function unless he had loads of sleep. Dick Ewell was lame and liverish and D. H. Hill had numerous afflictions. The list is endless.

But all these creaky people were in the pink of condition compared to some of the dillies of the more distant past. Naturally, the opinions of modern doctors as to what ailed a big shot centuries ago must be taken with a certain reserve, inasmuch as they often err in their diagnosis of contemporary specimens. Furthermore, devotees of each branch of the profession consider it a point of honor to fasten the disease that interests them most on as many celebrities as possible. Thus, poor old King James I is proudly portrayed by competing specialists as suffering from catarrh, gluttony, adenoids, tonsils, jaundice, diarrhea, septic teeth, arthritis, Bright's disease, piles, ulcers, and six kinds of heart trouble. Perhaps he did so suffer. If he did, he neatly typified for fifty-five years in his own royal person the variegated misery of all mankind.*

***Sprague, Marshall**: The Business of Getting Well, 1943.

Fraud in the Mails

In 1913 the Post Office Department decided to check into Interstate's* methods of operation. A new political administration was in office, and postal attorneys may not have known about Hayes' earlier efforts at conspicuous rectitude. . . . At any rate postal inspectors, following their usual procedure, began to write Interstate heartrending letters.

"There is something wrong with my testicles," one test letter began, "and I don't know what to make of it. I noticed for some time that they don't hang even and that the left one hangs lower. I ain't got the nerve to ask our doctor about it so am writing to you to find out what you think about it. Please use plain envelope."

Of course, this perfectly natural condition was, to Interstate, an ailment. You have "swollen testicles," the company answered, and need Man Medicine for "quick recovery."†

*Interstate was a mail-order company that advertised and sold Man Medicine.

†James Harvey Young: The Medical Messiahs, 1967.

The Viewing Box

Nephrocalcinosis

A 32-YEAR-OLD WOMAN was admitted to Wilford Hall USAF Hospital for evaluation of recurrent pyelonephritis. The patient had initially developed a renal infection during her first pregnancy 16 years previously. Since that time she had had many recurrences which were treated with a number of different urinary tract antibiotics. During the four years prior to admission she was almost completely symptom-free. Approximately six years before admission she was first noted to have renal calcifications. Both of the patient's parents had passed renal stones. She denied any personal or family history of tuberculosis.

The admission physical examination was unremarkable except for minimal bilateral costovertebral angle tenderness. A few red and white blood cells were seen on urinalysis. Serum electrolytes, calcium, phosphorus, and uric acid were normal. Urinary excretion of calcium and phosphorus was also normal.

A supine abdominal film (Figure 1) demonstrated multiple calcifications

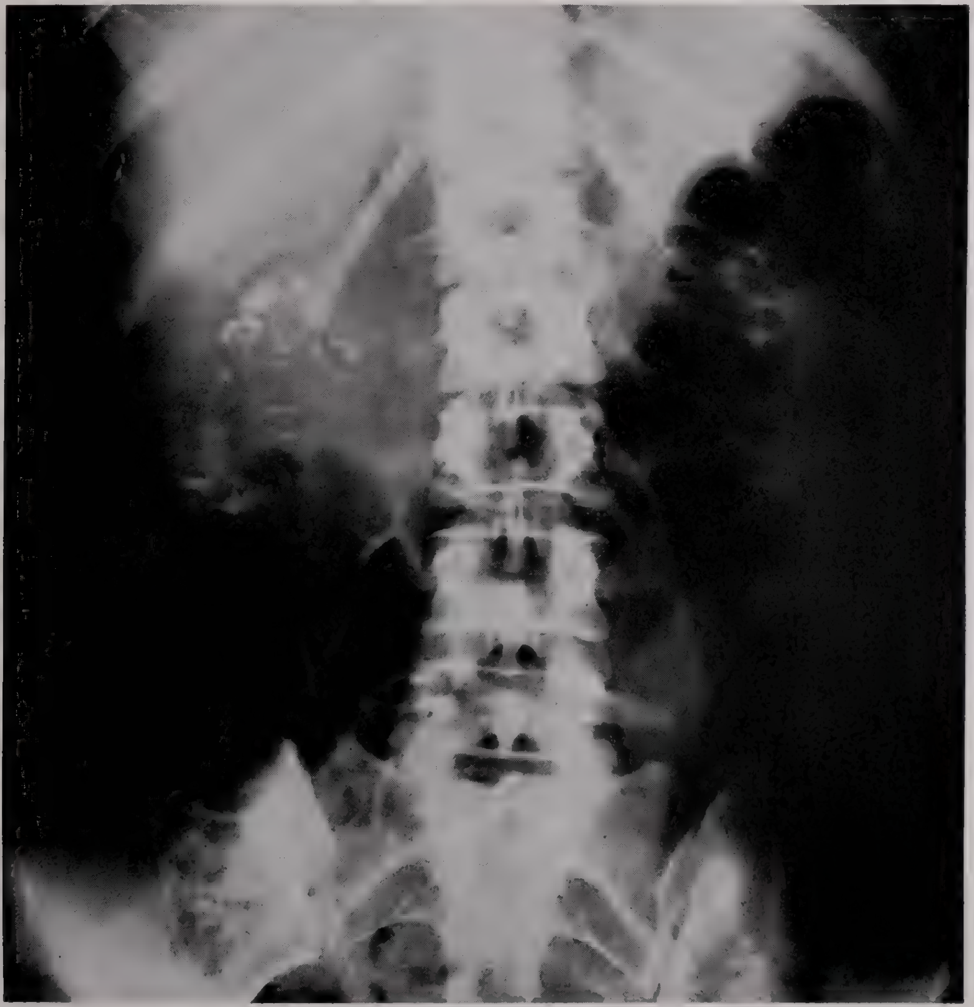

Figure 1

in the renal parenchyma bilaterally, which appeared to be in the area of the pyramids. The kidneys were normal in size and functioned well bilaterally on an intravenous urogram (Figure 2). There were many extracalyceal collections in the pyramids of the right kidney (Figure 3), most of them appearing to radiate out from the calyces.

The patient was readmitted on several subsequent occasions because of urinary tract calculi. One of these was analyzed and contained calcium and magnesium phosphates.

What is your diagnosis?

Diagnosis: Medullary Sponge Kidney.

In addition to medullary sponge kidney, the differential diagnosis of nephrocalcinosis is an extensive one. In this patient, however, those entities accompanied by hypercalcemia or hypercalciuria could be eliminated. These include primary and secondary hyperparathyroidism, sarcoidosis, hypercalcemia associated with malignancies, the calcium mobilization occurring with prolonged bed rest, milk-alkali syndrome, vitamin D intoxication, and idiopathic hypercalciuria. In addition, the serum and urinary findings permit exclusion of renal tubular acidosis, with or without amino-aciduria. The absence of oxalate in the analyzed stone makes oxalosis an extremely unlikely diagnosis. Finally, there is no radiographic evidence that infection, either tuberculous or pyogenic, represents the underlying etiology.

Medullary sponge kidney, or renal tubular ectasia, is a developmental abnormality in which there is dilatation of the renal tubules within the pyramids, with small diverticula or cysts arising from these tubules. On cut section these pyramids have the appearance of sponges. Disagreement exists as to the etiology of the lesion. One view is that back-pressure secondary to obstruction causes the tubular dilatation. A second view is that it is part of the spectrum of polycystic disease, since the two processes have been found in the same families and, in fact, in the same patient.

The clinical presentation of patients with medullary sponge kidneys is generally due to complications of this disease, as in this patient. Frequent infections and stone formation may lead to compromise of renal function; however, many never suffer any ill effects referable to this process. Renal

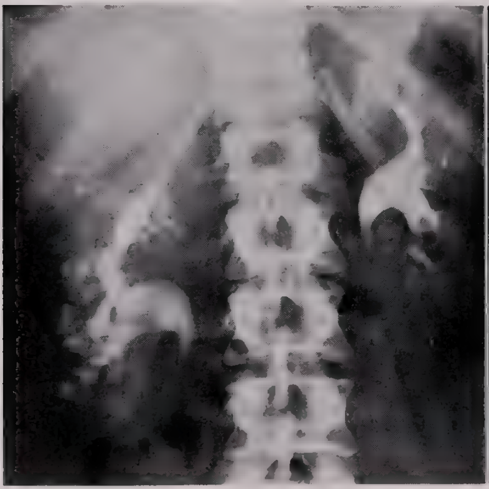

Figure 2

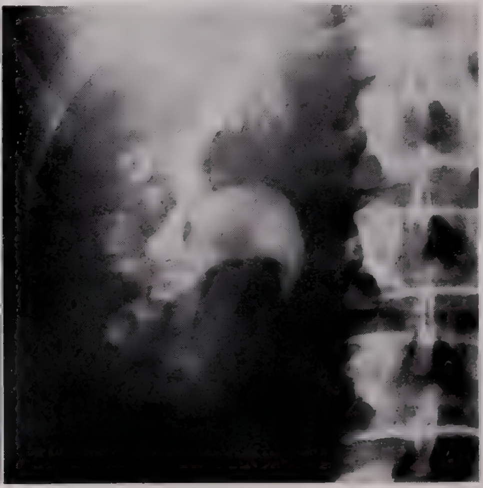

Figure 3

calcifications may be an unsuspected finding on an abdominal film.

Radiographically there is nephrocalcinosis which is generally bilateral, but not necessarily symmetric. Renal or ureteral stones may be present. A urogram may demonstrate dilated tubules radiating out from the calyces into the pyramids. In addition, small rounded collections of contrast material may be seen in the pyramids representing small cysts. When the changes of chronic pyelonephritis are superimposed, it may be impossible to determine the underlying process.

Medieval Science

In considering medieval science we cannot fail to be struck by two peculiarities, the solidarity and interdependence of all its branches, and the dominance of certain numbers in its basic conceptions. . . . It is seldom that we find a medieval physician content to confine his attention exclusively to the medical sciences, or unwilling to include in his studies astronomy and astrology, music and mathematics, and even ethics, metaphysics and politics.

The strange sect of the Ismailis or Esoterics instructed their missionaries to arouse the curiosity of the potential proselyte by such questions as "Why has a man seven cervical and twelve dorsal vertebrae?" "Why has each of the fingers three joints but the thumb only two?" and the like; and it was to them a fact of infinite significance that the number of joints on the two hands agreed with the number of permanent teeth, the number of days of the lunar month, and the number of letters in the Arabic alphabet. So in their cosmogony we notice the great part played by the numbers four, seven and twelve. Thus we have the four Natural Properties, Heat, Cold, Dryness and Moisture; the four Seasons; the four Humors, the four Winds, and the like. Also the seven Planets, the seven Climes, the seven Days of the Week, and the Seven Seas; the twelve Signs of the Zodiac, the twelve Months of the Year, and so on.*

FEATURE SPECIAL

Minnesota State Board of Medical Examiners

Notice of Hearing

Notice is hereby given that a public hearing will be held pursuant to M.S. 1967, Section 15.0412, Subdivision 4, in the above entitled matter, in the office of Minnesota State Board of Medical Examiners, 496 Lowry Medical Arts Building, Saint Paul, Minnesota, on April 19, 1969, commencing at 10:30 a.m. and continuing until all representatives of associations or other interested groups or persons have had an opportunity to be heard concerning adoption of the proposed amendments to the rules captioned above by submitting either oral or written data, statements, or arguments. Statements or briefs may be submitted without appearing at the hearing.

The proposed amendments to rules are:

I. Proposed amendment to Rule ME 4(b)(4).

Rule ME 4(b)(4) is hereby amended by adding thereto the following sentence. "Such evidence shall not be required, however, if the applicant: (a) was licensed by examination in a state which at the time of applicant's licensure therein did not require that he had been awarded a Certificate by The Educational Council for Foreign Medical Graduates, or (b) is a diplomate of a medical specialty board approved by the American Medical Association."

II. Proposed amendment to Rule ME 5(b)(3).

Rule ME 5(b)(3) is hereby amended by adding thereto the following sentence. "The evidence required in clause (a) hereof shall not be required, however, if the applicant is a diplomate of a medical specialty board approved by the American Medical Association."

III. Proposed amendment to Rule ME 7(a)(8).

Rule ME 7(a)(8) is hereby amended by adding thereto the following sentence. "The evidence required in clause (a) hereof shall not be required, however, if the applicant is a diplomate of a medical specialty board approved by the American Medical Association."

Minnesota State Board of Medical Examiners
J. P. Medelman, M.D.
Secretary-Treasurer

President's Letter (continued from page 387)

> "The surgeon should be learned, skilled, ingenious, and of good morals. Be bold in things that are sane, cautious in dangers; avoid evil cures and practices; be gracious to the sick, obliging to his colleagues wise in his predictions. Be chaste, sober, pitiful, and merciful; not covetous nor extortionate of money; but let the recompense be moderate, according to the work, the means of the sick, the character of the issue or event, and its dignity."

In his introduction to "The Apologie and Treatise of Ambroise Paré" Geoffrey Keynes notes, "There is no more potent stimulus to advance in surgery than the exigencies of war." Our military services which have known such men as Walter Reed, have made increasingly valuable contributions to the field of medicine, especially since World War II. Our guests from the United States Air Force exemplify this high level of achievement. Himself a veteran of the Medical Corps of the United States Navy (World War II), the undersigned takes particular pride in welcoming these colleagues from the Wilford Hall USAF Hospital.

O. L. N. Nelson, M.D.,
President
Minnesota State Medical Association

heavenly relief
for unearthly cough

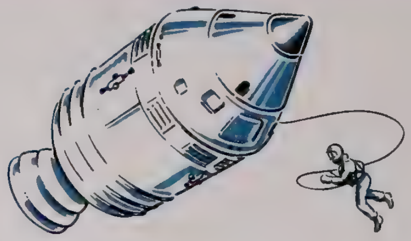
Benylin®
EXPECTORANT

Each fluidounce contains: 80 mg. Benadryl® (diphenhydramine hydrochloride, Parke-Davis); 12 grains ammonium chloride; 5 grains sodium citrate; 2 grains chloroform; 1/10 grain menthol; and 5% alcohol. An antitussive and expectorant for control of coughs due to colds or of allergic origin, BENYLIN EXPECTORANT is the leading cough preparation of its kind. BENYLIN EXPECTORANT tends to inhibit cough reflex... soothes irritated throat membranes. And its not-too-sweet, pleasant raspberry flavor makes BENYLIN EXPECTORANT easy to take. PRECAUTIONS: Persons who have become drowsy on this or other antihistamine-containing drugs, or whose tolerance is not known, should not drive vehicles or engage in other activities requiring keen response while using this preparation. Hypnotics, sedatives, or tranquilizers if used with BENYLIN EXPECTORANT should be prescribed with caution because of possible additive effect. Diphenhydramine has an atropine-like action which should be considered when prescribing BENYLIN EXPECTORANT. ADVERSE REACTIONS: Side reactions may affect the nervous, gastrointestinal, and cardiovascular systems. Drowsiness, dizziness, dryness of the mouth, nausea, nervousness, palpitation, and blurring of vision have been reported. Allergic reactions may occur. PACKAGING: Bottles of 4 oz., 16 oz., and 1 gal.

Parke, Davis & Company
Detroit, Michigan 48232

PARKE-DAVIS

410R69



Man in space, now fait accompli, re-emphasizes the importance of Uro-Phosphate therapy. Research into the effect of space travel on the astronaut reveals that weightlessness causes loss of bone calcium. As the bones are required to bear less and less of the weight of the body they lose calcium, increasing the calcium content of the urine. When physical activity is reduced, the acidity of the urine should be adjusted to keep increased calcium in solution . . . . a prophylaxis to prevent kidney or bladder calculi.

Uro-Phosphate®

NOW A SUGAR-COATED TABLET

Each tablet contains: METHENAMINE, 300 mg.; SODIUM ACID PHOSPHATE, 500 mg.

Uro-Phosphate gives comfort and protection when inactivity causes discomfort in the urinary function. It keeps calcium in solution, preventing calculi; it maintains clear, acid, sterile urine; it encourages complete voiding and lessens frequency when residual urine is present.

Uro-Phosphate contains sodium acid phosphate, a natural urinary acidifier. This component is fortified with methenamine which is inert until it reaches the acid urinary bladder. In this environment it releases a mild antiseptic keeping the urine sterile.

Uro-Phosphate is safe for continuous use. There are no contra-indications other than acidosis. It can be given in sufficient amount to keep the urine clear, acid and sterile. A heavy sugar coating protects its potency.

Dosage:

For protection of the inactive patient 1 or 2 tablets every 4 to 6 hours is usually sufficient to keep the urine clear, acid and sterile.

2 tablets on retiring will keep residual urine acid and sterile, contributing to comfort and rest.

A clinical supply will be sent to physicians and hospitals on request.

WILLIAM P. POYTHRESS & COMPANY, INC., RICHMOND, VIRGINIA 23217

Manufacturers of Ethical Pharmaceuticals

"The inconvenience of a cold"

r a cold, NTz® Nasal Spray provides rapid relief of ısal symptoms. Relief starts with the first spray which ›ens the inferior part of the common meatus. A second ray, a few minutes later, will shrink the turbinates to ılp provide sinus drainage and ventilation. Dosage ay be repeated every three or four hours as needed, r temporary relief of symptoms. NTz is well tolerated ıt overdosage should be avoided.

a sinusitis deterrent, NTz Nasal Spray can be used to ›ep the nasal passages open during a cold to help pre›nt development of acute sinusitis—or to help prevent e acute condition from becoming chronic.

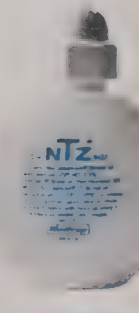
ıpplied: NTz Nasal Spray, plastic squeeze bottles of) ml.; NTz Nasal Solution, bottles of 30 ml. (1 fl. oz.) ith dropper.

NTz is more than a simple vasoconstrictor. It contains

Neo-Synephrine® (brand of phenylephrine) HCl 0.5 per cent, the major component, virtually synonymous with fast, efficient but gentle nasal vasoconstriction.

Thenfadil® (brand of thenyldiamine) HCl 0.1 per cent, topical antihistamine for reduction of rhinorrhea, sneezing or itching. It combats the allergic reactions that may occur in colds or sinusitis.

Zephiran® (brand of benzalkonium, as chloride, refined) 1:5000, antiseptic preservative and wetting agent to promote penetration and spread of the formula.



Winthrop Laboratories, New York, N.Y. 10016 Winthrop

painful night
leg cramps...
respond to specific
therapy with
QUINAMM™
(Quinine sulfate, 260 mg.,
Aminophylline, 195 mg.)

THE BETTMAN ARCHIVE

Just one tablet at bedtime • Prevents painful night leg cramps • Permits restful sleep

How many of your patients stamp their feet at night and lose sleep because of painful leg cramps? Unless prompted, they usually fail to report this distressing condition and suffer needlessly.

One tablet of QUINAMM at bedtime usually controls distressing night cramps and permits restful sleep with the initial dose.

Prescribing information—Composition: Each white, beveled, compressed tablet contains: Quinine sulfate, 260 mg., Aminophylline, 195 mg. **Indications:** For the prevention and treatment of nocturnal and recumbency leg muscle cramps, including those associated with arthritis, diabetes, varicose veins, thrombophlebitis, arteriosclerosis and static foot deformities. **Contraindications:** QUINAMM is contraindicated in pregnancy because of its quinine content. **Side Effects/ Precautions:** Aminophylline may produce intestinal cramps in some instances, and quinine may produce symptoms of cinchonism, such as tinnitus, dizziness, and gastrointestinal disturbance. Discontinue use if ringing in the ears, deafness, skin rash, or visual disturbances occur. **Dosage:** One tablet upon retiring. Where necessary, dosage may be increased to one tablet following the evening meal and one tablet upon retiring. **Supplied:** Bottles of 100 and 500 tablets.

THE NATIONAL DRUG COMPANY
DIVISION OF RICHARDSON-MERRELL INC.

ANTISECRETORY SEDATIVE

Antrocol

Antrocol provides the prompt, predictable antisecre tory action of the belladonna alkaloid, atropine, forti fied with sedation and blended with Bensulfoid, con tributing to slow, even absorption.

Each Antrocol tablet or capsule contains 0.324 mg. o atropine sulfate, which is twenty-four thousandths o a milligram more than the smallest effective dos specified in U.S.P., Vol. 17. This slight increase in th smallest effective dose of the antisecretory facto (atropine) is all the average patient can tolerat without discomfort.

One Antrocol tablet or capsule taken three time daily lessens emotional stress and maintains a gastri function that is not conducive to the development o peptic ulcer.

Antrocol is also useful in the treatment of pepti ulcer. Dosage up to 8 tablets or capsules per day t obtain the desired antisecretory titer. When ulcer ha healed, one Antrocol tablet or capsule morning an evening gives protection against recurrence.

Each tablet or capsule contains:

Atropine Sulfate	0.324 mg.
Phenobarbital (may be habit forming) ..	16 mg.
Bensulfoid, see white section P.D.R. ...	65 mg.

Side-effects: Toxic levels of atropine may produce flushing, dry mouth, blurred vision, tachycardia, or urinary retention. Precautions: Do not use in glaucoma. Use cautiously in prostatic hypertrophy.

Federal law prohibits dispensing without prescription.

ANTISECRETORY SEDATIVE

Dermatology

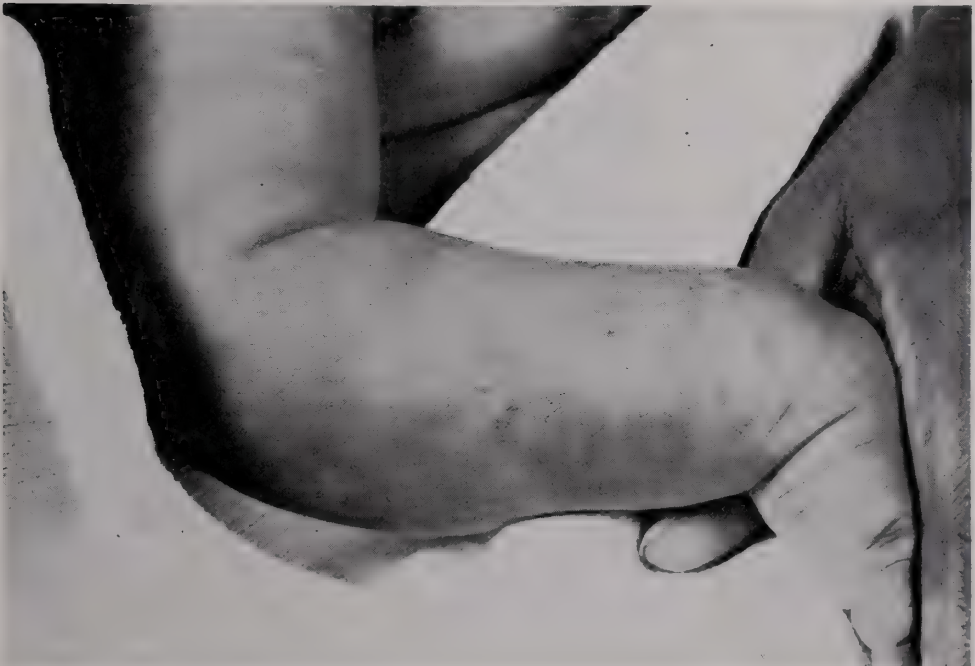
Systemic Lupus Erythematosus in the Newborn

THE OCCURRENCE OF SYSTEMIC LUPUS erythematosus in a new-born infant is a distinct rarity. Several authors[1-4] reported skin changes consistent with this uncommon entity. Jackson[5] reported that discoid lupus erythematosus was produced in an infant in placental transmission of the lupus erythematosus cell factor from the mother who had systemic lupus erythematosus. McCuistion and Schoch[4] also had a unique case involving a newborn with discoid lupus erythematosus; the mother had acute disseminated lupus erythematosus 11 months post partum.

The present report concerns a newborn infant who demonstrated clinically all of the characteristic features of disseminated discoid lupus erythematosus at birth.

Case Report

A negro infant girl, born December 26, 1967, was the product of a full-term pregnancy which was complicated only by a urinary tract infection. She was noted to have a dusky erythematous, depressed and atrophic eruption over the malar eminences and forehead. The referring physician reported that these sharply demarcated, irregular patches were present at birth. During the three months following birth, the lesions became more scattered until they included the frontal hairline and forehead, cheeks, chin, chest, arms and back. The original areas on the cheeks became confluent, and follicular plugging and scale formation was particularly evident in these patches. The skin lesions (Figure) were unresponsive to hydrocortisone cream



Figure—Clinically obvious lesions of lupus erythematosus at age three months.

during the first few months, and new skin lesions continued to appear well into the fourth month.

The infant developed well from a birth weight of seven pounds, two ounces and remained in the 90th percentile for weight and the 75th percentile for height. A systolic heart murmur discovered at one month was diagnosed as possible tetralogy of Fallot, although a pulmonic valvular stenosis could not be ruled out definitely.

Skin biopsy was performed March 27, 1968, and a supravital bone marrow on the same date revealed typical lupus erythematosus cells; therefore the diagnosis was changed from the initial impression of disseminated discoid lupus erythematosus to systemic lupus erythematosus. The lupus erythematosus cell test was negative in the peripheral blood. The antinuclear antibody titer was 1:10. The white blood count was 7,800 with 23 percent neutrophils and 71 percent lymphocytes. The sedimentation rate was 2 mm/hr, the hemoglobin 10.8 gm/100 ml, and the hematocrit 33 percent. Urinalysis was normal. Latex globulin slide agglutination for rheumatoid arthritis was negative. VDRL was nonreactive. Blood urea nitrogen was 15 mg/100 ml, and serum protein electrophoresis was within normal limits.

Both parents received laboratory tests including the serologic test for syphilis, lupus erythematosus preparations (peripheral blood), and latex fixation. All of these tests were normal. No physical abnormality or significant familial historical finding could be elicited from the parents.

Comment

The familial incidence of lupus erythematosus is well documented. Rona[6] and Sequeira[7] presented siblings with the disease at the turn of the century, and many authors[8-12] have reported familial lupus erythematosus since that time.

Bridge and Foley[13] demonstrated that transplacental passage of the lupus erythematosus factor did occur. They identified lupus erythematosus cells in the mother, in the cord blood, and in the bone marrow of the normal infant. The lupus erythematosus cell phenomenon disappeared when the infant was four months of age. Beck,[14] in an excellent study, identified antinuclear antibody (7S globulin) in the sera of infants at birth in titers similar to those in the maternal sera of three mothers who had systemic lupus erythematosus. However, evidence of lupus erythematosus did not develop in the infants.

It is difficult to investigate the sequence of events necessary for the actual development of typical lupus erythematosus lesions in the newborn. The problems of lowered fertility[15] and high fetal mortality[16] in systemic lupus erythematosus allow few opportunities for a study of the effects of passively transferred auto-antibodies in infants born to affected mothers. Therefore the exact mechanism for transfer of this ancient skin and systemic disease from an affected mother to her infant remains a mystery. It is even more difficult to understand how an apparently normal and unaffected couple can become the parents of a newborn with obvious lupus erythematosus lesions.

Summary

A newborn infant with clinically obvious lesions of lupus erythematosus has been described. A bone marrow supravital stain revealed typical lupus erythematosus cells. The skin lesions increased in number and continued to spread to previously uninvolved sites, even into the fourth month. The parents had no physical or laboratory changes suggestive of lupus erythematosus, and there was no family history of the disease.

Fracture Conference

Fracture Dislocation of the Proximal Radial Epiphysis

A nine-year-old male fell from a tree 30 minutes prior to being seen at the emergency room of Wilford Hall USAF Hospital. He claimed that he fell on his hands with both arms straight. He had severe pain and swelling of the right wrist, associated with moderate pain of the left elbow and resistance to any movement of the left forearm. The neurovascular status of both hands was intact.

X-rays showed a fracture of the distal right radius with volar displacement (Figures 1 and

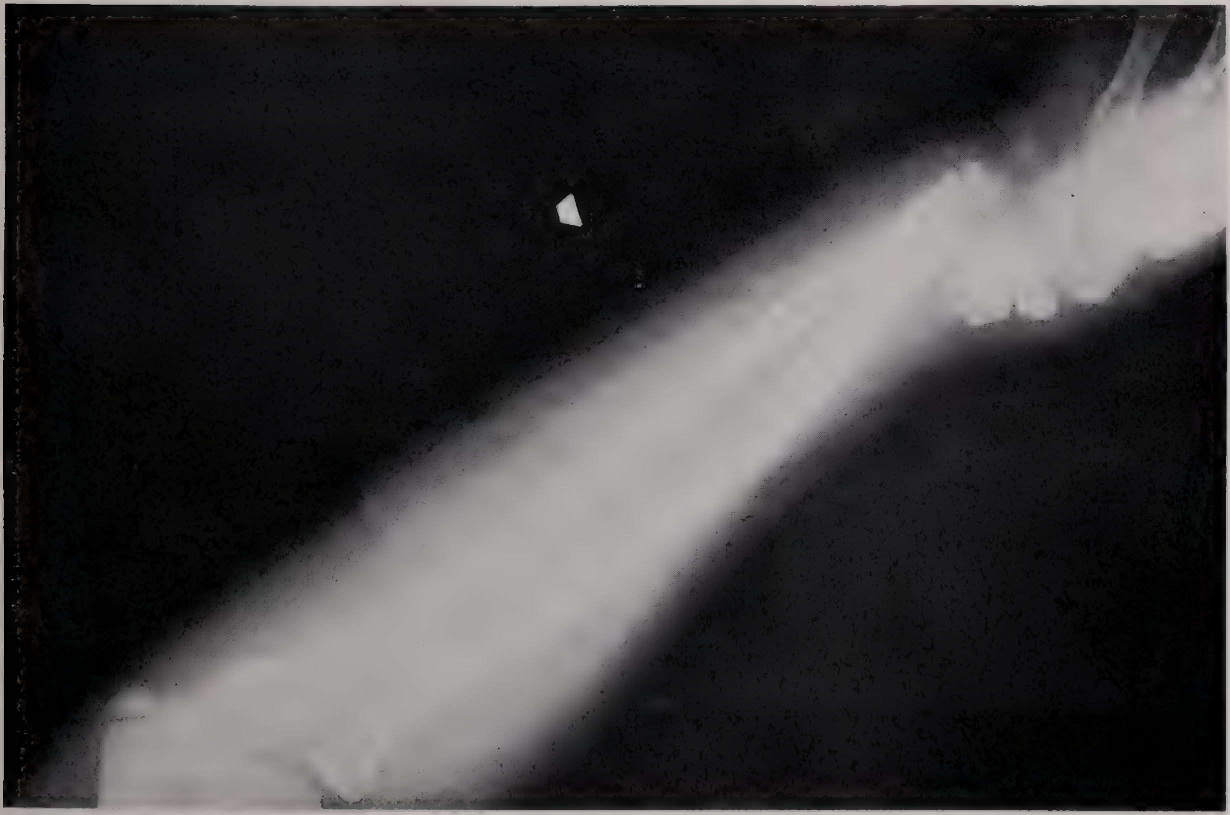

Fig. 1—Displaced fracture of the right radius; anteroposterior view.

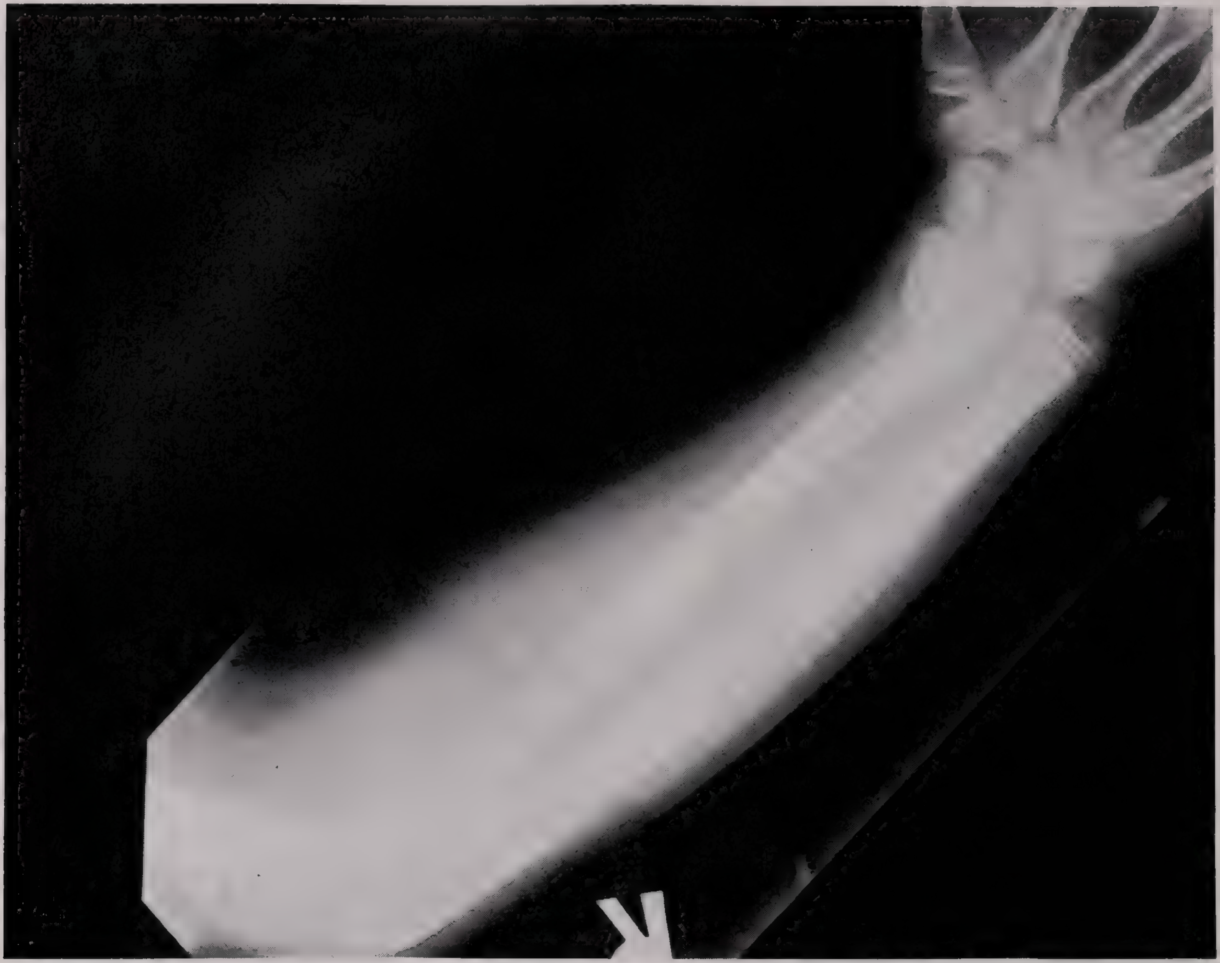

Fig. 2—Displaced fracture of the right radius; lateral view.

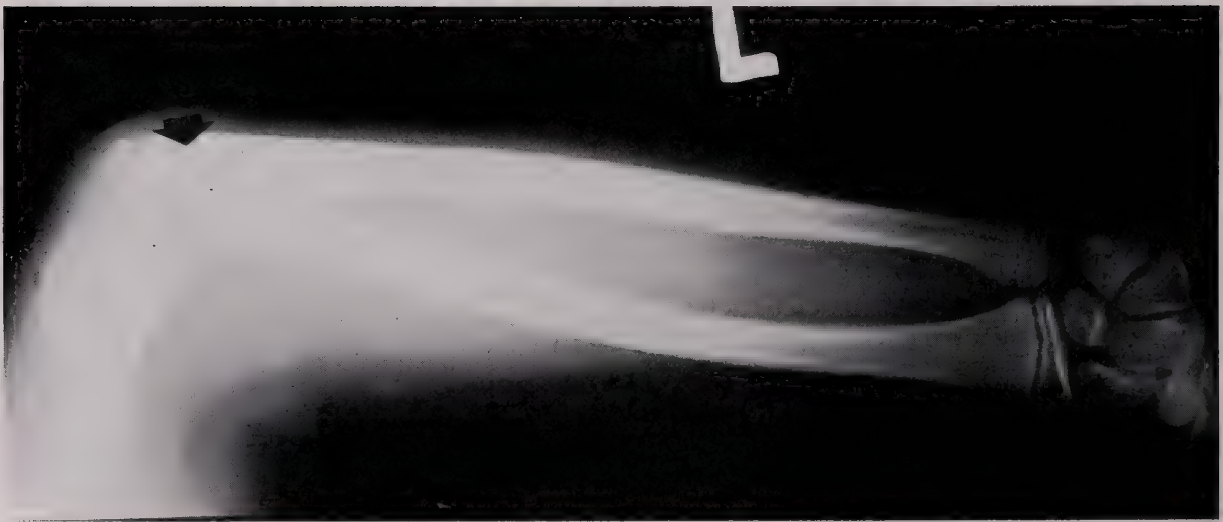

Fig. 3— Fracture-dislocation of the proximal epiphysis of the left radius.

2), also a fracture of the left radial head, with lateral displacement of more than 60 degrees (Figure 3).

The patient was taken to the operating room and, under general anesthesia, a closed reduction of the fracture-dislocation of the radial head was attempted. However, the angulation of the proximal radial epiphysis, as determined on the anteroposterior x-ray, was not improved. An incision was made over the lateral epicondyle of the humerus curving distally over the proximal 4 cm of the ulna. After the subcutaneous tissues and fascia had been split in the line of the incision, the interval between the anconeus and extensor carpi ulnaris muscles was developed. Then the radial head was found with the articular surface pointing laterally and slightly distally, completely out of contact with the remainder of the radius.

A buttonhole-shaped rent was seen in the orbicular ligament. The radial head, or the proximal radial epiphysis, was manipulated toward the rent. With digital pressure on the proximal radial head and with the forearm adducted, the proximal radial epiphysis slipped through the rent and into normal alignment (Figure 4). The fracture was stable during supination and pronation, both in flexion and in extension. After closure of the wound, anterior and posterior splints were applied. The fracture of the distal right radius was reduced by

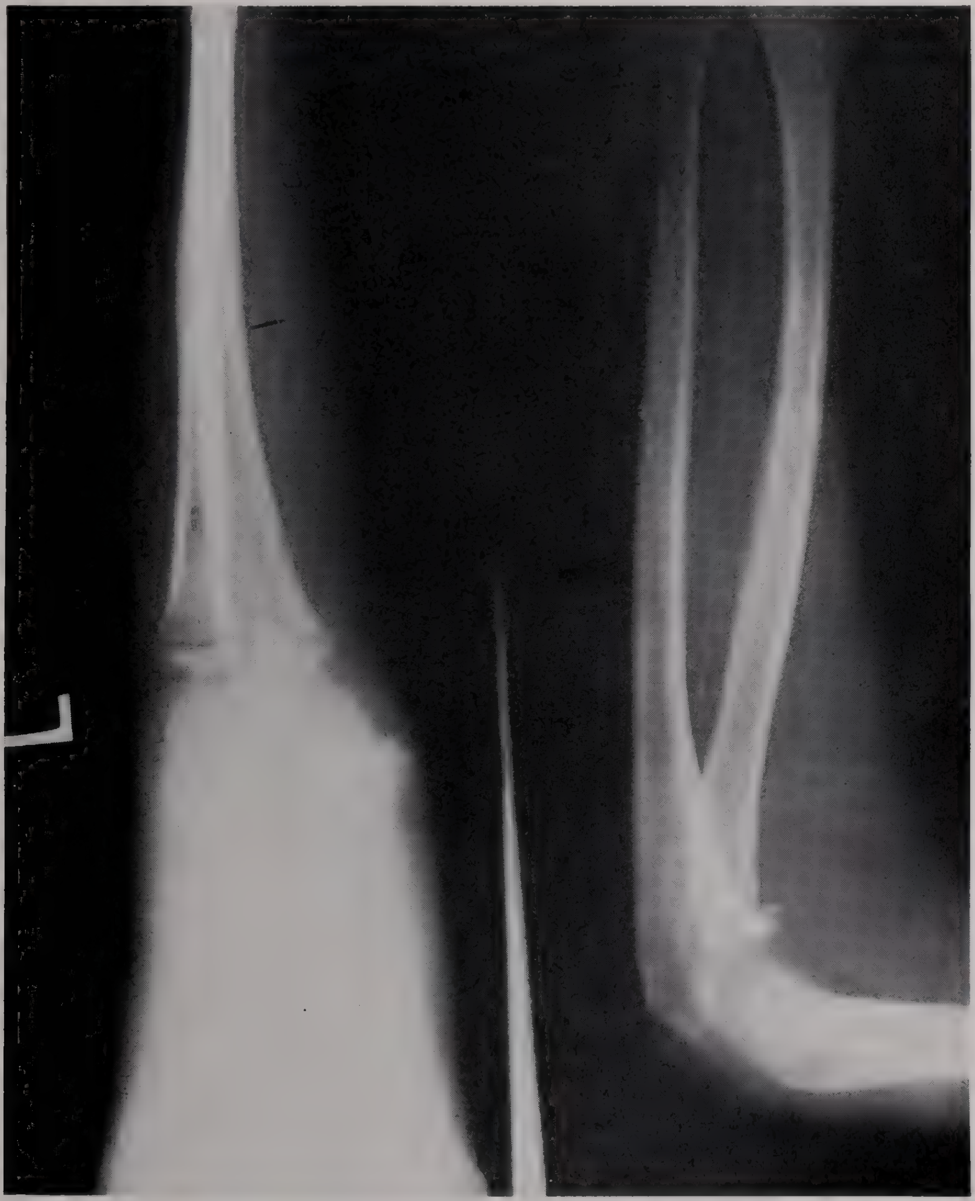

Fig. 4—X-ray following open reduction of fracture-dislocation of proximal radial epiphysis.

closed manipulation, and anterior and posterior splints were applied (Figure 5).

External immobilization of the left elbow was discontinued at three weeks (Figure 6). Gentle active motion was started, and the patient had a full range of motion at two months.

Discussion

Fracture-dislocation of the proximal radial epiphysis is a relatively rare injury seen in children between five and 14 years of age. The mechanism of injury is a fall on the hand with the forearm supinated and the elbow fully extended. With the elbow in extension, the slight valgus of the carrying angle directs the distal force toward the radiohumeral joint, and displacement of the proximal radial epiphysis results.

Removal of the radial head is a disastrous form of treatment in children,[1] for 25 percent of the growth in length of the radius occurs at the proximal radial epiphysis. Hence, removal may cause not only cubitus valgus at the elbow, but also radial deviation of the hand as a result of continued normal growth of the ulna.

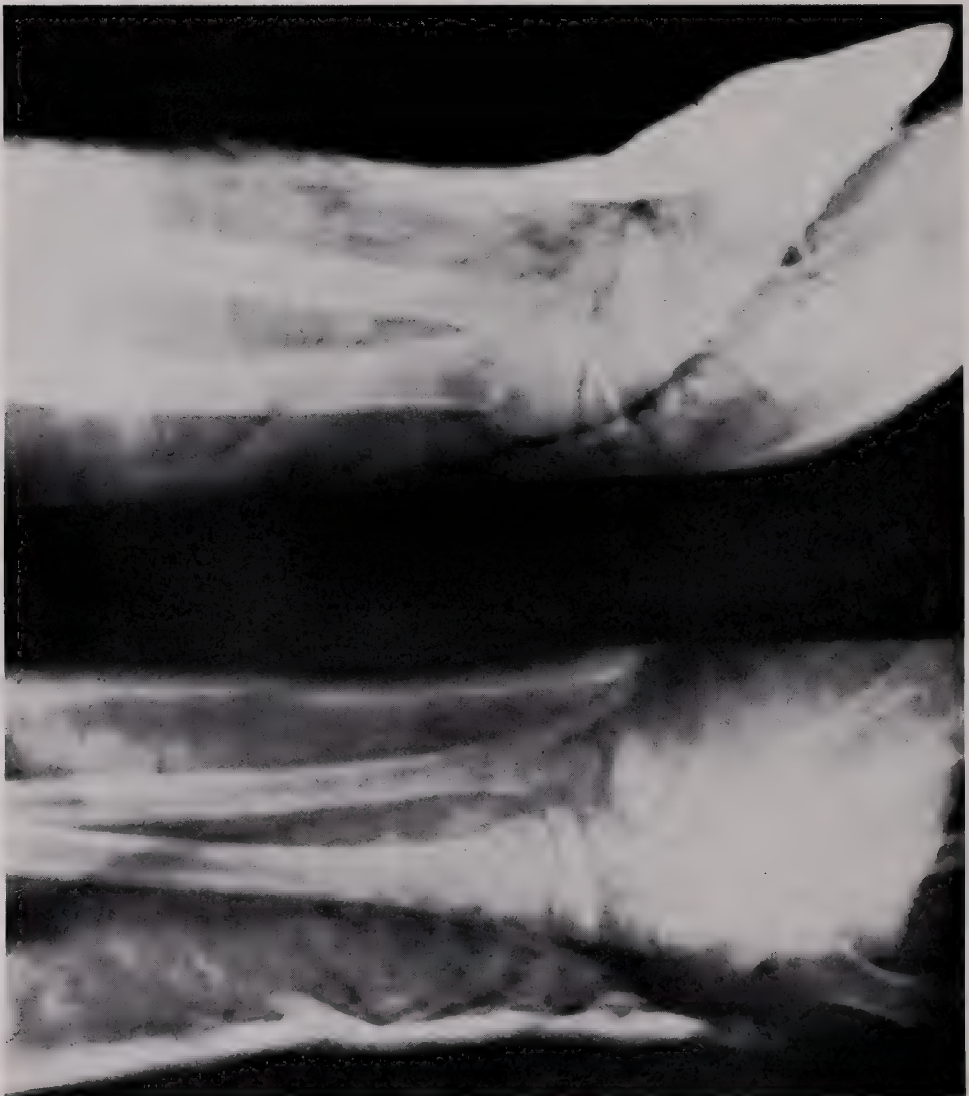

Fig. 5—Post-reduction x-ray of fracture of right distal radius.

The extent of the angular or rotational displacement of the proximal radial epiphysis, as seen on the anteroposterior x-ray of the elbow, determines the treatment. No reduction is needed for angulation from 0 to 30 degrees. A good result can be expected from immobilization for 21 days and then active exercises. When the angulation is from 30 to 60 degrees, a closed reduction should be attempted. Digital pressure is applied over the proximal radial epiphysis with the forearm adducted and simultaneous moderate supination and pronation of the forearm. According to Blount,[1] closed reduction is quite effective for an angulation of less than 45 degrees.

If closed reduction cannot bring the angulation down to less than 45 degrees, an open reduction should be done through the posterolateral approach to the radial head. For angulation of more than 60 degrees, closed reduction should be attempted, even though a satisfactory reduction is not likely. Repeated attempts at closed reduction should be resisted, for they can damage the epiphysis or destroy the orbicular ligament. Gentle open reduction of the proximal radial epiphysis should then be done. If the fracture is unstable after reduction, a small Kirschner wire can be used, but it must be

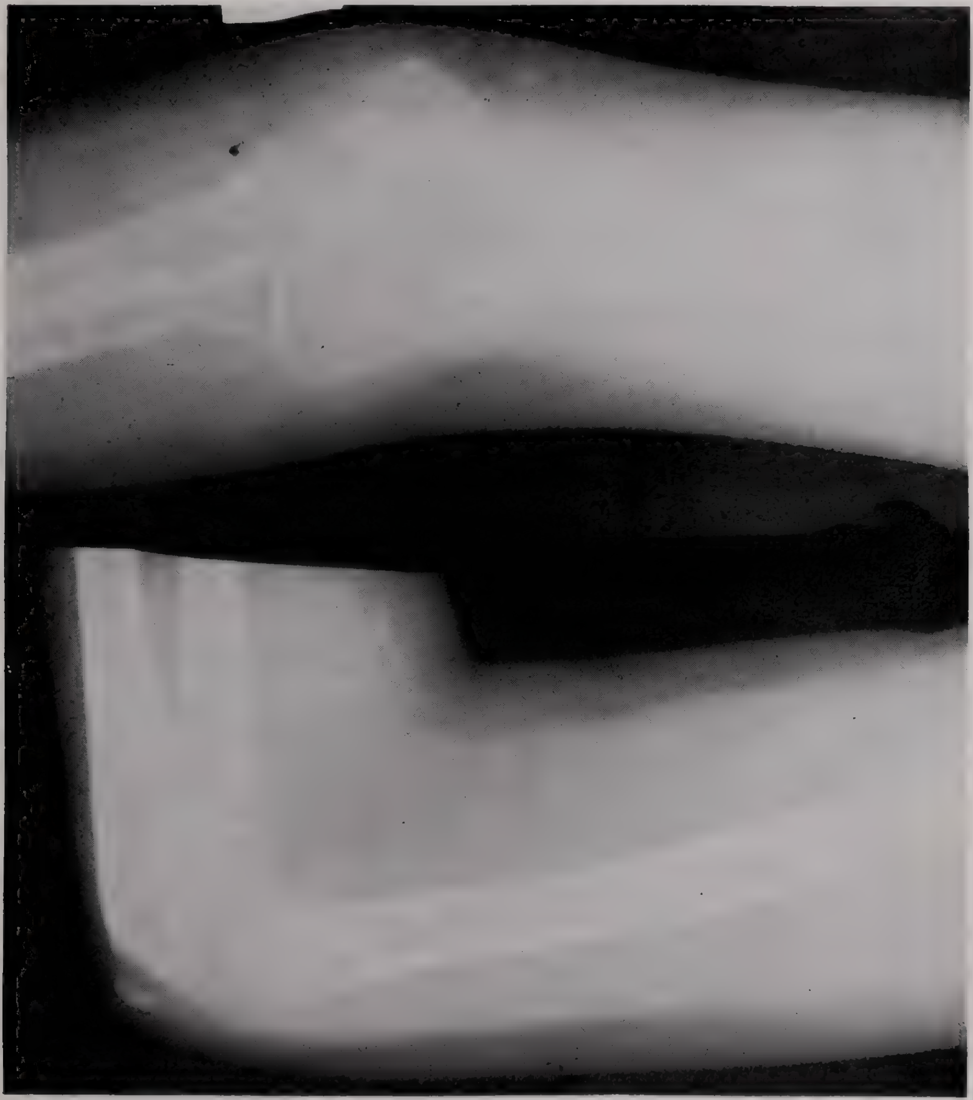

Fig. 6—X-ray taken three weeks post reduction of the proximal left radial epiphysis.

placed through the capitellum and the center of the proximal radial epiphysis.[2] Unless these requirements are met, damage to the epiphysis and premature closure are likely to occur. The Kirschner wire should be removed at three weeks and gentle active motion should be started.

Some authors believe that reduction will result in some limitation of motion when the final angulation exceeds 20 degrees.[3-5] Blount concedes this, but there is only slight limitation of supination with angulation of less than 45 degrees and usually the patient is not aware of this limitation.[1]

If the fracture is more than three weeks old, open reduction should not be performed, regardless of the rotational deformity,[1] because of the risk of radio-ulnar synostosis and severe limitation of motion.[2] The deformity should be left alone, and the radial head removed at skeletal maturity only if necessary.

Adequate treatment of the fracture depends upon recognition of the angular deformity on the anteroposterior x-ray of the elbow. Awareness of the fracture may depend upon the practice of obtaining x-rays of both ends of a fractured bone.

Cowboy Doctors Made Mileage

Trying to care for the sick and hurt scattered over immense regions, cowboy doctors racked up cross-country riding records that rivaled those of the Pony Express. Dr. J. E. Hodge, Slim Buttes, the Dakotas, regularly rode 50 to 60 miles to the bedside of a patient. Dr. Urling C. Coe was accustomed to covering 80 miles of Oregon bunch grass country in a day; he clipped off 35 miles in three and a half hours over rough trails. When the Christmas tree caught fire in a hall crowded with ranch families at Silver Lake, Oregon, scores were fearfully burned. Dr. Bernard Daly rode 100 miles through the snow from Lakeview to find 38 victims already dead. He treated 36 and saved all but five with the assistance of cowboy nurses. Another Oregon doctor, F. C. Harley, Canyon City, rode so fast over primitive roads that he had to carry his hat in his hand to keep it from blowing away. Once he made a horseback call 250 miles away in Winnemucca, Nevada, and probably established the long-distance record for a cowboy doctor riding to his patient.*

PRELUDIN
PHENMETRAZINE
HYDROCHLORIDE

Preludin®
phenmetrazine hydrochloride

Preludin is indicated only as an anorexigenic agent in the treatment of obesity. It may be used in simple obesity and in obesity complicated by diabetes, moderate hypertension (see Precautions), or pregnancy (see Warning). *Contraindications:* Severe coronary artery disease, hyperthyroidism, severe hypertension, nervous instability, and agitated prepsychotic states. Do not use with other CNS stimulants, including MAO inhibitors. *Warning:* Do not use during the first trimester of pregnancy unless potential benefits outweigh possible risks. There have been clinical reports of congenital malformation, but causal relationship has not been proved. Animal teratogenic studies have been inconclusive. *Precautions:* Use with caution in moderate hypertension and cardiac decompensation. Cases involving abuse of or dependence on phenmetrazine hydrochloride have been reported. In general, these cases were characterized by excessive consumption of the drug for its central stimulant effect, and have resulted in a psychotic illness manifested by restlessness, mood or behavior changes, hallucinations or delusions. Do not exceed recommended dosage. *Adverse Reactions:* Dryness or unpleasant taste in the mouth, urticaria, overstimulation, insomnia, urinary frequency or nocturia, dizziness, nausea, or headache. *Dosage:* One 25 mg. tablet b.i.d. or t.i.d. Or one 75 mg. Endurets tablet a day, taken by midmorning. *Availability:* Pink, square, scored tablets of 25 mg. for b.i.d. or t.i.d. administration, in bottles of 100 and 1000. Pink, round Endurets® prolonged-action tablets of 75 mg. for once-a-day administration, in bottles of 100 and 1000. (B) R3-46-560-B

Preludin® **Endurets®**
phenmetrazine hydrochloride **prolonged-action tablets**

PRELUDIN
PHENMETRAZINE
HYDROCHLORIDE
ENDURETS
PROLONGED - ACTION
TABLETS

They run a good chance of losing weight.

Exercise and Preludin run together in helping patients to lose weight.

Preludin often puts a natural curb on appetite and frequently promotes a sense of well-being. By boosting a dieter's spirit, Preludin may help patients get the exercise you may prescribe.

One Endurets tablet taken between breakfast and midmorning usually provides daylong and early-evening suppression of appetite.

Mild ulcerative colitis may be triggered here...

In mild ulcerative colitis, a number of factors can precipitate an attack: for instance, dietary indiscretion, such as eating raw foods, or emotional overreaction, such as that aroused by financial difficulties. No matter what causes the patient's sensitive colon to "act up," he soon suffers from acute discomfort...and often, from anxiety and apprehension as well. Such patients frequently respond well to adjunctive dual-action Librax® therapy.

Librax combines, in a single convenient capsule, the well-known antianxiety effect of Librium® (chlordiazepoxide HCl) and the dependable anticholinergic /antispasmodic effect of Quarzan® (clidinium Br). Therefore, as Librax helps to relieve the patient's excessive anxiety and reduce his overreaction to stress, it also, at the same time, helps to control hypersecretion and hypermotility, thus relieving spasm and abdominal discomfort.

With Librax, the dosage schedule is simple: 1 or 2 capsules, t.i.d. or q.i.d., will in most cases bring the patient significant relief of both the emotional and physical elements that contribute to his psychovisceral disorder.

Before prescribing, please consult complete product information, a summary of which follows.

INDICATIONS: Indicated as adjunctive therapy to control emotional and somatic factors in gastrointestinal disorders.

CONTRAINDICATIONS: Patients with glaucoma; prostatic hypertrophy and benign bladder neck obstruction; known hypersensitivity to chlordiazepoxide HCl and/or clidinium bromide.

WARNINGS: Caution patients about possible combined effects with alcohol and other CNS depressants. As with all CNS-acting drugs, caution patients against hazardous occupations requiring complete mental alertness (*e.g.*, operating machinery, driving). Though physical and psychological dependence have rarely been reported on recommended doses, use caution in administering Librium (chlordiazepoxide hydrochloride) to known addiction-prone individuals or those who might increase dosage; withdrawal symptoms (including convulsions), following discontinuation of the drug and similar to those seen with barbiturates, have been reported. Use of any drug in pregnancy, lactation, or in women of childbearing age requires that its potential benefits be weighed against its possible hazards. As with all anticholinergic drugs, an inhibiting effect on lactation may occur.

PRECAUTIONS: In elderly and debilitated, limit dosage to smallest effective amount to preclude development of ataxia, oversedation or confusion (not more than two capsules per day initially; increase gradually as needed and toler-

or here.

ted). Though generally not recommended, if
ombination therapy with other psychotropics
eems indicated, carefully consider individual
pharmacologic effects, particularly in use of po-
entiating drugs such as MAO inhibitors and
phenothiazines. Observe usual precautions in
presence of impaired renal or hepatic function.
Paradoxical reactions (*e.g.*, excitement, stimula-
ion and acute rage) have been reported in psy-
hiatric patients. Employ usual precautions in
reatment of anxiety states with evidence of im-
pending depression; suicidal tendencies may be
present and protective measures necessary. Vari-
ble effects on blood coagulation have been
eported very rarely in patients receiving the
drug and oral anticoagulants; causal relation-
hip has not been established clinically.
ADVERSE REACTIONS: No side effects or
manifestations not seen with either compound
lone have been reported with Librax. When
chlordiazepoxide hydrochloride is used alone,
drowsiness, ataxia and confusion may occur,
especially in the elderly and debilitated. These
are reversible in most instances by proper dosage adjustment, but are also occasionally observed at the lower dosage ranges. In a few instances syncope has been reported. Also encountered are isolated instances of skin eruptions, edema, minor menstrual irregularities, nausea and constipation, extrapyramidal symptoms, increased and decreased libido—all infrequent and generally controlled with dosage reduction; changes in EEG patterns (low-voltage fast activity) may appear during and after treatment; blood dyscrasias (including agranulocytosis), jaundice and hepatic dysfunction have been reported occasionally with chlordiazepoxide hydrochloride, making periodic blood counts and liver-function tests advisable during protracted therapy. Adverse effects reported with Librax are typical of anticholinergic agents, *i.e.*, dryness of mouth, blurring of vision, urinary hesitancy and constipation. Constipation has occurred most often when Librax therapy is combined with other spasmolytics and/or low residue diet.

two good reasons for prescribing LIBRAX®

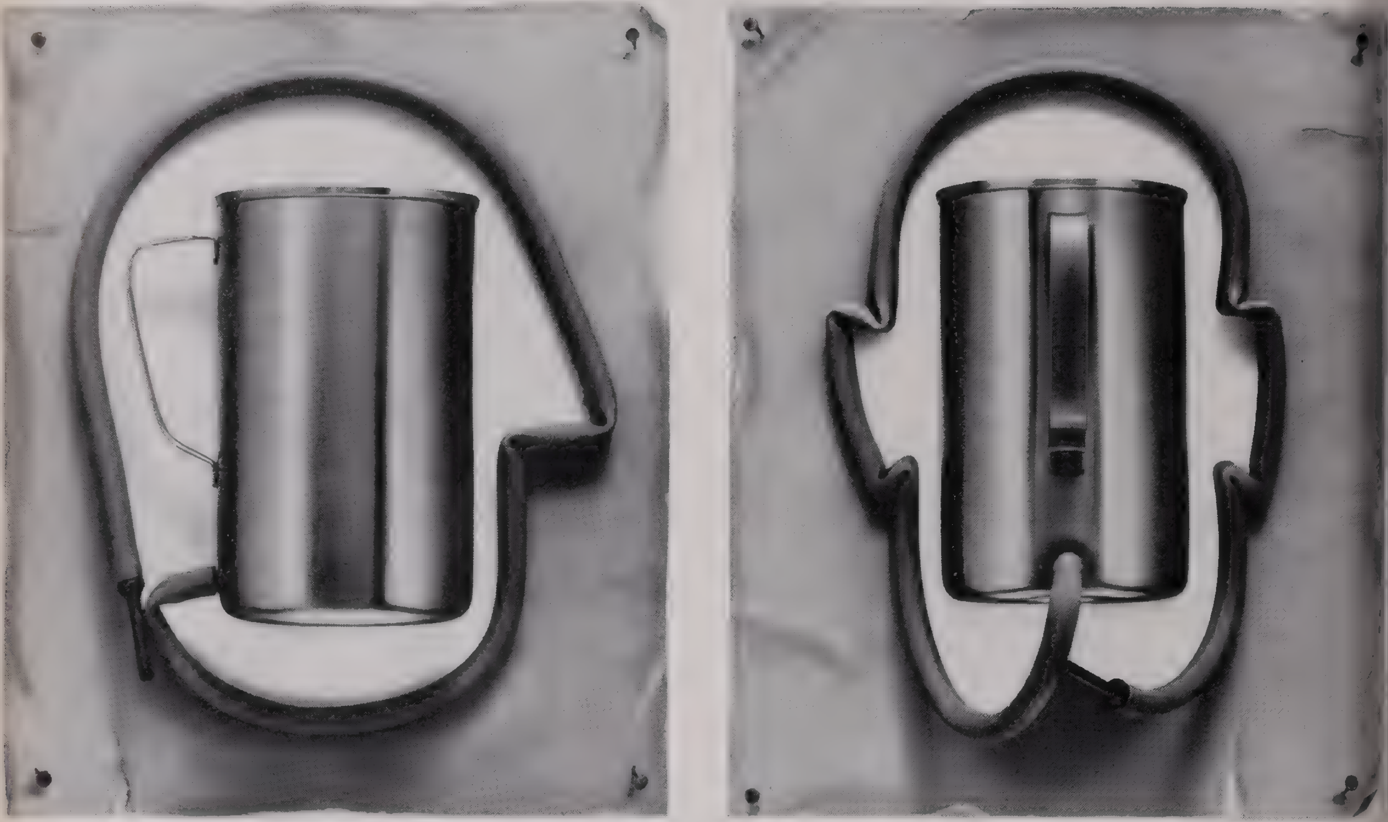
Public Enema No.1



Claim the rewards of sparing your patients the tubes and tribulations of unpleasant enemas.

Compared to enemas, Dulcolax suppositories are a gentler and simpler way to empty the bowel. Gone are the tubing, the "accidents", and the bruised egos. Just one suppository, inserted against the bowel wall, usually brings about an evacuation within 15 minutes to an hour.

In the hospital, order Dulcolax for constipation or bowel cleansing. Your patients will often prefer it to embarrassing enemas. And you can be sure nurses will appreciate the saving in time and effort.

Dulcolax tablets taken at night usually result in a bowel movement the following morning. A combination of tablets at night and a suppository the next morning generally cleans the bowel thoroughly in preparation for surgery or special procedures. Keep in mind, however, that the drug is contraindicated in the acute surgical abdomen.

Dulcolax®...it's predictable

Tumor Conference

Glioblastoma Multiforme

RECENT INTEREST in the treatment of glioblastoma multiforme[1,2] prompted a review of the experience at Wilford Hall USAF Hospital, in an attempt to determine the incidence of brain tumors in general, the validity of staging the gliomas and the survivability of the higher stages of astrocytomas; and to determine if there has been any improvement or prolongation of survival by the addition of radiotherapy.

Method

The records of patients diagnosed as having brain tumors, as accumulated in the USAF Central Tumor Registry, were reviewed to determine diagnosis, stage and location, and treatment of the disease. The incidence of the various brain tumors was compared with a series of Cushing[3] and Courville.[4] The quality of survival was determined by the Karnofsky scale[5]; and longevity of survival was calculated on a straight-line formula of number of patients living at five years, divided by the total number diagnosed, for those patients diagnosed prior to 1 July 1963. Patients diagnosed since 1 July 1963 have a calculated length of survival, based on the Berkson and Gage[6] technique for calculation of survival rates and percentages.

Incidence

Table 1 depicts the total number of brain tumor types diagnosed during this period. A comparison of the series from Wilford Hall USAF Hospital with Cajal's and Cushing's series is interesting in several respects. Dr. Cushing obviously saw far more pituitary tumors than either of the other two groups but, in contrast, had very few metastatic tumors in his series, whereas the Wilford Hall and Cajal experiences are almost identical in this regard.

Astrocytoma-Glioblastoma

Table 2 is a further breakdown of the gliomatous brain tumors. The astrocytomas (113; 49.3%) include those with pathologic Grade of I, II, or

III. Sixteen astrocytomas were diagnosed as Grade IV, but are listed with the glioblastoma multiforme. In all three series the astrocytoma/glioblastoma group comprised 72 to 89% of the gliomas, comprising by far the most common type of brain tumor.

Metastatic to the Brain

The second most common brain tumor is that associated with sarcoma or carcinoma metastatic to the brain. A total of 102 patients, comprising 22.4% of the series, were in this category: 12.7% of these patients had metastases from sarcomas; 18.6% developed brain or meningeal involvement from lymphoma/leukemia; and 68.6% had a solid carcinoma metastatic to the brain (Table 3). A subdivision of the carcinoma patients showed that 44% of the brain metastases arose from the lung, followed in decreasing incidence by gastrointestinal tumors, breast carcinoma, and genitourinary tumors.

From Pituitary

The third most common tumor in this series was that arising from the pituitary. It is interesting that in Cushing's series this was the second most common form of brain tumor, while in the Cajal series it was fifth in the order of frequency. Two thirds of the patients with pituitary tumors had chromophobe* adenomas (Table 4). One fourth had eosinophilic tumors, and 13% had mixed or basophilic tumors. This breakdown in tumor type was consistent in the three series.

Other Tumors

Other tumors formed decreasing numbers and percentages of the overall tumors found. A list of frequency of the occurrence of tumors as determined by the Wilford Hall USAF Hospital experience in all age groups shows the astrocytoma to be by far the most common brain tumor, and also by far the most common brain tumor found supratentorially, comprising 135 of the 194 supratentorial tumors. Infratentorial tumors were most commonly astrocytomas (28; 27%), ependymomas (21; 20%), and medulloblastomas (17; 16%). Meningiomas were almost exclusively supratentorial in that 41 of the 44 meningiomas were located over the cerebral hemispheres and only two were found in the posterior fossa. One meningioma was in the third ventricle. All of the medulloblastomas were in the infratentorial region. There were 33 tumors found in the vermis or cerebellar hemisphere, four of them hemangioblastomas, four sarcomas, ten astrocytomas, ten medulloblastomas, and five ependymomas.

Survival

The absolute numbers and survival statistics for patients with various types and grades of gliomatous brain tumors is seen in Table 5.

Ependymoma

Thirty-one patients were diagnosed as having ependymomas, occurring in a variety of locations. Nine originated in the cerebral hemispheres, one on the pons, one in the basal ganglia, and 20 in the posterior fossa. Five of these were in the cerebellum and eleven in the fourth ventricle. The exact location of four could not be determined. These patients had a 20% five-year

survival, and a median survival of 16.5 months. Location of the ependymoma did not seem to affect the survival or duration of survival in that seven of the 10 patients with supratentorial lesions and 12 of 21 patients with infratentorial lesions expired, with no difference in the median survival of the two groups.

Meningioma

There were 44 patients with meningiomas, having a 69% five-year survival. The meningiomas were primarily located over the cerebral hemispheres, with only two being found in the posterior fossa. Ten patients were diagnosed as having oligodendrogliomas. One patient has lived beyond five years, another three are living less than five years, and six have expired. Eight of the ten oligodendrogliomas were found in a frontal lobe. As expected, all 17 medulloblastomas were located infratentorially. These patients have a poor prognosis, with only 18% surviving five years, the median survival being 17.5 months. Three of the fourteen patients with acoustic neuromas have expired, two as a result of operative mortality and one from a large angle tumor which could not be fully excised. The overall five-year survival rate in this disease is 86%, but 100% if one considers only those patients who survived the postoperative period. This experience is identical to that reported by Ahluwali and Buxton[7] who had an 11% operative mortality in 102 patients with acoustic neuroma.

Astrocytoma

Seventeen patients had astrocytoma Grade I. Twelve are still living for a 74% five-year survival, and a median survival of 46.5 months. All but one of the astrocytomas Grade I were cerebral, the exception being located in the cerebellum. There were 52 with Grade II astrocytoma, 25 of whom are still living, with 35% five-year survival, and 37.5 months median survival. Thirty-four of the 52 patients had supratentorial tumors, the rest being posterior fossa, primarily cerebellar. It is interesting that patients with astrocytoma Grade II, having supratentorial or infratentorial lesions, showed no difference in the length of survival. Forty-four patients had Grade III and 50 patients Grade IV (glioblastoma multiforme) astrocytomas. There were no survivals beyond 39 months in these patients, and the median survival was 5.5 months.

Therapy

Several neurosurgeons have been responsible for the management of these patients; hence the mode of therapy, i.e., surgery, radiation, or surgery plus irradiation, has been totally unselected and purely a reflection of the individual surgeon's opinion of the value of radiation.

Radiation

Table 6 depicts the mode of therapy for the astrocytomas. Those patients treated with radiation alone actually had a biopsy of the tumor, but an attempt to extirpate the tumor would have compromised the patient's quality of survival. The results of therapy in the gliomatous brain tumors revealed that patients with Grade I astrocytomas who were treated with surgery did quite well, living an average of 65 months post treatment.

TOTAL	25		76		13		49	

Surgery and Radiation

Fifty-two patients were diagnosed as having Grade II astrocytomas. Six had biopsies alone with no further treatment and lived an average of one month. Twenty treated with surgery alone had a median survival of 43 months. Nine who had a biopsy followed by irradiation had a 30-month median survival. The 17 patients who were treated with surgery followed by radiation had a median survival of 48 months. Thirty-four of the 52 patients had lesions located in the cerebral hemispheres; nine had cerebellar lesions, and sixteen had infratentorial lesions. There was no difference in the survival of the patients with astrocytoma Grade II, whether the lesion was supra- or infratentorial.

Biopsy Only

Forty-four patients had a Grade III astrocytoma. Seven had a biopsy alone with no further therapy and lived an average of two months. Seventeen treated with surgery alone had a median survival of seven months. Three patients had no biopsy at all. One of these lesions, located in the pons, was treated with irradiation, empirically; of the two patients with basal ganglia lesions, one was treated empirically with irradiation, the other not at all. These diagnoses were later confirmed at autopsy. The median survival of patients treated with radiation alone was ten months. Seventeen treated with surgery followed by irradiation had a median survival of 15 months. In 36 of the 44 patients with astrocytoma Grade III, the lesion was located in the cerebral hemisphere. There were only five patients with infratentorial lesions and, although their survival in each category was quite poor, the number of cases was not large enough to affect the overall duration of survival in this group.

A total of 50 patients were diagnosed as having pathological Grade IV astrocytoma or glioblastoma multiforme. Nine had no treatment and a median survival of two months. Twenty-five were treated with surgery alone, with a median survival of 5.5 months. Only one patient was treated with radiation following biopsy of the lesion. The tumor in this patient was located in the pons and surgical extirpation could not be accomplished. Fifteen patients had surgery followed by irradiation, with a 20-month median survival. Forty-five of these 50 patients had lesions located in the cerebral hemispheres. Only two had cerebellar lesions; three had lesions in the pons. Again, including infratentorial lesions with the rest of the glioblastoma multiforme lesions did not reflect unfavorably upon the overall survival; in fact, the longest duration of survival (39 months) occurred in a patient with a cerebellar lesion which was treated with surgical extirpation followed by irradiation.

Extensive Resection and X-ray

Comparison of the treatment and results in patients with diagnosis of Grade III as compared with Grade IV astrocytoma (glioblastoma) showed no significant difference in the results of these two groups. Therefore Grades III and IV astrocytomas (glioblastomas) could be considered as similar tumors and treated in an identical manner. In Jelsma and Bucy's[1] series of 162 patients, six with glioblastoma lived for longer than three years. Their treatment of choice is extensive resection followed by radiation therapy, since it appears that radiation therapy improves quality of survival for the first 18 months after therapy. Patients who survived longer than 18 months showed no improvement in the quality of survival even with radiation therapy added. Buckley[2] reviews the role of radiation in cerebral gliomas and reports that radiation alone increases length of survival. In his series, patients treated with surgery had a 2.5-month median survival postoperatively; those treated with radiation lived a median of 19.5 months following treatment, and those treated with surgery and radiation had a 12-month median survival.

The present series confirms the fact that patients with astrocytoma Grade I are best treated with surgery alone, and that radiation adds nothing to their survival or quality of survival. Patients with Grade II astrocytoma appear to do well with surgery or surgery plus irradiation, but not as well with radiation alone. In the higher grade astrocytomas, i.e., Grade III or Grade IV (glioblastoma multiforme) patients appear to do best with surgery plus irradiation. It would be our recommendation that patients have a generous internal decompression, followed by x-ray therapy; this will nearly double the survival time of patients with the higher grade astrocytomas. Radiation also prolongs life, even when only a confirmatory biopsy is possible due to the tumor location. Therefore it would be our recommendation that patients with the higher grade astrocytomas be given the benefit of surgical extirpation of the tumor if this is possible without compromising the patients' subsequent quality of survival. This conclusion is in accord with the views of Jelsma and Bucy in their series of 162 patients. This treatment should afford a patient who survives the immediate postoperative period approximately one year of relatively good-quality survival, although the chances of living with any degree of useful function beyond the second year are nil.

Conclusion

Recommendations for treatment of patients with gliomas, particularly the higher grade astrocytomas, are surgery alone for Grade I astrocytoma, surgery plus radiation for Grade II astrocytoma, radiation or surgery plus radiation for patients with Grade III or IV (glioblastoma multiforme) astrocytomas.

So he'll breathe easier:

relieve anxiety while you relieve pain.

Relief of pain is usually a major goal in traumatic conditions. But often of importance, too, is alleviation of anxiety and tension that may heighten patient discomfort.

Single-prescription, non-narcotic Equagesic may effectively relieve pain. *And* ease anxiety and tension.

TABLETS

Equagesic®

(meprobamate and ethoheptazine citrate with aspirin)

Wyeth®

IN BRIEF.

Contraindications: History of sensitivity or severe intolerance to aspirin, meprobamate or ethoheptazine citrate.

Warnings: USE IN PREGNANCY: Safety for use during pregnancy or lactation has not been established; therefore, it should be used in pregnant patients or women of child-bearing age only when the physician judges its use essential to the patient's welfare.

Precautions: Keep out of reach of children. Not recommended for patients 12 years old or less. Carefully supervise dose and amounts prescribed, especially for patients prone to overdose themselves. Excessive prolonged use of meprobamate in susceptible persons—as alcoholics, ex-addicts, severe psychoneurotics—has resulted in dependence or habituation. Withdraw gradually after prolonged excessive dosage to avoid possibly severe withdrawal reactions including epileptiform seizures. Warn patients of possible reduced alcohol tolerance, with resultant slowed reactions and impaired judgment and coordination. If drowsiness, ataxia or visual disturbances (impairment of accommodation and visual acuity) occur, reduce dose. If symptoms persist, patients should not operate machinery or drive. After meprobamate overdose, prompt sleep, reduction of blood pressure, pulse and respiratory rates to basal levels, and hyperventilation are reported. Give cautiously and in small amounts to patients with suicidal tendencies. Treat attempted suicide (has resulted in coma, shock, vasomotor and respiratory collapse and anuria) with gastric lavage and appropriate symptomatic therapy (CNS stimulants and pressor amines as indicated). Two instances of accidental or intentional significant overdosage with ethoheptazine and aspirin have been reported. These were accompanied by CNS depression (drowsiness and lightheadedness) but resulted in uneventful recovery. On basis of pharmacologic data, CNS stimulation could be anticipated, with nausea, vomiting and salicylate intoxication (requires induced vomiting or gastric lavage, specific parenteral electrolyte therapy for ketoacidosis and dehydration, and observation for hypoprothrombinemic hemorrhage [usually requires whole blood transfusions]).

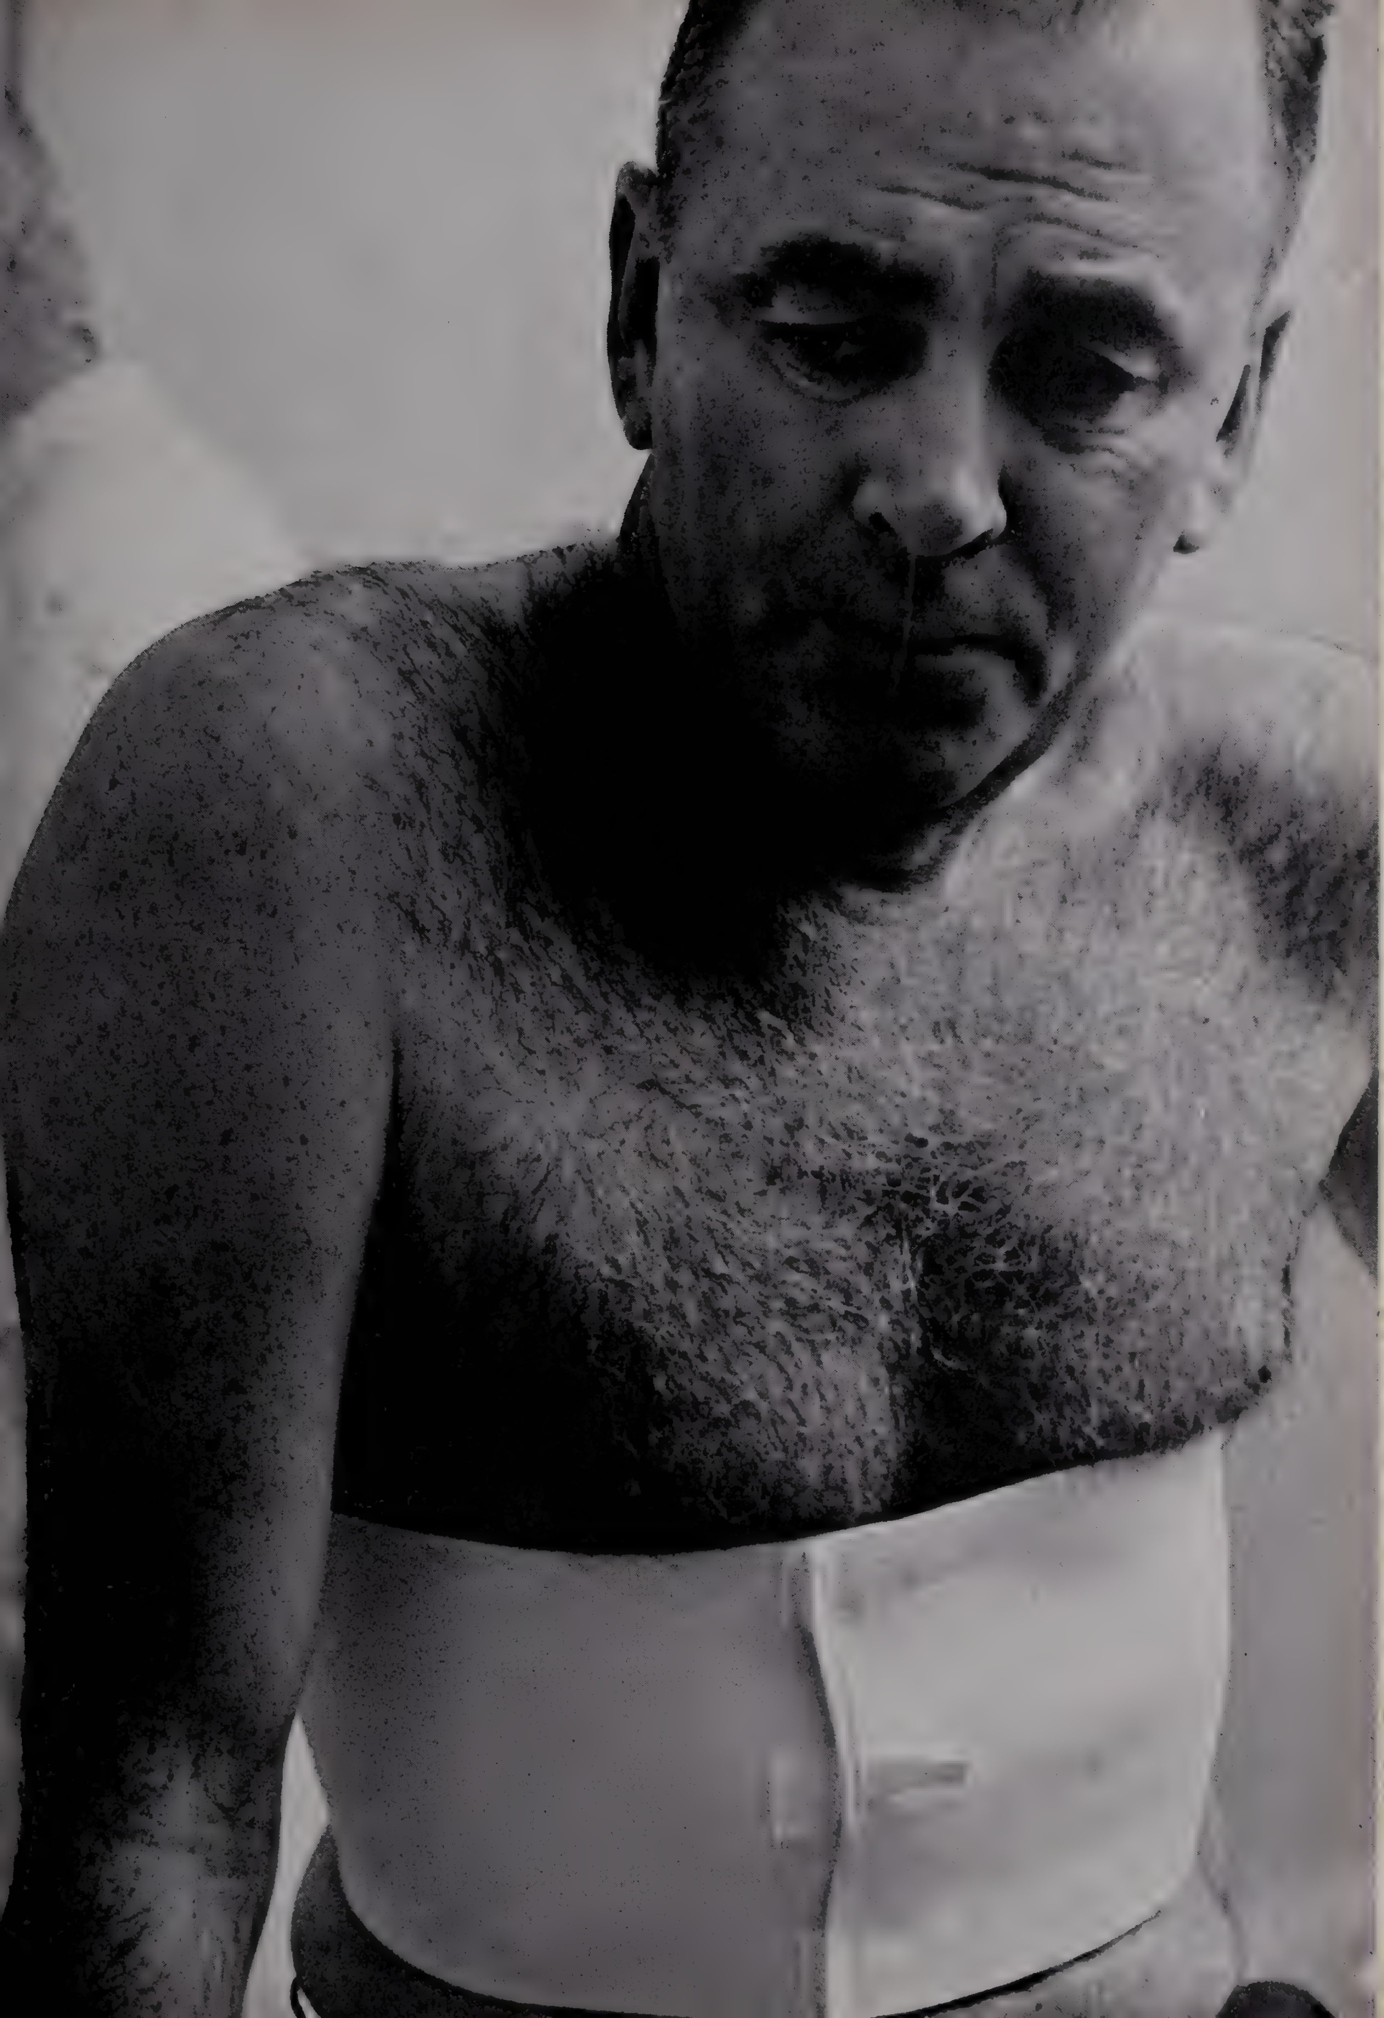
Adverse Reactions: Ethoheptazine and aspirin may cause nausea with or without vomiting and epigastric distress, in a small percentage of patients. Dizziness is rare at recommended dosage. Meprobamate may cause drowsiness, ataxia and rarely allergic or idiosyncratic reactions. These reactions, sometimes severe, can develop in patients receiving only 1 to 4 doses. Such patients may have had no previous contact with meprobamate and may or may not have an allergic history. Mild reactions are characterized by urticarial or erythematous maculopapular rash. Acute nonthrombocytopenic purpura with cutaneous petechiae, ecchymoses, peripheral edema and fever have been reported. If allergic reaction occurs, discontinue meprobamate; do not reinstitute. Severe reactions, observed very rarely, include fever, fainting spells, angioneurotic edema, bronchial spasms, hypotensive crises (1 fatal case), anaphylaxis, stomatitis and proctitis (1 case) and hyperthermia. These cases should be treated symptomatically including, when indicated, such medication as epinephrine, antihistamine and possibly hydrocortisone. A few cases of leukopenia, usually transient, have been reported on continuous use. Rarely, aplastic anemia (1 fatal case), thrombocytopenic purpura, agranulocytosis, and hemolytic anemia have been reported, almost always in presence of known toxic agents.

Overdosage: See precautions section for management of overdosage.

Composition: 150 mg. meprobamate, 75 mg. ethoheptazine citrate and 250 mg. aspirin per tablet.

Wyeth Laboratories Philadelphia, Pa.

Photo professionally posed.



in cerebrovascular disorders

Arlidin increases blood flow

Arlidin decreases cerebral vascular resistance, increases cardiac output, helps maintain mean arterial pressure.

Arlidin helps control vasoconstriction, vasospasm, and ischemia.

Arlidin may thus relieve symptoms of cerebrovascular insufficiency, such as vertigo, lightheadedness, and mental confusion.

Arlidin also increases blood flow to the eye and inner ear to help manage ischemic disorders of those organs.

Arlidin is well tolerated and relatively free of severe adverse reactions.

DOSAGE: Usual effective dosage ½ to 1 tablet t.i.d. or q.i.d.; increased, if necessary, to 2 tablets t.i.d. or q.i.d. Parenterally, 0.5 cc. by subcutaneous or intramuscular injection; increased gradually to 1 cc. one or more times daily, as needed. SIDE EFFECT: Occasional palpitation. PRECAUTIONS: Use with caution in the presence of a recent myocardial lesion, paroxysmal tachycardia, severe angina pectoris, thyrotoxicosis. CONTRAINDICATION: Acute myocardial infarction.
SUPPLIED: Tablets, 6 mg., scored; bottles of 100 and 1000. Parenteral, 5 mg. per cc., 1 cc. ampuls (5 per box); 10 cc. multiple-dose vials (1 per box).

**Mark Waters was a chain smoker.
Wonder who'll get his office?**

Too bad about Mark. Kept hearing the same thing everyone does about lung cancer. But, like so many people, he kept right on smoking cigarettes. Must have thought, "been smoking all my life... what good'll it do to stop now?" Fact is, once you've stopped smoking, no matter how long you've smoked, the body begins to reverse the damage done by cigarettes, provided cancer or emphysema have not developed. Next time you reach for a cigarette, think of Mark. Then think of your office —and your home.

Doppler Shifted Ultrasound

History and Applications in Clinical Medicine

THE TECHNOLOGY REQUIRED to study blood flow by detection of the Doppler frequency shift in backscattered ultrasound has been developed and reported in the literature during the last 15 years. The basic principles have had several important applications to clinical medicine, largely because the instrument can be used transcutaneously and nondestructively. The purpose of this paper is to review the short history of this new technique, describe the physical principles involved, and discuss the clinical applications.

History

As early as 1957, Satomura, of Osaka University in Japan, adapted Doppler ultrasound engineering principles to the "inspection of cardiac functions."[1] Subsequently, Franklin et al., of the University of Washington School of Medicine, used the Doppler ultrasonic flowmeter in experimental animals.[2] Franklin continued this research at the Scripps Institute, where he adapted the flowmeter to telemetry in order to study blood flow in unrestrained animals.[3] More recently Benchimol and Franklin et al. carried out radio telemetry of human blood flow.[4] Stegal and Rushmer applied the Doppler velocity sensor transcutaneously.[5] Callagan, at the National Naval Medical Center, first undertook detection of the human fetal heart beat by Doppler ultrasonic techniques, and reported it in 1964.[6] Ware, of Southwest Research Institute, described the use of Doppler ultrasonic detection of arterial wall motion (kinetoarteriography) as a means of indirectly determining arterial systolic and diastolic pressures and, in collaboration with several laboratories of the Air Force Systems Command, further developed the system.[7-9]

Technique

The basic principles of the Doppler ultrasonic velocity sensor are fundamental to the various specific applications. Several terms will be used in describing Doppler instruments. *Ultrasound* is defined as any acoustical or mechanical energy that occurs above the limits of human audibility, i.e., usually above 20,000 Hertz (Hz)—one Hz being equal to one cycle per second. Ultrasonic vibrations can be created in the Megahertz (MHz) region by the use of piezoelectric crystals.

Some crystal materials, such as lead zirconate-titanate, exhibit the *piezoelectric effect,* which is the ability of a material to change shape when voltage is applied or, conversely, to create voltage when the crystal shape is deformed.

The *Doppler effect* is the principle by which the frequency is changed when waveform energy is reflected from a moving surface. The change is linear, and it can be additive or subtractive according to whether the reflecting surface is moving toward or away from the source of wave propagation. High frequency ultrasonic waves (0.5 MHz to 15 MHz) penetrate tissue, and reflect from various surfaces, such as blood corpuscles, arterial walls, and surfaces of organs. When 8 MHz ultrasound is reflected from surfaces moving at 0.5 cm/sec to 150 cm/sec, the Doppler shift that occurs is detected and amplified by the instrument, and then presented as a signal within the human audio range.

The instrumentation basic to the Doppler flowmeter is shown in a block diagram (Figure 1). A radio frequency oscillator drives one crystal in a transducer assembly, and a receiver detects the difference in frequency between the transmitted and reflected ultrasound. The output of the receiver is amplified and heard through earphones or a loudspeaker. The pitch of the audio signal is proportional to the velocity of the reflective surface, and the volume is proportional in part to the area of the moving reflective surface. The volume also depends upon the transducer configuration, the angulation of the transducer in relation to the direction of the reflective surface movement, the efficiency of the coupling to the cutaneous surface, and the sensitivity of the equipment. When the system is used as a blood flow detector, it provides an output signal with a frequency that has a linear relationship to blood velocity. Blood flow volume (cc/min) can be determined only when the dimensions of the vessel being studied are known. The dimensions of the lumen seldom are known when the instrument is used transcutaneously.

Basically, the Doppler ultrasonic instrument can provide a sonic or graphic representation of the motion of a reflective tissue surface. The applications of this instrument vary with the type of tissue studied; accordingly, it can be used to detect blood velocity, to determine blood pressure, or to detect a fetal heart beat.

Clinical Uses

The Doppler blood velocity detector employing 5 to 10 MHz ultrasound can be used to evaluate peripheral vascular disease (Figure 2). Used transcutaneously, the instrument lacks the capability of measuring absolute volume flow.

Peripheral Vascular Disease

The clinician uses the instrument in a manner similar to a stethoscope by listening for meaningful sound patterns, which consist of variations in amplitude and pitch. The instrument is remarkably sensitive; it is possible to locate selectively arterial or venous flow in many areas of the body, especially in the extremities. The normal arterial signal recorded from the peripheral arteries has two components: a rise and fall in frequency during systole, followed by a second smaller rise consistent with diastole. Little experience is required for an observer to distinguish velocity signals in stenotic and normal arteries, in arteries proximal and distal to an acute occlusion, and in arteriovenous fistulas. Abnormalities in venous signals also can be detected by the Doppler instrument.[10]

The sensitivity of the equipment allows it to give useful information from otherwise inaccessible arteries, e.g., intercostal arteries. Visceral and deep arteries can be detected, but sometimes anatomical identification is difficult. It is difficult to study intracranial and pulmonary vasculature by this method, for acoustical energy at ultrasonic frequencies is not conducted well by osseous or pulmonary (air-filled) tissue.

When the Doppler ultrasonic instrument is used transcutaneously, the patient experiences neither pain nor discomfort. Although ultrasonic damage to the ciliary body and the cochlea has been reported, it has occurred at very high power levels only.

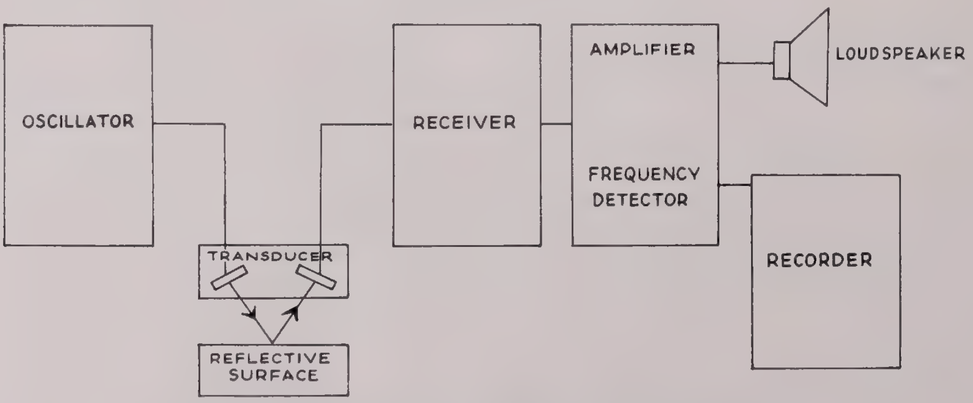

Fig. 1—Block diagram of Doppler ultrasonic flowmeter.

Blood Pressure

Blood pressure can be taken by Doppler ultrasonic techniques. One method of obtaining the systolic blood pressure is to measure the blood flow distal to an occlusive cuff with a Doppler instrument. This procedure is similar to palpating the return of a pulse distal to an occlusive cuff, but is much more sensitive.

An adaptation of the Doppler motion detector makes it possible to determine both systolic and diastolic pressure levels. The transducer is placed under the pneumatic cuff immediately distal to its center and over an artery (Figure 3). The signals resulting from arterial wall motion are emphasized, and the blood flow signals de-emphasized. If the cuff is inflated above systolic pressure levels, the artery remains closed at all times. If the cuff is deflated slowly, when the systolic pressure is reached the artery opens and closes as each pulse wave is allowed to pass. When the pressure is below diastolic levels, the arterial wall movement is not detected.

Taking blood pressure by this method is almost the same as taking it by auscultation of Korotkoff sounds. Instead of listening with a stethoscope over the artery beneath or distal to the cuff, one listens with earphones or a loudspeaker while a special flat transducer is placed under the cuff immediately distal to its center. The endpoints are the same and Doppler sounds appear in manner quite similar to Korotkoff sounds.

Clinical applications of developmental instruments have demonstrated their value for use with patients in shock, for infant blood pressure, and in special situations, such as a high-noise environment.

Fetal Heart Tones

Commercial instrumentation has encouraged widespread use of the Doppler ultrasonic method for determining fetal life. The ultrasonic waves are reflected from the moving fetal cardiac surface (Figure 4): a technique more sensitive than conventional methods, such as the fetoscope and the fetal electrocardiogram. The presence of a fetal heart beat can be detected at 12 weeks of gestation in all patients, and even as early as 10 weeks in some.[11] Multiple gestation can be detected by hearing

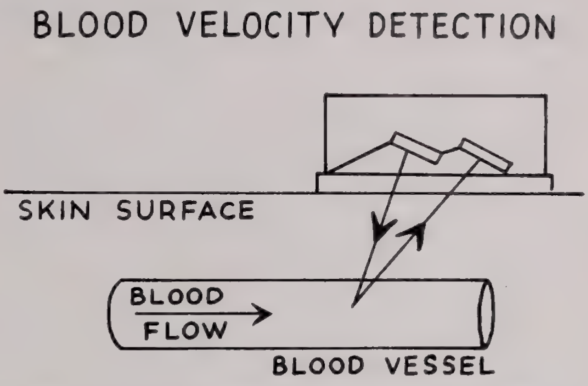

Fig. 2—Use of Doppler apparatus as a blood velocity detector. Ultrasonic beam is reflected from erythrocytes and a shift in frequency is detected.

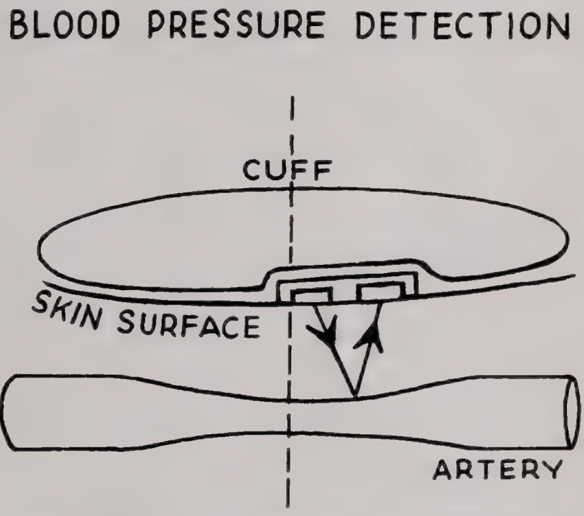

Fig. 3—Use of Doppler apparatus to determine blood pressure. Instrument is used to detect arterial wall motion.

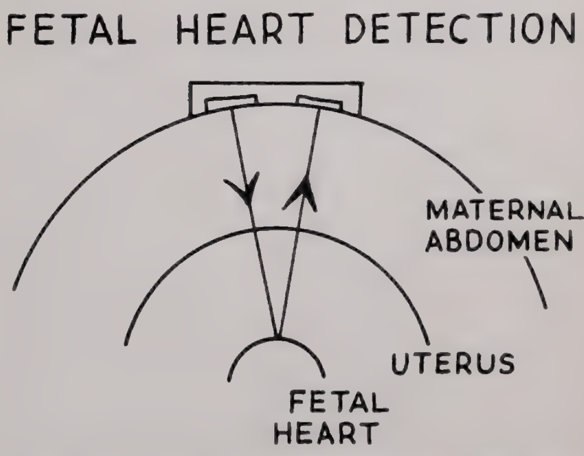

Fig. 4—Use of Doppler apparatus as a fetal heart detector. Ultrasonic waves are reflected from the moving fetal cardiac surface.

more than one heart rate. Another advantage of this method is the ability to localize the placenta from its blood flow pattern. In obstetrical applications, low level 2.5 MHz ultrasound is most widely used without discomfort to the mother or known harm to the fetus.

Comment

The clinical applications described are important to surgeons, pediatricians, obstetricians and anesthesiologists. However, a physician is reluctant to add more "fancy gadgets" to his already immense armamentarium. Preferring to depend upon his senses, aided by the readily available stethoscope, a physician frequently rejects the idea of adopting new diagnostic procedures. Use by the authors of both developmental and commercial Doppler ultrasonic instruments has demonstrated their value in a variety of situations. Equipment available commercially is portable, reliable, and easy to use.

Summary

Japanese and American investigators have applied the Doppler ultrasonic velocity sensor to medicine. Its operation depends upon the use of a pair of piezoelectric crystals which transmit and receive a beam of ultrasound, and incur a frequency shift that is transformed into a discernible audio signal. The Doppler ultrasonic velocity sensor or one of its derivatives has an extensive variety of clinical applications. It can be used to detect fetal heart beats earlier than conventional methods; to aid in diagnosing arterial and venous abnormalities, especially of the extremities; and to determine blood pressure under particularly difficult circumstances. The instrument is easy to operate and causes the patient no discomfort, because it functions transcutaneously.

Clinical Path Conference

Granulomatosis in Infancy and Childhood

Case Presentation

A 27-month-old Japanese-American male was referred to Wilford Hall USAF Hospital from Tachikawa AFB, Japan, because of recurrent pneumonia.

He had been hospitalized at age 15 months for a left lower lobe pneumonia and at age 18 months for a right lower lobe pneumonia, both of which had responded slowly to antibiotics. No causative organisms had been demonstrated. At age 21 months he was admitted because of a persistent, recurrent right lower lobe infiltrate. Although he became afebrile after antibiotic therapy, the infiltrate persisted. A thoracotomy was performed and the right lower lobe was resected. Multiple necrotizing granulomas were found diffusely distributed in the tissue (Figure 1). No organisms were seen in the sections, but cultures grew *Candida* sp. from the lung and *Staphylococci* and *Pseudomonas* sp. from the trachea. He recovered uneventfully from the operation and was discharged on no medication. Four months later, a right middle lobe infiltrate appeared.

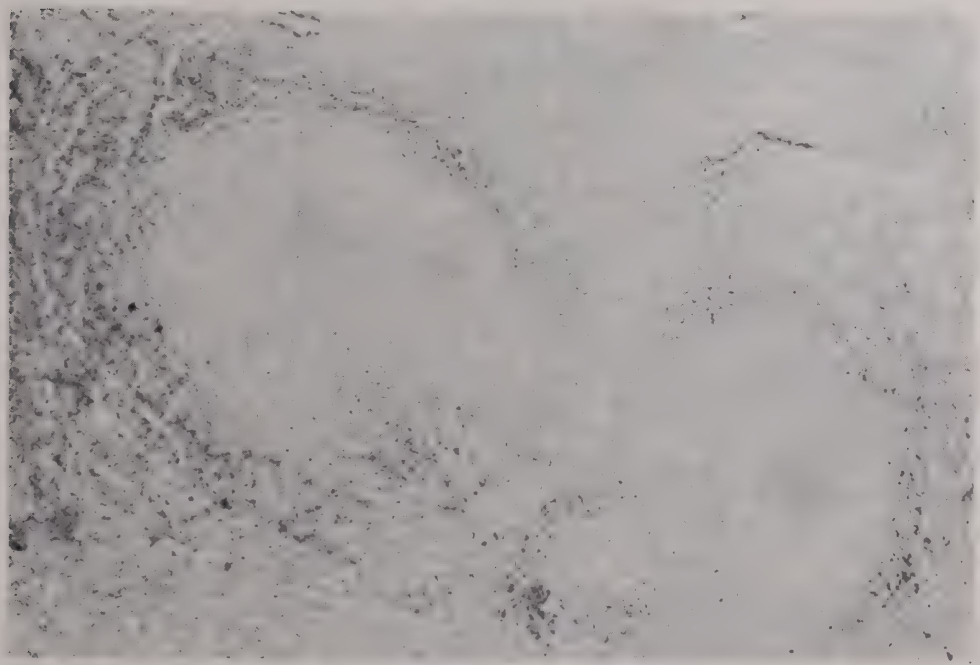

Fig. 1—Granulomas in right lower lobe of lung (100 X).

BREAK IN PAGINATION IS PUBLISHER'S ERROR

Past History

The patient was the product of a normal pregnancy. His birth weight was eight pounds, nine ounces. At nine months of age, bilateral incision and drainage of cervical lymph nodes was done (results of cultures not available). He had suffered from a severe but poorly described skin rash the previous summer and had had otitis media at ages two and 11 months.

Family History

Family history revealed that a male sibling had died at age three months of pneumonia, and an eight-year-old male sibling was alive and well.

Examination

On admission, physical examination revealed a 62 cm, 12.2 kg, irritable male whose temperature was 98.2° F, pulse 140, and respirations 40/min. Healed bilateral cervical scars and a right thoracotomy scar were present. There was mild respiratory distress and he was retracting bilaterally at the bases. The heart was of normal size without murmurs. The abdomen was soft without organomegaly. There was no lymphadenopathy. The tonsils were present and normal.

Laboratory Studies

The urinalysis was normal. The hematocrit was 32% with 10 gm% hemoglobin. Total white blood cell count was 15,900 with 57% neutrophils and 43% lymphocytes. Erythrocyte sedimentation rate (Westergren) was 52 uncorrected and 25 corrected. Serum sodium was 143 mEq/L, potassium 5.1 mEq/L, chlorides 103 mEq/L and bicarbonate 17 mEq/L. Sweat sodium was 7 mEq/L and the chlorides were 2 mEq/L.

Serum protein electrophoresis revealed a total protein of 7.1 gm% with albumin 3.1 gm%, alpha—1 globulin 0.3 gm%, alpha—2 globulin 1.0 gm%, beta—globulin 1.0 gm% and gamma—globulin 1.7 gm%. Immunoglobulin levels were: IgG—1240 mg% (nl range—600 to 1000 mg%), IgA—788 mg% (nl range—112 ± 41) and IgM—109 mg% (mean—116). Titers against typhoid O and H were less than 1:80 on admission and rose to 1:80 and 1:160, respectively, after a typhoid booster. Delayed hypersensitivity response was normal as measured by DNFB skin testing. Skin tests for fungi and tuberculosis (intermediate PPD) were negative. A Kveim test was negative. The blood group was AB.

A liver biopsy disclosed no abnormalities. Examination of the bone marrow showed a granulocytic hyperplasia with a mild increase in plasma cells and eosinophils. Cultures of the marrow were negative.

Progress

The patient remained relatively asymptomatic until one month after admission, when he began to spike fevers to 104° F, and decreased breath sounds were heard over the right lung base. Chest films showed the persistent right middle lobe infiltrate with a pleural effusion. Penicillin therapy was begun. Attempts at thoracentesis were unsuccessful.

One week later, a right middle lobe lobectomy was done. Chronic necrotizing granulomatous inflammation similar to that found in the right lower lobe was seen. No organisms were found in the tissue, but Aerobacter-Klebsiella was cultured.

Two days after surgery, the patient's temperature returned to normal, and a three-pound weight gain was noted over the next week. Dehiscence of the thoracotomy incision occurred on the seventh postoperative day. Kanamycin was given for 14 days postoperatively. The incision did not heal, but his condition remained otherwise stable and he was discharged on the 61st hospital day on no medications.

Admission Seven Months Later

The patient remained relatively well following discharge except for periodic unexplained fevers which were treated with Ampicillin. Two weeks prior to admission, fever was noted and his appetite decreased.

Physical examination revealed a chronically ill, irritable child with nuchal rigidity and an open thoracotomy wound. The temperature was 101.6° F, the pulse 100, and respirations 36. The weight was 13.7 kg. The cerebrospinal fluid was clear and no cells were found. Pressure was not measured. The glucose was 56 mg% and the protein 90.8 mg%. A blood glucose was not done. Cultures, gram stain and India ink preparations were negative.

The fever subsided but the nuchal rigidity persisted. Three weeks later the temperature was 101° F and hyperactive deep tendon reflexes and a positive Babinski on the left were noted. No papilledema was found. The white blood cell count was 24,000 with 67% neutrophils, 1% bands, 25% lymphocytes and 7% eosinophils. The hematocrit was 37% with a hemoglobin of 11.1 gm%. Cultures of the throat, urine, bone marrow, and spinal fluid for bacteria, acid-fast bacilli and fungi were negative. Skin tests for tuberculosis and fungi remained negative. A chest film showed a right pleural effusion with a shift of the mediastinum to the left and a right upper lobe pneumonia. An electroencephalogram was interpreted as "abnormal—generally slow." A brain scan was normal. A ventriculogram showed minimally dilated lateral ventricles. The opening pressure of the ventricular fluid was 600 mm of water. A cell count was 1100/mm^3 with 69% polymorphonuclear and 31% lymphocytes. The protein was 34 mg% and the glucose was 58 mg%.

Treatment with isoniazid, para-amino salicylic acid and streptomycin was begun on an empirical basis. His condition remained essentially unchanged until two weeks later when a 4-cm fluctuant mass was noted in his right upper mid-back. Physical examination showed blurring of the optic discs bilaterally but was otherwise unchanged. Total white blood cell count was 16,600 with a normal differential. Blood urea nitrogen was 6 mg% and repeated urinalyses were normal. Cultures of the spinal fluid, throat, urine and stool were negative. Complement fixation tests for Histoplasmosis were 1:64 and for Coccidioidomycosis were 1:32.

An incision and drainage of the back mass was done and cultures revealed *Aspergillus fumigatus*. Amphotericin B was administered intravenously at a dose of 10 mg/kg over a period of three weeks. Spiking fevers and several episodes of seizure activity characterized by opisthotonus developed. His condition slowly deteriorated and he expired two months after admission.

Discussion

Dr. Edgar O. Ledbetter:*

In summary, this boy had otitis media, severe dermatitis and cervical adenitis during his first year, was plagued by chronic, recurrent lobar pneumonia throughout his second and third years, and despite the administration of a wide variety of antimicrobial agents he expired at age 40 months with lobar pneumonia and severe encephalomyelitic signs. A male sibling had died of pneumonia in early infancy.

Deficiency Syndromes

The various antibody deficiency syndromes were excluded by the demonstration of typhoid antibody production, the presence of abundant plasma cells in the bone marrow, his capacity to develop delayed hypersensitivity, and elevated serum immunoglobulin levels.

The Wiskott-Aldrich syndrome was suggested by the family history, dermatitis, recurrent infection, and elevated serum IgA levels; but thrombocytopenia and hemorrhagic diatheses were not mentioned. Isohemagglutinins have been low or absent in patients with this syndrome but would not have been helpful since his blood type was AB.

Hypergammaglobulinemia is frequently found in children with chronic infection and may be present in patients with histiocytosis-X or sarcoidosis, both of which were excluded by the pathology of the resected lung tissue. Sarcoid granulomas show little or no necrosis and tend to remain discrete rather than becoming confluent. Hilar lymph node enlargement is usually striking. In contrast with the lobar involvement present in this patient, diffuse cystic or nodular pulmonary infiltrates are characteristic of histiocytosis-X; necrosis and granuloma formation are uncommon.

The differential diagnosis is limited in this patient by the findings of granulomatous lobar pneumonia and the chest wall mass from which *Aspergillus fumigatus* was cultured.

Fungus Infections

Soft tissue abscesses may occur with any of the fungal infections, being more common in actinomycosis and coccidioidomycosis. Actinomycosis requires anaerobic incubation for growth. Other organisms such as anaerobic streptococci and various aerobic and anaerobic gram-negative bacilli are frequently found in the suppurative drainage of actinomycotic abscesses. Spherules can often be demonstrated in wet preparations of material aspirated from soft tissue abscesses caused by coccidioidomycosis.

---

*Department of Pediatrics, Wilford Hall USAF Hospital.

"Cold" staphylococcal abscesses involving the skin, subcutaneous tissue, lungs or mastoids have been reported in children without demonstrable predisposing systemic disease (Job's syndrome), but there was no culture evidence for staphylococcal infection in this patient's chest mass.

Central nervous system invasion is a frequent complication of pulmonary nocardiosis, cryptococcosis and mucormycosis occurring less often with actinomycosis and aspergillosis. These organisms may be extremely difficult to demonstrate in the spinal fluid; and negative cultures, smears, and India-ink preparations do not rule out fungus infection.

A. fumigatus is a frequent laboratory contaminant with worldwide distribution. Most infections by this and other opportunistic pathogens are seen in patients with leukemia, lymphoma, diabetes mellitus, and hypogammaglobulinemia or in patients receiving corticosteroids, antimetabolites, immunosuppressives, and/or antimicrobials. Pulmonary mycetomas secondary to *A. fumigatus* are usually found in association with destructive lung disease of some other etiology, such as cavitary tuberculosis. The soft tissue mass from which *A. fumigatus* was grown was evidence of dissemination, most likely from the lungs, and Aspergillus meningoencephalitis could explain this boy's central nervous system abnormalities. Although we cannot be sure that his cerebrospinal fluid glucose levels were normal, since simultaneous blood glucose determinations were not available, normal cerebrospinal fluid glucose levels have been present in other cases of Aspergillus meningitis.

Familial Granulomatous Disease of Childhood

The failure to demonstrate organisms in the sections of the lobectomy specimens leaves the etiology of the earlier pulmonary granulomas in question. Except for the absence of hepatosplenomegaly, this child's chronic granulomatous process and clinical course resembled fatal (chronic) granulomatous disease of childhood first reported by Berendes et al. This familial entity is characterized early by recurrent suppurative lymphadenitis and chronic dermatitis, followed by chronic progressive pulmonary disease and hepatosplenomegaly. Caseous granulomas are usually found in the lymph nodes, liver, spleen and lungs. Pigmented lipid histiocytes have been demonstrated in the lymph nodes, liver, spleen, thymus, and intestinal tract, but have not been found in involved lung tissue (Figure 2). Although these periodic acid-Schiff-positive lipid histiocytes are not pathognomonic for this disease, they have been prominent in most reported cases.

The cause for chronic granulomatous disease of childhood has not been determined. No immunologic deficiencies have been recognized among the reported cases. Gamma globulin levels are consistently elevated. The serum levels of IgG, IgM, and IgA have been variable, but one or more of these three components has been disproportionately increased in several patients. Defective bactericidal function and metabolic abnormalities of polymorphonuclear leukocytes from these patients have been demonstrated. Although their polymorphonuclear leukocytes appear morphologically normal, are present in adequate numbers, and are able to migrate and phagocytose bacteria, their intracellular bactericidal activity against certain organisms, including *Staphylococcus aureus* and *Serratia marcescens,* is reduced. These leukocytes, however, have been shown to retain their bactericidal capacity for various streptococci. This disease can now be differentiated from other granulomatous diseases in children by the nitro-blue tetrazolium reduction test, an in-vitro leukocyte function test which allows recognition of abnormal leukocytes in the patients with the disease as well as in the female carriers.

Patients with chronic granulomatous disease of childhood are commonly infected by organisms of an avirulent and relatively non-invasive type such as were cultured from the patient presented, i.e., Staphylococci, Pseudomonas, Aerobacter-Klebsiella, Candida, and Aspergillus. For reasons unknown, children with chronic granulomatous disease of childhood develop granulomas in response to infection by these organisms, just as a normal person's tissue responds to the organisms which cause tuberculosis and brucellosis. Pneumococcal, streptococcal and Hemophilus infections have been rare.

Histoplasmosis and coccidioidomycosis have not been reported in patients with chronic granulomatous disease of childhood. The rise in this patient's histoplasmin and coccidioidin complement fixation titers may have been the result of repeated skin testing with these antigens.

Infections tend to be chronic and recurrent in children with this hereditary defect of leukocyte function, and prolonged specific antimicrobial therapy is required for their control. Despite vigorous treatment of their infections, most children have a fatal outcome in early childhood.

Clinical Diagnosis

1. Fatal (chronic) granulomatous disease of childhood.
2. Pulmonary aspergillosis with subcutaneous and central nervous system dissemination.

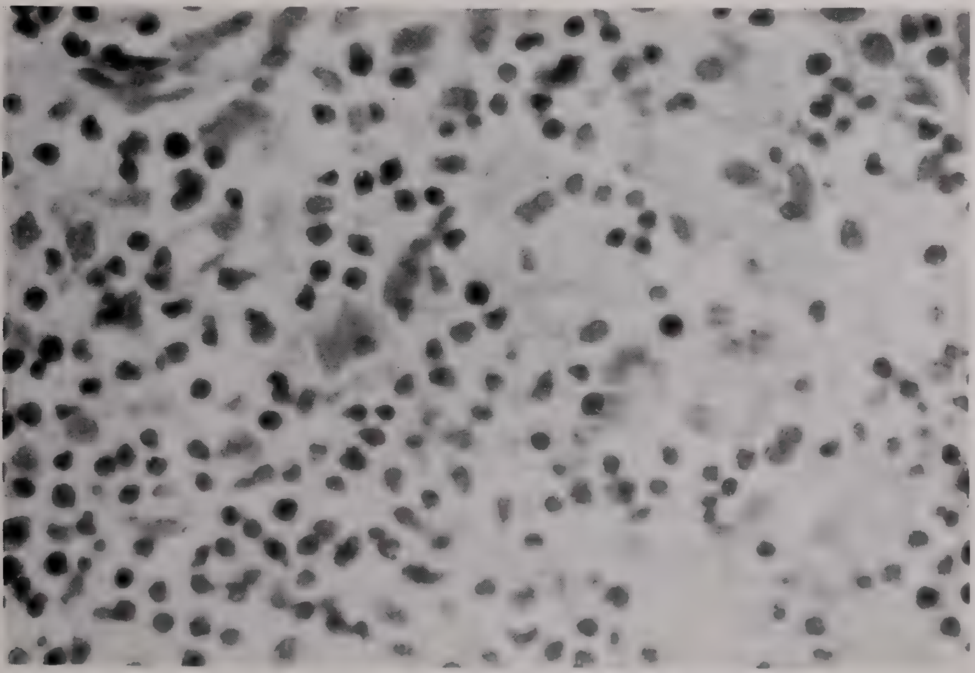

Fig. 2—Pigmented lipid histiocytes in lymph node (Periodic acid-Schiff Stain. X 430).

Comments

Dr. Howard H. Johnson:*

Have the female cases reported been familial?

Dr. Ledbetter:

Most cases reported have been in boys. Leukocyte function studies of affected families provide evidence that the disease is usually transmitted as an X-linked recessive trait. The mode of inheritance for the female cases has not been definitively established. Family members of the female cases have not been found to be affected.

Dr. Howard F. Koch:†

What organ systems other than the lungs are commonly involved with infection in children with this disease?

Dr. Ledbetter:

Osteomyelitis, pericarditis, hepatic abscesses and perirectal abscesses have been present in several reported cases.

Dr. George S. Fidone:‡

How effective is amphotericin B in the treatment of aspergillosis?

Dr. Ledbetter:

Treatment of Aspergillus infections with amphotericin B and other agents available has been unsuccessful. Surgical resection, when feasible, has been the only effective mode of treatment.

Pathological Discussion

Dr. Richard W. Ransom:#

At autopsy, the patient was extremely cachectic, weighing only 12.7 kg. The thoracotomy wound and the ulcerated mass on the back showed no evidence of healing, but no gross pus was present.

The right pleural cavity was obliterated by dense fibrous adhesions. No fluid was found. The right upper lobe showed broad bands of fibrous tissue and a few scattered yellow-brown granular areas in the parenchyma, and the pleura was covered with a gray-green shaggy membrane. A single necrotizing granuloma was found microscopically. No pigmented lipid histiocytes were seen. Sections from the right lung near the thoracotomy incision showed branching, septate hyphae consistent with Aspergillus sp. (Figure 4). The left lung was normal at autopsy.

The spleen weighed 100 grams (normal range for age: 37-39 grams). The cut surface was marked by a diffuse fine, golden-brown granularity. Microscopically, multiple necrotizing granulomas were seen. Large numbers of pigmented lipid histiocytes were present at the periphery of the granulomas. No organisms were found.

There was a diffuse lymph node hyperplasia and the majority of the nodes contained focal areas of yellow-green granularity. A single mesenteric node contained a cluster of 1-3 micra rounded organisms in macrophages demonstrated with the Gomori methenamine silver stain (Figure 3). Pigmented lipid histiocytes were abundant in the nodes (Figure 2).

---

*Chairman, Department of Pediatrics, Wilford Hall USAF Hospital.

†Pediatric Hematologist, Wilford Hall USAF Hospital.

‡Chief, Pediatric Clinic, Wilford Hall USAF Hospital.

#Senior Resident, Department of Pathology, Wilford Hall USAF Hospital.

The granulomas in all organs showed an outer rim of plasma cells, histiocytes and fibroblasts with a central area of polymorphonuclear leukocytes and nuclear debris.

The thymus weighed one gram and was involuted. The adrenals were somewhat atrophied also.

The brain weighed 1300 grams (normal range for age: 1141 - 1191 grams). The cerebral hemispheres showed marked flattening and widening of the gyri. The meninges over the hemispheres were clear but the basilar

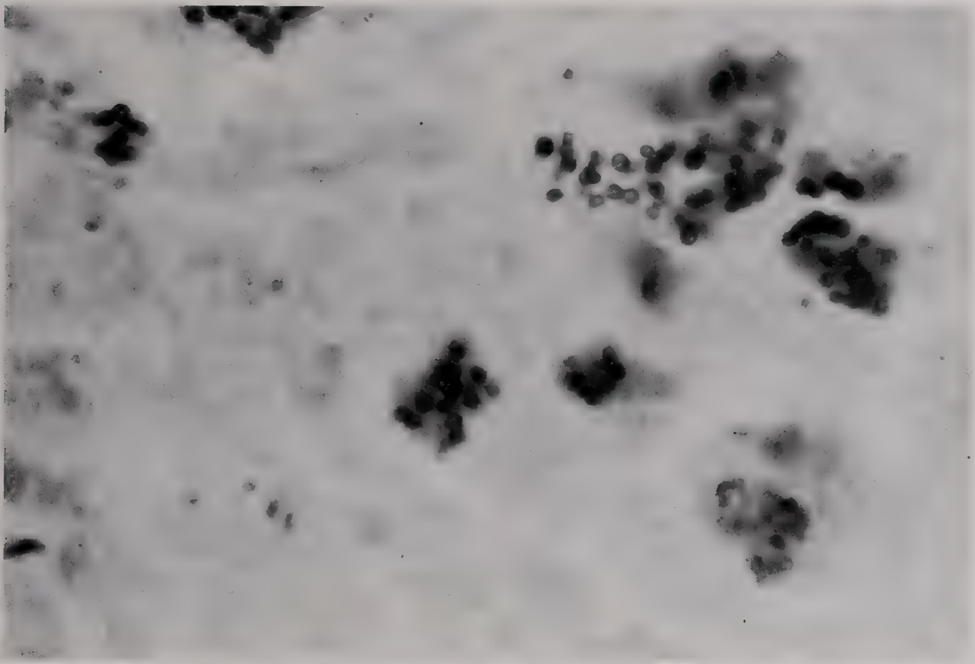

Fig. 3—Unidentified organisms in mesenteric lymph node (Gomori methenamine silver stain. X 970).

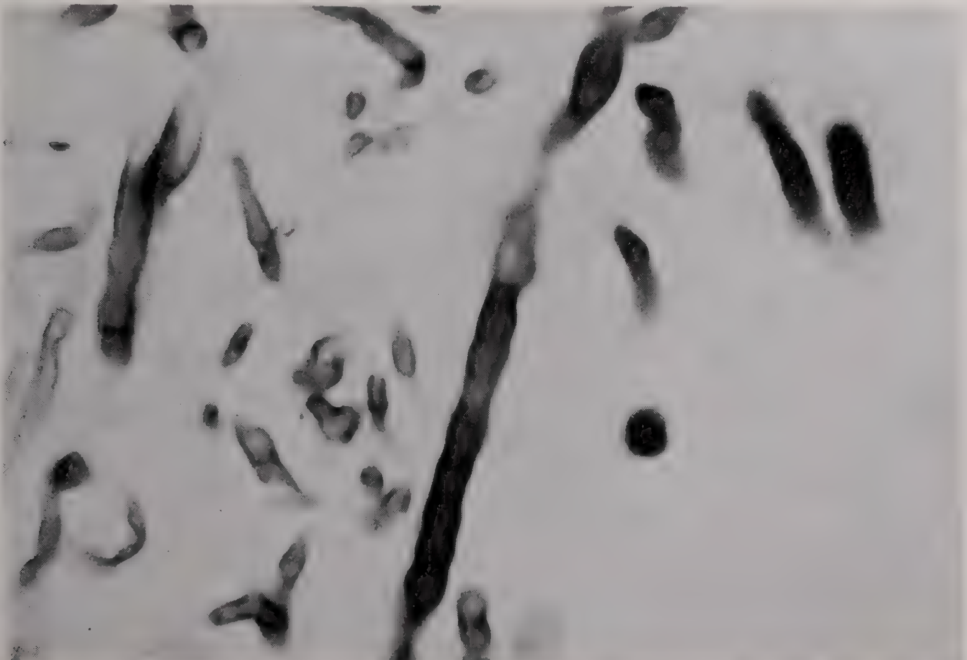

Fig. 4—Branching septate hyphae (*Aspergillus fumigatus*) in meninges of cervical spinal cord. (X 970).

meninges were thickened and opacified. A subarachnoid collection of yellow purulent material was found at the base of the cerebellum. On sectioning the brain, marked dilatation of the ventricular system was apparent. Focal accumulations of yellow exudate were found throughout the ventricular system. The cervical spinal cord also showed marked thickening of the meninges and accumulations of purulent material. Sections from the fourth ventricle and spinal cord stained with the Gomori methenamine silver stain showed organisms similar to those in the pleura (consistent with *Aspergillus* sp.). No bacteria were demonstrated in the tissue, although *Staphylococcus aureus* and *Escherichia coli* were cultured from the cerebellum and spinal fluid at autopsy.

The remainder of the organs were essentially normal. The liver was within normal weight range (502 grams) and showed no granulomas, although there was a diffuse, predominantly portal, infiltrate of pigmented lipid histiocytes.

Dr. Ledbetter:

The absence of hepatosplenomegaly in this case is unusual and may be explained by the relatively short duration of his illness. It is assumed that his liver would have been enlarged had he lived longer.

Final Anatomic Diagnoses

Morphologic findings consistent with Fatal (Chronic) Granulomatous Disease of Childhood.

Secondary systemic infection with *Aspergillus* fumigatus with meningitis, obstructive hydrocephalus and cerebral edema.

Unidentified organisms in mesenteric lymph node—? *Histoplasma capsulatum* — ? *Pneumocystis carinii* — ? conidia of *Aspergillus*.

DECLOMYCIN®
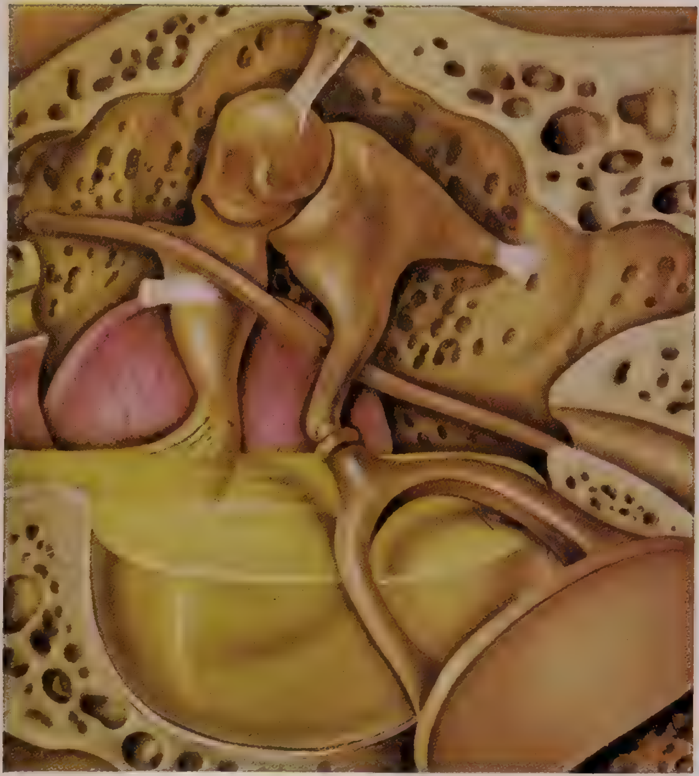
DEMETHYLCHLORTETRACYCLINE



You've made it one of your specific in acute otitis media

DECLOMYCIN acts against many strains of H. influenzae, pneumococci and streptococci, the most common invaders. In otitis media, where it is difficult to isolate the causative organism, this coverage may be important. However, some strain may be resistant and other pathogens can be involved.

You've found the high serum levels of DECLOMYCIN important, too. Its prolonged actio permits convenient 300 mg b.i.d. or 150 mg q.i.d. administration.

When specimens are obtainable, your culture studies will indicate the usefulness of DECLOMYCIN.

Effectiveness: DECLOMYCIN Demethylchlortetracycline should be equally or more effective therapeutically than other tetracyclines in infections caused by organisms sensitive to the tetracyclines.

Contraindication: History of hypersensitivity to demethylchlortetracycline.

Warning: In renal impairment, usual doses may lead to excessive accumulation and liver toxicity. Under such conditions, lower than usual doses are indicated, and, if therapy is prolonged, serum level determinations may be advisable. A photodynamic reaction to natural or artificial sunlight has been observed. Small amounts of drug and short exposure may produce an exaggerated sunburn reaction which may range from erythema to severe skin manifestations. In a smaller proportion, photoallergic reactions have been reported. Patients should avoid direct exposure to sunlight and discontinue drug at the first evidence of skin discomfort. Necessary subsequent courses of treatment with tetracyclines should be carefully observed.

Precautions: Overgrowth of nonsusceptible organisms may occur. Constant observation is essential. If new infections appear, appropriate measures should be taken. In infants, increased intracranial pressure with bulging fontanels has been observed. All signs and symptoms have disappeared rapidly upon cessation of treatment.

Side Effects: Gastrointestinal system—anorexia, nausea, vomiting, diarrhea, stomatitis, glossitis, enterocoliti pruritus ani. Skin—maculopapular and erythematous rashes; a rar case of exfoliative dermatitis has been reported. Photosensitivit onycholysis and discoloration of the nails (rare). Kidney—rise in BU apparently dose-related. Transient increase in urinary output, some times accompanied by thirst (rare). Hypersensitivity reactions—urt caria, angioneurotic edema, anaphylaxis. Teeth—dental staining (ye low-brown) in children of mothers given this drug during the latter ha of pregnancy, and in children given the drug during the neonatal per od, infancy and early childhood. Enamel hypoplasia has been seen i a few children. If adverse reaction or idiosyncrasy occurs, discontinu medication and institute appropriate therapy. Demethylchlortetra cycline may form a stable calcium complex in any bone-forming tissu with no serious harmful effects reported thus far in humans.

Average Adult Daily Dosage: 150 mg q.i.d. or 300 mg b.i.d. Shoul be given 1 hour before or 2 hours after meals, since absorption i impaired by the concomitant administration of high calcium conte drugs, foods and some dairy products. Treatment of streptococc infections should continue for 10 days, even though symptoms hav subsided.

DECLOMYCIN®
DEMETHYLCHLORTETRACYCLINE

Capsules: 150 mg; **Tablets:** film coated, 30 mg, 150 mg and 75 mg of demethylchlortetra cycline HCl.

now she can cope...

thanks to

Butisol SODIUM®
(SODIUM BUTABARBITAL)

the "daytime sedative" for everyday situational stress

When stress is situational—environmental pressure, worry over illness—the treatment often calls for an anxiety-allaying agent which has a prompt and predictable calming action and is remarkably well tolerated. Butisol Sodium (sodium butabarbital) meets this therapeutic need.

After 30 years of clinical use . . . still a first choice among many physicians for dependability, safety and economy in mild to moderate anxiety.

Contraindications: Porphyria or sensitivity to barbiturates.

Precautions: Exercise caution in moderate to severe hepatic disease. Elderly or debilitated patients may react with marked excitement or depression.

Adverse Reactions: Drowsiness at daytime sedative dose levels, skin rashes, "hangover" and systemic disturbances are seldom seen.

Warning: May be habit forming.

Usual Adult Dosage: As a daytime sedative, 15 mg. (¼ gr.) to 30 mg. (½ gr.) t.i.d. or q.i.d.

Available for daytime sedation: Tablets, 15 mg. (¼ gr.), 30 mg. (½ gr.); Elixir, 30 mg. per 5 cc. (alcohol 7%).

BUTICAPS® [Capsules Butisol Sodium (sodium butabarbital)] 15 mg. (¼ gr.), 30 mg. (½ gr.).

McNEIL

McNeil Laboratories, Inc., Fort Washington, Pa.

If you think the pink pill for U.R.I. symptoms is built for speed and endurance you're on the right track.

Here is a tablet that begins to relieve symptoms of upper respiratory infection quickly—a tablet that works for hours to make it easy for your patient to enjoy continuous relief.

Novahistine Singlet combines effective dosage of an antipyretic-analgesic with a vasoconstrictor-antihistamine formulation to relieve not only the congestion, but also the fever and the aches and pains that almost always accompany upper respiratory infections.

A total daily dosage of 3 or 4 tablets will normally provide the continuous relief your patient expects. Use with caution in patients with severe hypertension, diabetes mellitus, hyperthyroidism or urinary retention. Caution ambulatory patients that drowsiness may result.

Grand Rounds

Left Atrial Myxoma

Historical Perspective

Dr. Eliot Schechter:*

Medical writing regarding cardiac tumors dates historically from a comment of Senac[1] in 1783 that "the heart is too noble an organ to be attacked by a primary tumor." The pathologist first showed him wrong. Only recently (1952) the first preoperative or ante-mortem diagnosis of a myxoma in the heart was made. The first successful surgical removal of a myxoma was not until 1955, although some attempts had been made earlier. This lesion is seen in .05% (five out of 10,000) of autopsies. Clinically, it is diagnosed even less frequently. The importance of today's discussion is that a recognized myxoma is a curable lesion; yet, like many things in medicine, if you don't think about a diagnosis you'll never recognize it. It is important for those of us who see patients to be aware of myxoma so that, although rare, we can recognize and treat it appropriately.

The stimulus for today's discussion is a patient who was referred here several weeks ago.

Case History

Dr. James Kay:†

The case is that of a 34-year-old white male who was admitted to Wilford Hall USAF Hospital on 14 April 1968. His present illness dates from 1 April 1968. At that time he was riding horseback and experienced some nausea, which he thought was related to the horseback riding. Over the next few minutes, he developed some abdominal discomfort and then a feeling of weakness in his legs, which shortly progressed to a feeling of numbness and tingling. He felt that his legs were very cold. He was taken to the Emergency Room at Clark Air Base where physical examination revealed pale, pulseless lower extremities bilaterally. An aortogram done immediately revealed nonvisualization of the terminal aorta. He was taken to the operating room where the bifurcation of the aorta was exposed through a lower midline abdominal incision, and approximately 60 cc of blood clot, containing tissue, was removed. The left lower extremity pulses remained poor, and a left femoral incision was made with removal of approximately 10 cc of clot from the left femoral artery.

---

*Chief, Cardiology Service, Department of Medicine, Wilford Hall USAF Hospital, Lackland Air Force Base, Texas.

†Intern, Cardiology Service, Department of Medicine, Wilford Hall USAF Hospital, Lackland Air Force Base, Texas.

Past history revealed that for approximately three years prior to this illness he had noticed soreness and tightness in both legs, primarily in the calves. He stated that after playing volleyball or basketball he would get cramps in his legs, often lasting three to four weeks. Approximately one year before, he had had a similar episode; he was swimming and noted weakness and tingling in the right calf area. This quickly disappeared with rest and he thought no more of it.

Comments

Dr. Schechter:

There are a couple of points to emphasize in the history. Emboli are frequent; about 40% of patients with myxomas have them. Most arise from myxomas in the left atrium and are peripheral emboli, but right atrial myxomas can produce pulmonary emboli, and occasionally a left ventricular myxoma will produce a peripheral embolus.

The present patient had a peripheral embolus, which made the case relatively simple, because examination of the embolus gave the diagnosis. But his history is unusual: he had leg symptoms dating back 2½ years; and one year ago he had an attack similar to the present one. Also note that the attack itself was atypical. The typical presentation of a patient with a peripheral embolus is exemplified in a case reported by Brewin.[2] "A man, age 42, a heavy worker in the timber trade, collapsed at his work at 4 P.M. on December 14 and was taken to the Prince of Wales General Hospital. While lifting timber he had, without warning, a pain in his back and loss of the use of both legs." This is typical of a peripheral embolus, particularly one to the bifurcation of the aorta. It is an acute, sudden, catastrophic, vascular occlusion, not the story of our patient. His atypical picture may be a clue, however.

Looking over the literature, there are reports of myxomas similar to that of the present patient. Young and Hunter[3] reported a 10-year-old girl with a seven-day history beginning with aching in the legs, then vomiting and diarrhea, progressing to anuria and death. At autopsy, they found a myxomatous embolus, which occluded both renal arteries and almost completely occluded the descending aorta. They postulated that the gelatinous tumor originally lodged high in the aorta and partially occluded both the aorta and the mesenteric vessels. Then, because of the gelatinous nature of the tumor, it gradually slid down the aorta under the pressure of the blood and was forced out into the renal vessels while clearing the mesenteric circulation; the vomiting and diarrhea disappeared but anuria developed.

Gerbode[4] reported a patient who had an aortic embolus. No diagnosis of myxoma was made, however. The patient recovered for 20 months before he had another embolus, at which time the diagnosis was made and the myxoma removed successfully. A patient reported by Differding et al.[5] had an eight-month history beginning with hemiplegia, then lightheadedness, then syncope, and finally a saddle embolus. The total course ran a little over eight months with repeated emboli. Thus, the facts that the present patient had symptoms for several years and that his presentation was atypical for thrombotic embolus, are consistent with what has been reported in myxomas.

Physical Examination

Dr. Kay:

Physical abnormalities at the time of admission to Wilford Hall USAF

Hospital were limited to the cardiovascular system. The patient had no neck-vein distention. His carotid pulses were normal. He had decreased pulses in the left posterior tibial and dorsalis pedis arteries. The point of maximum impulse was in the fourth intercostal space at the midclavicular line. The first heart sound was palpable. There were no thrills or lifts noted. S_1 was very loud. S_2 split normally. He had an early diastolic low-pitched *sound,* and an atypical murmur beginning with the second heart sound and of short duration.

Comments

Dr. Schechter:

In Goodwin's review of myxomas,[6] mitral murmurs were very common, mitral insufficiency murmurs being reported in 22 out of 45 cases and mitral stenosis murmurs in 27 out of 45 cases. Early diastolic sounds were frequent, occurring in about 50% of patients. There is bias in this series, however. These figures are based on a survey of practicing cardiologists in England. They apply to myxomas that are diagnosed ante mortem, based on a positive history or physical findings.

Greenwood,[7] in his review based on autopsy cases, presented a somewhat different picture of the physical findings in patients with myxomas, concluding that the typical patient with myxoma shows atypical or difficult-to-hear murmurs. In the present patient the physicians at the hospital at Clark Air Base described a mitral diastolic rumble. When we examined him, he did have a loud S_1 and an early diastolic sound, which could indicate the diagnosis of mitral stenosis. None of us confirmed the presence of murmurs to suggest either mitral stenosis or mitral insufficiency. It is interesting that postoperatively the loud first sound and the diastolic sound both disappeared. The point of the murmur changing with position is frequently made. When you talk of changing murmurs, you must remember that the murmur of mitral stenosis increases with exercise and is sometimes heard better in positions other than supine, i.e., left lateral, left lateral recumbent, leaning forward, or on hands and knees. The fact that a diastolic rumble is heard better in one position than in another does not indicate that it is caused by a myxoma.

Laboratory Studies

Dr. Kay:

An initial CBC showed a white count of 10,800 with a normal differential. The patient had a hemoglobin of 11.8 gm and a hematocrit of 37%. His sedimentation rate uncorrected was 48. BUN, a creatinine, fasting blood sugar, SGOT, SGPT, lactic dehydrogenase, bilirubin, and protein electrophoreses were normal. He was not specifically studied for hemolysis. A lung scan was within normal limits. He was afebrile for the first two days after admission. On the third day, he ran a fever of 102.6° F. Appropriate cultures were taken, but the reason for the fever was never determined. He was afebrile after that and on the eighth day was catheterized.

Comments

Dr. Schechter:

The manifestations of left atrial myxomas can be divided into four broad groups: hemodynamic, hematologic, biochemical, and nonspecific or constitutional. There are two major hemodynamic abnormalities. The first is obstruction of blood flow, most commonly at the mitral orifice. Syncope may be the presenting symptom produced by a tumor obstructing flow and temporarily interrupting cardiac output. Pulmonary congestion may occur as a result of interference with outflow from the left atrium. The second abnormality is embolization as discussed above: single or multiple. Emboli may consist of the entire tumor or small fragments of it.

Hematologic abnormalities are frequent, occurring in approximately 45% of patients.[8] There has been evidence, based mostly on blood smears, that this is due to hemolysis. In one case[9] red cell survival was shown to be shortened. This shortened survival was corrected following removal of the myxoma. It seems reasonable that the hemolysis in patients with myxomas is the same as in patients with intracardiac prosthesis, that is, due to mechanical trauma. Polycythemia has been reported in one patient with a right atrial myxoma,[10] in whom there was polycythemia for several years before the tumor was recognized and removed. The preoperative arterial saturation was 93%. Postoperatively, this improved to 99%, with regression of the polycythemia. It was postulated that this was secondary to multiple small pulmonary emboli with arterial unsaturation.

Biochemical abnormalities have been found in many of these cases. Hyperglobulinemia is the most frequent, occurring in about one third of patients with myxomas. On electrophoresis, the globulins are generally normal, being increased in quantity rather than altered in quality. There has been interest in determining whether these globulins were antibodies, but thus far there has been no conclusive evidence. It has been suggested that there are abnormal mucopolysaccharides released from the myxoma that stimulate antibody formation.

Constitutional findings are frequent in left atrial myxomas; 90% show some type of constitutional manifestation. Fever is the most common, occurring in over 50% of the patients; cachexia is less common, occurring in about 30% of patients, and anorexia or malaise also occurs in about 30%.

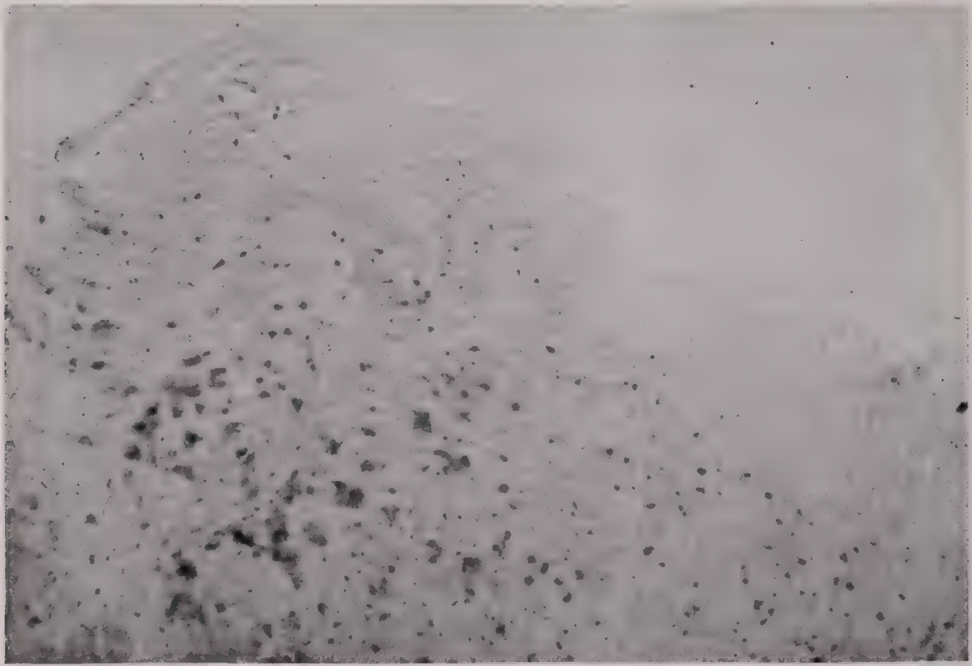

Fig. 1—Photomicrograph of saddle embolus showing a non-stratified structure irregularly flecked with calcium deposits and a loose myxoid background. H. E. original magnification times 25.

Pathologic Findings

Dr. William M. Wahle:*

The first photomicrograph (Figure 1) of the material removed at Clark Air Base represents the saddle embolus; I think you can appreciate that this is not an ordinary blood clot. The outside of the material shows an endothelial lining; furthermore, it is not stratified like a normal clot. It has definite structure composed of a rather nondescript eosinophilic background. Scattered throughout this material are small flecks of calcium which represent areas of dystrophic calcification, and there are numerous small nuclei scattered through the background material. The surgeon astutely recognized that this was not a usual clot and the pathologist at Clark Air Base suggested that this might be coming from a cardiac myxoma because of its characteristic features. The next photograph (Figure 2) represents a magnified view showing an occasional flattened nucleus that lines the outside of this clot. The amorphous ground substance which makes up the bulk of this tumor is noted.

Comments

Dr. Schechter:

This points out one very important lesson: Any time a peripheral embolus is removed, it ought to be examined completely, because very often this is the clue that cinches the diagnosis.

Having had the diagnosis made for us at the time the patient was referred here, one may ask: why catheterize him at all. I think there was a good reason for cardiac catheterization since, at least in some of the cases reported, including two which were autopsied, the embolus consisted of the entire tumor. In one patient who embolized and had the diagnosis made by examina-

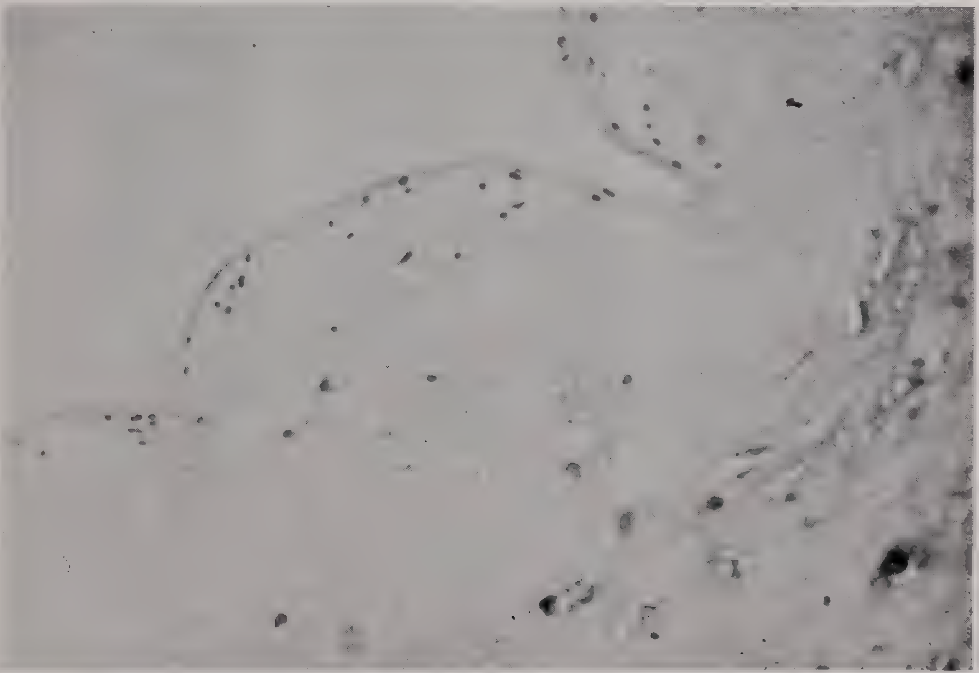

Fig. 2—Photomicrograph of saddle embolus showing an occasional endothelial cell compressed on the luminal side. An amorphous type of ground substance supports the irregularly shaped cells. H. E. original magnification times 100.

tion of the embolus,[11] no filling defects were noted within the heart on angiogram. The surgeons elected not to operate, and for a period of eight months to the time of the report she has done well. Before one submits a patient to open heart surgery, it is wise to make sure there is a lesion. Also it is helpful to know whether you are dealing with an atrial or ventricular tumor. Rare cases of systemic embolization from right atrial tumors and pulmonary embolization from left atrial tumors have been reported.[12] Catheterization is relatively benign compared to the eventual surgery. It is wise to give the surgeon as much information as possible beforehand rather than trust that when he has the chest open on the operating table he will be able to sort out what may be a very confusing picture.

Cardiac Catheterization Data

Dr. Morton Korn:*

The present patient had right-heart and retrograde left-heart catheterization. The arterial catheter was inserted retrograde into the left atrium. Angiography was performed in the left atrium. Figure 3 shows the right anterior oblique view during systole. The globular filling defect in the atrium is unmistakable evidence of a space-occupying lesion—in this case, the myxoma. Figure 4 shows diastole. The filing defects have moved across the plane of the mitral valve. Figures 5 and 6 show systole and diastole in the left anterior oblique projection. Again, the filling defects can be shown.

---

*Formerly Officer-In-Charge, Cardiac Catheterization Laboratory, Wilford Hall USAF Hospital. Current Address: Cardiopulmonary Laboratory, Mt. Sinai Hospital, Miami Beach, Florida.

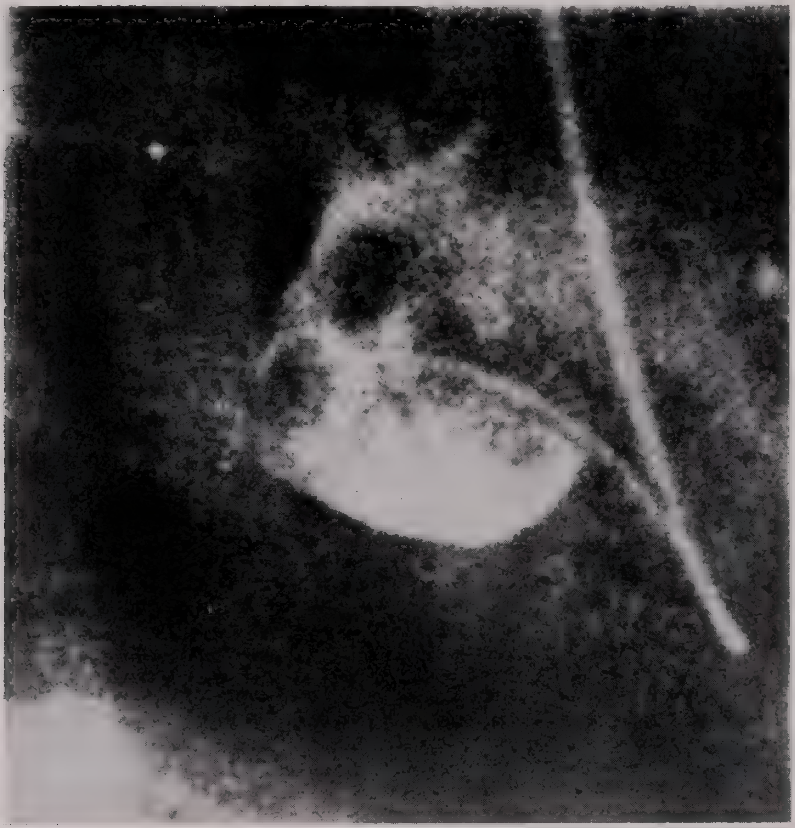

Fig. 3—Left atrial injection. Right anterior oblique view during systole.

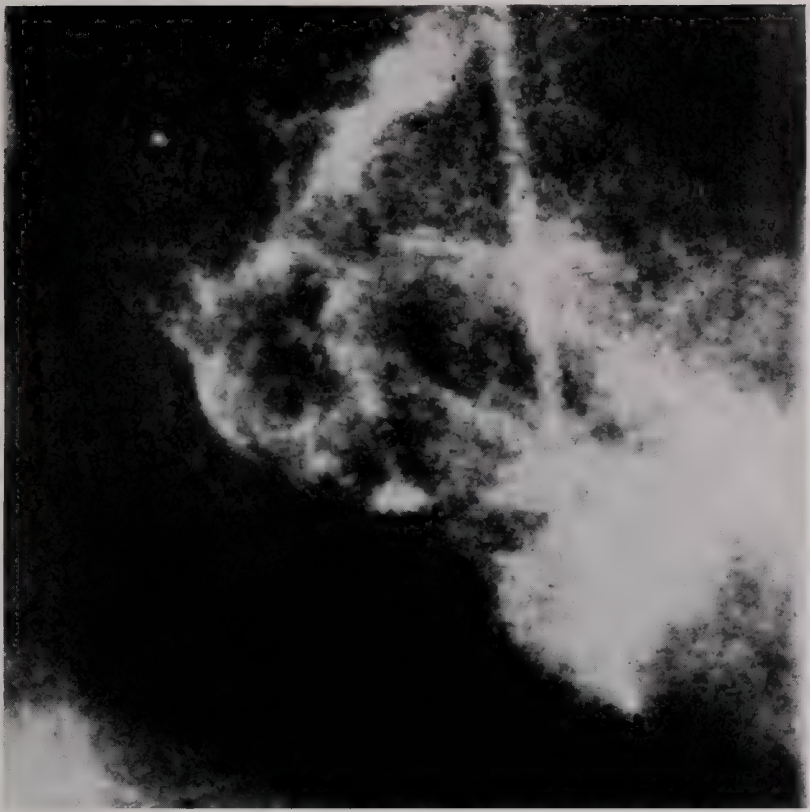

Fig. 4—Left atrial injection. Right anterior oblique view during diastole.

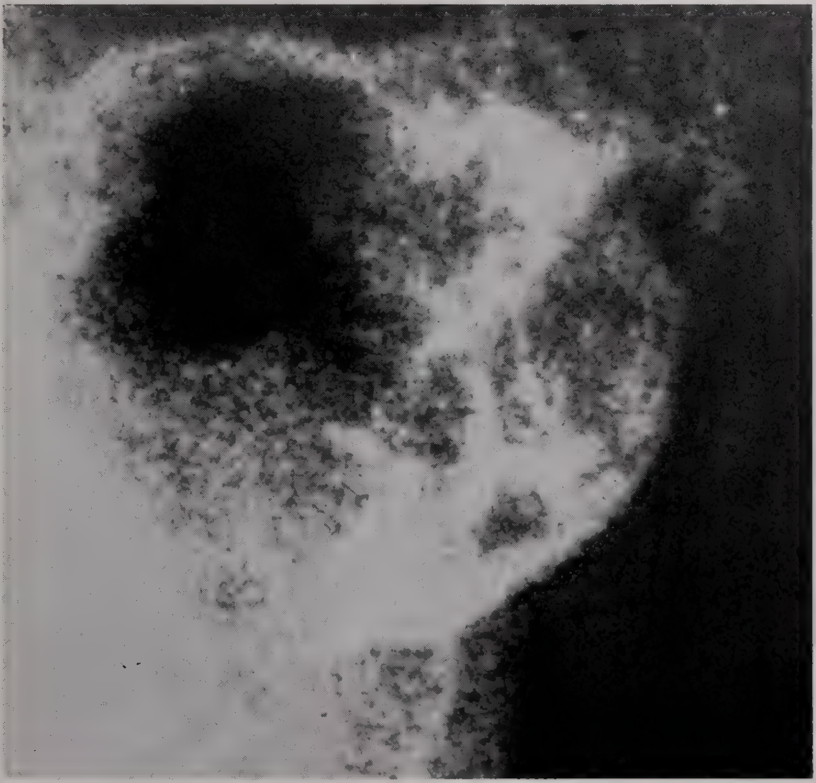

Fig. 5—Left atrial injection. Left anterior oblique view during systole.

The cardiac outputs and intracardiac pressures were normal.

It is possible to get both false-positive and false-negative results in patients with myxomas. The most common problem is a false-positive in which non-opacified dye draining from the pulmonary veins into the left atrium is interpreted as a filling defect. For this reason, it is wise to take several different projections and see whether these filling defects are constant, or seem related to blood draining from the pulmonary veins.

Surgical Findings

Dr. Byron N. Dooley:*

The present patient at surgery was found to have a very large gelatinous mass filling almost the entire left atrium. On palpation of the atrium externally, you could feel a very definite thump against a palpating finger;

---

*Chief, Thoracic Surgery Service, Department of Surgery, Wilford Hall USAF Hospital, Lackland Air Force Base, Texas.

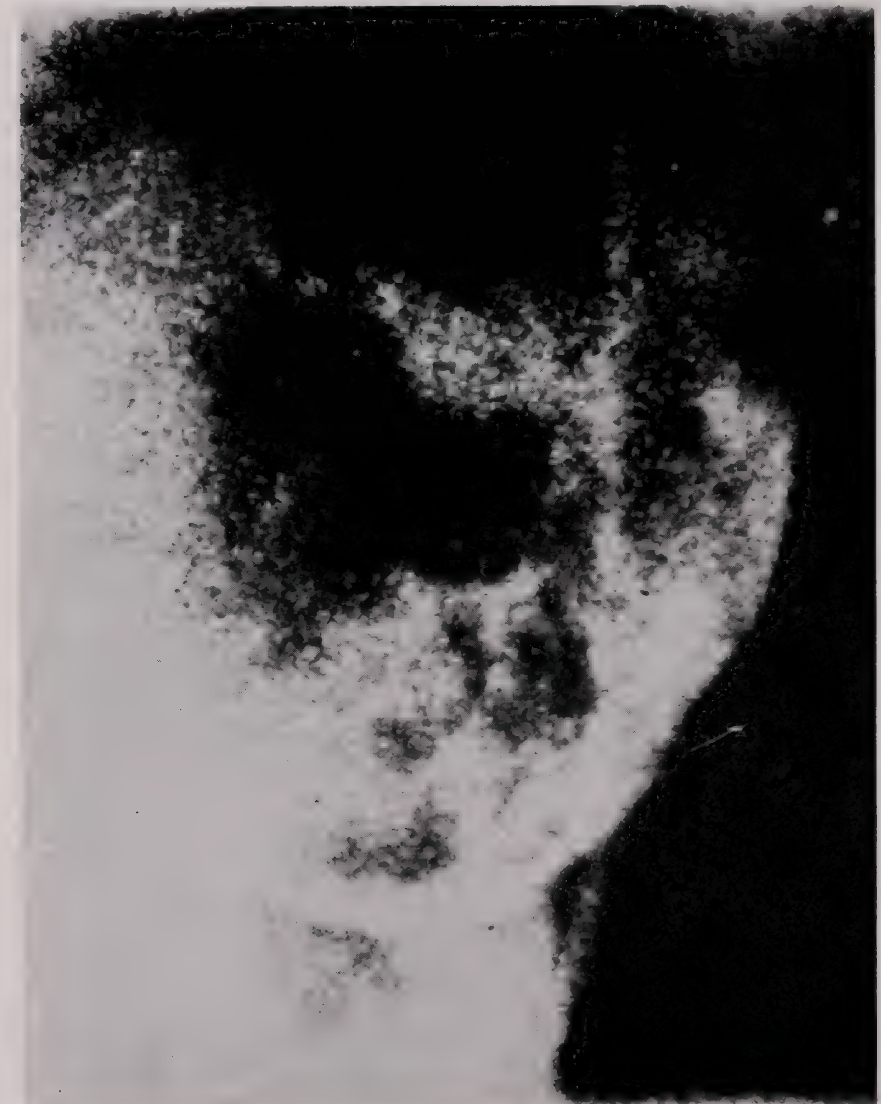

Fig. 6—Left atrial injection. Left anterior oblique view during diastole.

to the surgeons through the years the thump has been one of the warnings that perhaps there was a myxoma present in the left atrium. Prior to the days of open heart surgery, a great many surgeons were caught doing closed mitral valvulotomies, only to their chagrin to find that the left atrium was filled with either clot or tumor. We think that the horse-and-buggy days of open heart surgery and cardiology are all behind us now, and I feel very strongly that diagnostic workup, including cardiac catheterization, is definitely necessary in patients undergoing heart surgery today. It is very difficult when operating on the heart to explore it as you can the abdomen or the chest and know what you are doing both anatomically and physiologically. We feel that we always want to know where things are and what we are dealing with prior to surgery. This tumor was very easily removed under extracorporeal circulation.

The results in general with tumors of the heart have been very good and we feel that a very aggressive approach should be taken to them. We have operated upon six patients with cardiac tumors since 1962. Five of them are alive today and doing quite well. Three of these have been myxomatous tumors. Two of these patients presented with peripheral emboli, as did the present patient. One came in with mitral obstructive symptoms. None of the patients with myxomas has died. The success has been mainly due to extracorporeal circulation. The heart-lung machine that we are currently using at Wilford Hall is the Travenol Disposable Bubble Oxygenator, which is available in the operating room at all times for any thoracic operation. It is quickly set up and is all-disposable. The unit is primed in adults with Ringer's lactate and with no homologous blood. The surgical approach to

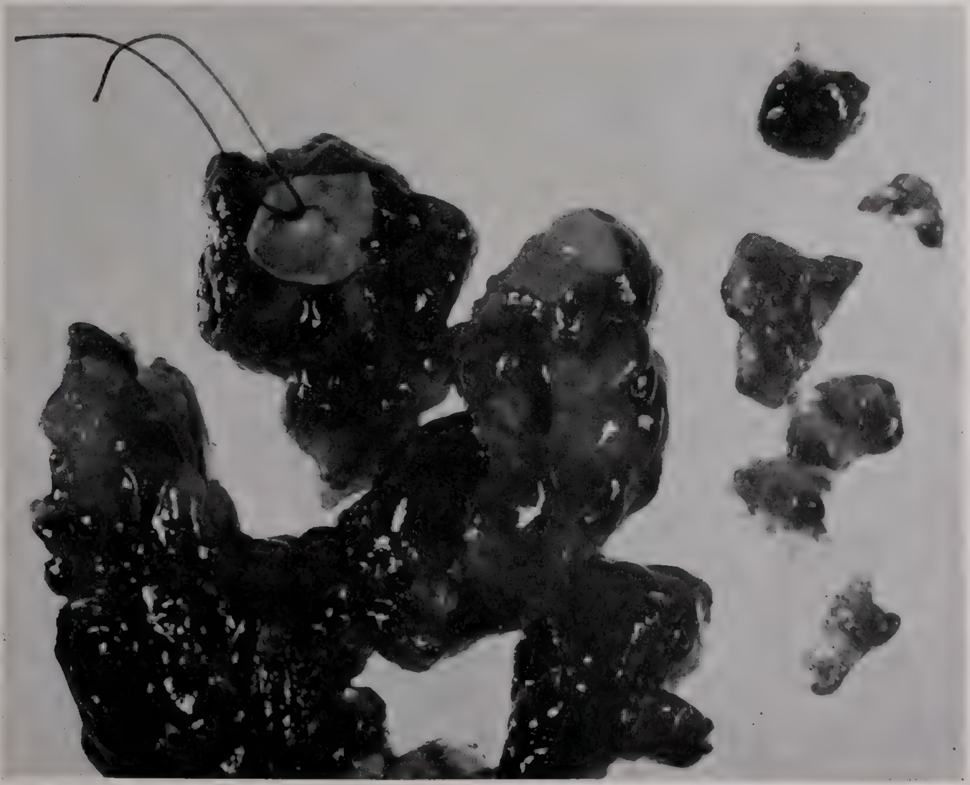

Fig. 7—Gross photograph of the cardiac myxoma. The smaller fragments represent particles that were very loosely attached to the main polypoid tumor.

tumors has been relatively standardized. Since most tumors are myxomas and most are in the atrial chambers, we approach them in a manner similar to that for valve replacements. In the present patient a right thoracotomy was used; by making a left atrial incision we could expose the myxoma inside the left atrium. The tumor was attached by a 1-cm base, and we were able to excise that portion of the atrial septum and resuture it in addition to

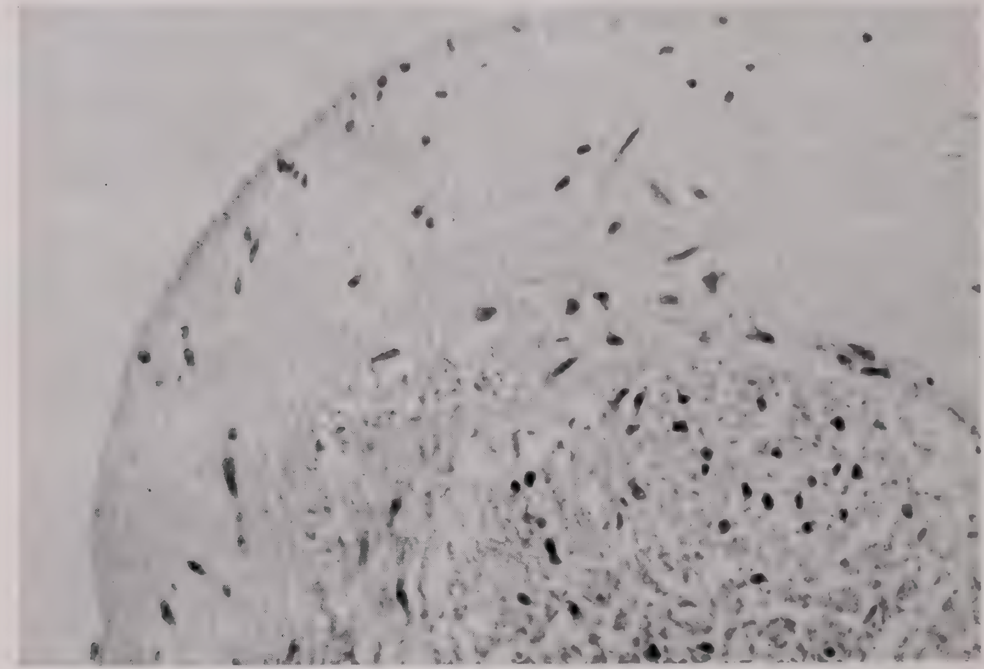

Fig. 8—A section of a normal mitral valve. The loose connective tissue of the subendocardial portion of the valve shows a close similarity to that seen within the tumor. H. E. original magnification times 100.

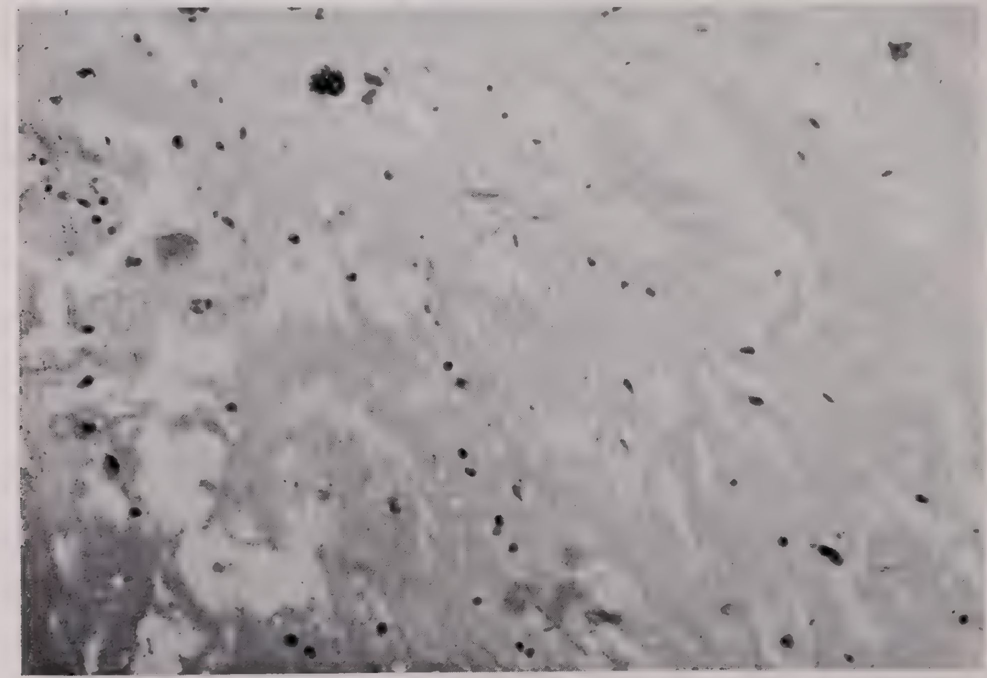

Fig. 9—Photomicrograph of the tumor revealing the loose PAS and Alcian Blue-positive ground substance supporting the irregularly shaped cells. PAS original magnification times 150.

removing all of the tumor.

Pathological Findings

Dr. Wahle:

This is the gross photograph of the tumor removed from the patient (Figure 7). The suture is through the point of attachment. The tumor is supported on a rather thin, delicate stalk. The mass is quite polypoid and friable. Cardiac myxomas are divided grossly into two types. This type, which is usually very jelly-like and loose in consistency, fragments quite easily, giving rise to emboli. The second type is a more globoid round structure that usually has no papillations, is firmer and, therefore, does not readily give rise to emboli. This photograph (Figure 8) shows the myocardial fibers and the subendocardial tissue of a normal mitral valve.

I want to draw your attention to the loose ground substance in this normal valve, as I think we can see the same thing in the tumor. Notice the small stellate cells scattered throughout the normal subendocardial portion of the mitral valve. This is a high-power view of the tumor (Figure 9) showing the amorphous ground substance and the irregularly shaped cells scattered throughout the background. At times the cells appear to be forming small blood vessels and, in fact, many authors and authorities believe that these cells are actually modified endothelioid cells rather than fibroblasts. A periodic acid Schiff stain performed on this tumor suggests that the ground substance is a mucopolysaccharide rather than fibrin or elements of blood clot. A modified Alcian Blue stain, done at pH 3.4, shows unstained material in the midst of Alcian Blue-positive mucopolysaccharide. The unstained material has the characteristics of fibrin.

Conclusion

Dr. Schechter:

Left atrial myxomas are certainly the most common of the primary cardiac tumors. Fortunately, myxomas are also the tumors most amenable to surgical cure. For this reason, it behooves each of us to keep in mind the features of myxomas as discussed today. Even if you see only one patient with a myxoma in your practice, that should be a cure.

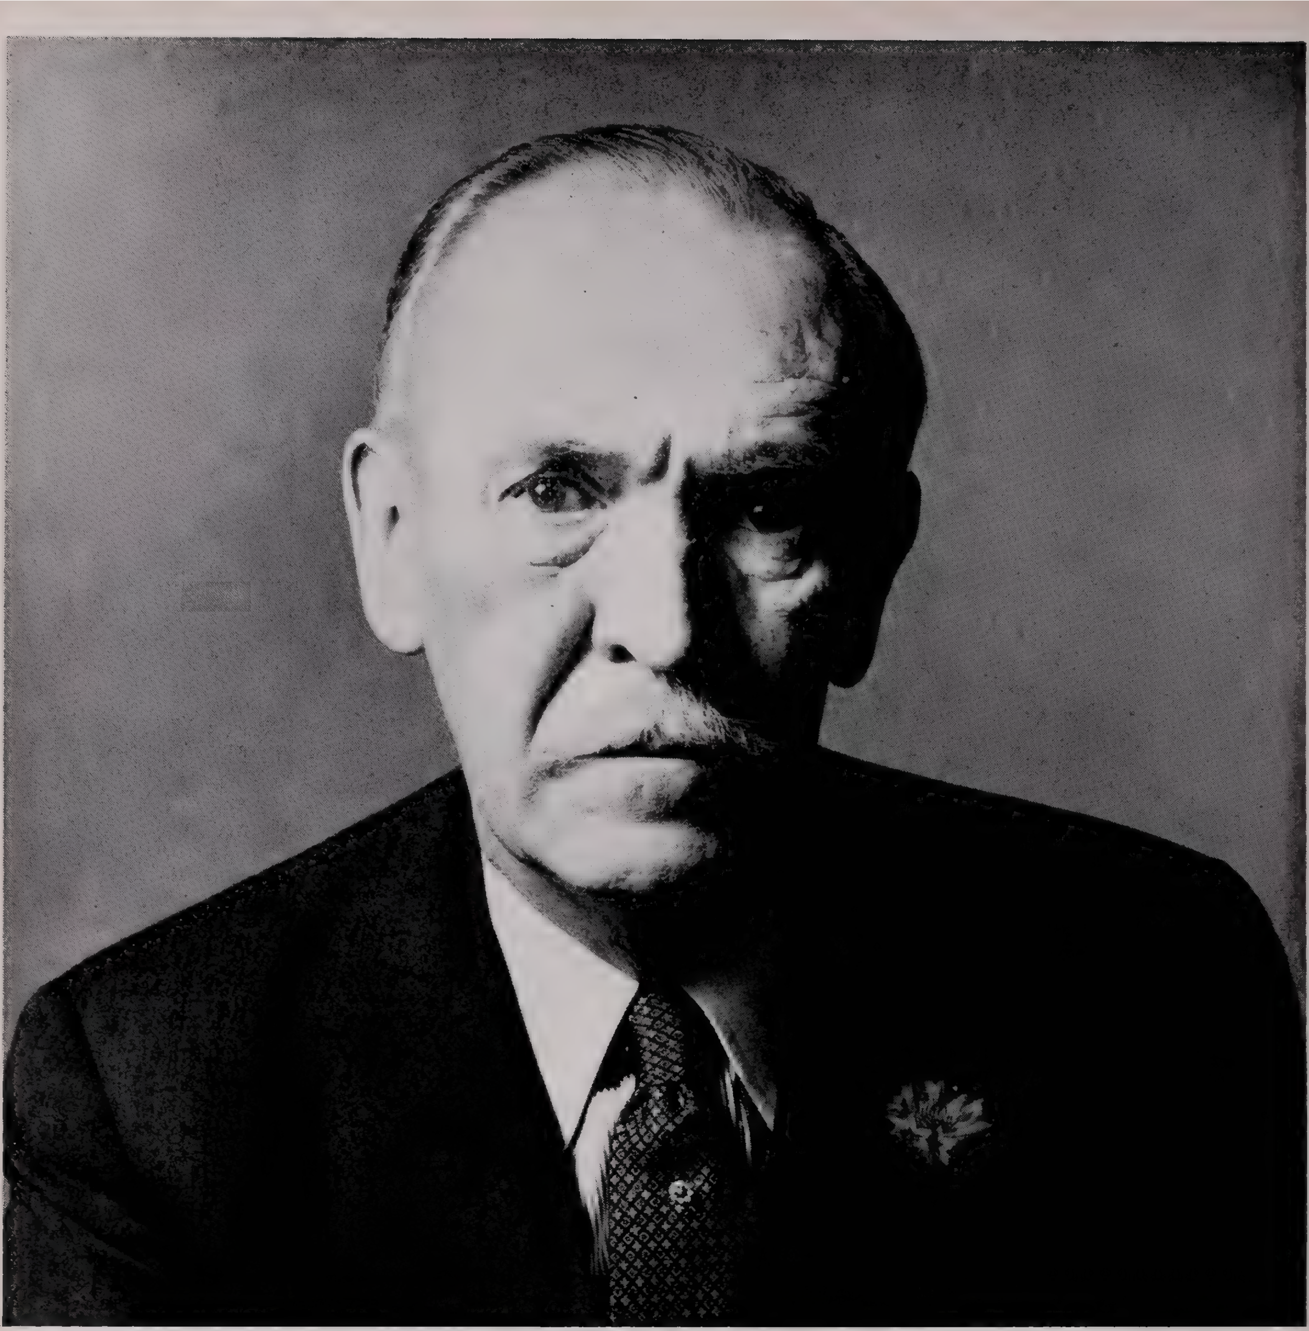
If children grew up according to early indications, we should have nothing but geniuses.—Goethe



Help the Needy!

This patient may appear to "have everything" but, like so many people getting along in years, he may well be in need—*medically.* Though there is no evidence of organic disease, he does have symptoms (fatigue, vague aches and pains, malaise) that may be indicative of—

a need to maintain anabolic balance... to counteract declining gonadal hormone secretion and forestall premature degenerative changes related to estrogen deficiency;

a need for mood elevation... to impart a gentle emotional uplift;

a need for nutritional supplementation... to compensate for the poor eating habits and subsequent dietary insufficiency of so many older people.

For these needs, consider MEDIATRIC for your next "needy" patient... medically.

MEDIATRIC provides specific agents to fulfill a need in the three areas:

1. **Gonadal steroids** [PREMARIN® (conjugated estrogens-equine), an orally active, natural estrogen, and methyltestosterone] for physiologic and metabolic benefits.
2. **Methamphetamine** to provide gentle elevation of mood.
3. **Nutritional supplements** specially selected to meet the requirements of the elderly individual.

Mediatric®

tablets • capsules • liquid
Steroid-nutritional compound

	Each MEDIATRIC® Tablet or Capsule contains:	Each 15 cc. (3 teaspoonfuls) of MEDIATRIC® Liquid contains:
Conjugated estrogens-equine (PREMARIN®)	0.25 mg.	0.25 mg.
Methyltestosterone	2.5 mg.	2.5 mg.
Methamphetamine HCl	1.0 mg.	1.0 mg.
Cyanocobalamin	2.5 mcg.	1.5 mcg.
Intrinsic factor concentrate	8.0 mg.	—
Thiamine HCl	—	5.0 mg.
Thiamine mononitrate	10.0 mg.	—
Riboflavin	5.0 mg.	—
Niacinamide	50.0 mg.	—
Pyridoxine HCl	3.0 mg.	—
Calcium pantothenate	20.0 mg.	—
Ferrous sulfate exsic.	30.0 mg.	—
Ascorbic acid	100.0 mg.	—
		Contains 15% alcohol†

† Some Loss Unavoidable.

Contraindication: Carcinoma of the prostate, due to methyltestosterone component.

Warning: Some patients with pernicious anemia may not respond to treatment with the Tablets or Capsules, nor is cessation of response predictable. Periodic examinations and laboratory studies of pernicious anemia patients are essential and recommended.

Side Effects: In addition to withdrawal bleeding, breast tenderness or hirsutism may occur.

Suggested Dosages: *Male and female*—1 Tablet or Capsule, or 3 teaspoonfuls Liquid, daily or as required.

In the female: To avoid continuous stimulation of breast and uterus, cyclic therapy is recommended (3 week regimen with 1 week rest period—Withdrawal bleeding may occur during this 1 week rest period).
In the male: A careful check should be made on the status of the prostate gland when therapy is given for protracted intervals.

Supplied: No. 752—MEDIATRIC Tablets, in bottles of 100 and 1,000.
No. 252—MEDIATRIC Capsules, in bottles of 30, 100, and 1,000.
No. 910—MEDIATRIC Liquid, in bottles of 16 fluidounces.

Valium® (diazepam) *t.i.d.* and *h.s.*

B.A. (*cum laude*)...V.P. (at thirty-two)...symbols that illuminate the quality of a life...the satisfactions of achievement, as well as its price...the pressures and stresses that can often create cardiac manifestations of psychic tension. For this kind of patient—with no demonstrable pathology—consider the singular benefits of Valium (diazepam).

With its pronounced calming action, Valium can relieve psychic tension promptly, attenuating its somatic signs and symptoms. Further, Valium is distinctly useful when somatic and depressive symptomatology (secondary to psychic tension) coexist. And Valium is generally well tolerated; in proper maintenance dosage, it seldom dulls the senses or interferes with functioning.

When psychic tension-related insomnia appears, an *h.s.* dose added to the *t.i.d.* schedule helps promote sleep.

Before prescribing, please consult complete product information, a summary of which follows:

Indications: Tension and anxiety states; somatic complaints which are concomitants of emotional factors; psychoneurotic states manifested by tension, anxiety, apprehension, fatigue, depressive symptoms or agitation; acute agitation, tremor, delirium tremens and hallucinosis due to acute alcohol withdrawal; adjunctively in skeletal muscle spasm due to reflex spasm to local pathology, spasticity caused by upper motor neuron disorders, athetosis, stiff-man syndrome, convulsive disorders (not for sole therapy).

Contraindicated: Known hypersensitivity to the drug. Children under 6 months of age. Acute narrow angle glaucoma.

Warnings: Not of value in psychotic patients. Caution against hazardous occupations requiring complete mental alertness. When used adjunctively in convulsive disorders, possibility of increase in frequency and/or severity of grand mal seizures may require increased dosage of standard anticonvulsant medication; abrupt withdrawal may be associated with temporary increase in frequency and/or severity of seizures. Advise against simultaneous ingestion of alcohol and other CNS depressants. Withdrawal symptoms have occurred following abrupt discontinuance. Keep addiction-prone individuals under careful surveillance because of their predisposition to habituation and dependence. In pregnancy, lactation or women of childbearing age, weigh potential benefit against possible hazard.

Precautions: If combined with other psychotropics or anticonvulsants, consider carefully pharmacology of agents employed. Usual precautions indicated in patients severely depressed, or with latent depression, or with suicidal tendencies. Observe usual precautions in impaired renal or hepatic function. Limit dosage to smallest effective amount in elderly and debilitated to preclude ataxia or oversedation.

Side Effects: Drowsiness, confusion, diplopia, hypotension, changes in libido, nausea, fatigue, depression, dysarthria, jaundice, skin rash, ataxia, constipation, headache, incontinence, changes in salivation, slurred speech, tremor, vertigo, urinary retention, blurred vision. Paradoxical reactions such as acute hyperexcited states, anxiety, hallucinations, increased muscle spasticity, insomnia, rage, sleep disturbances, stimulation, have been reported; should these occur, discontinue drug. Isolated reports of neutropenia, jaundice; periodic blood counts and liver function tests advisable during long-term therapy.

Pediatrics

The Battered Child Syndrome

Part IV—Summary

REALIZATION THAT CHILD abuse does exist and recognition of the subtleties of the less-than-obvious case are important in protecting the abused child against further trauma or even death. Some of the major alerting findings include: a history of previous trauma; lesions (burns, fractures, bruises, etc.) in different stages of healing; evidences of injury disproportionate with the history given; and the lack of appearance of new lesions following removal of the child to a new environment.

The incidence is unknown, but in one survey 10% of all children seen in an Emergency Room for trauma were found to be victims of child abuse. If this is anything near the true incidence, then there are many more cases than are being recognized or reported.

There can be a large variation in abuse ranging from withholding feedings, emotional neglect, and over-zealous spanking, to homicide. The spectrum is very broad, and those patients actually presented for care represent only the "iceberg effect" with a greater number being unseen.

Repeated trauma occurs in 30 to 50% of the children and the *death rate is 10%.* This emphasizes the importance of recognizing and reporting, and the institution of appropriate protective measures for these patients.

Potentially, anyone can abuse a child. The abuser can come from any walk of life, socio-economic group, race, or educational level. He has a low frustration level and is usually impulsive. Some are overtly psychotic, often classified as having character disorders; but by no means is this always the case. Many are purported to have been beaten themselves. While being interviewed they often display little affect. Often one or both parents or the guardians are the assailants, and one may "cover" for the other while being interviewed.

Minnesota passed the beginnings of a reporting law in 1963 which, as amended in 1965 and 1967, stands today. All health personnel who suspect a case of child abuse are required by law to report such a case under penalty of law (three months and/or $100.00 maximum penalty) for not reporting. This law was suggested and revised under impetus from the Minnesota State Medical Association and the Minnesota Department of Public Welfare. A case is reported first by telephone and later by written statement including names, addresses, extent and type of injury, history obtained, and other pertinent data such as x-rays (skulls, long bones), etc. These reports are made to the police and welfare departments. They then investigate the reports and dispose of the cases appropriately. The person who makes the report is *not* liable and medical privilege is waived. When court proceedings are necessary, the greatest emphasis is on the protection of the child instead of punishment of the assailant; and cooperation of the physician is of great importance. If a specific law (murder, assault, etc.) has been broken, then appropriate action against the assailant will be taken.

Because of increasing awareness of the syndrome and the reporting law, more cases are being reported annually. It is seriously doubted that the actual incidence of abuse is changing.

The authors suggest that the state law be amended to permit any person to report a suspected battered child without fear of liability, if such report is given in good faith. We also suggest that Minnesota establish a central reporting agency where known and suspected cases can be filed so that, if a case appears in an Emergency Room or physician's office, it can be promptly determined if that patient has previously been reported to be a battered child. Such an approach may help to identify those who use different facilities each time the child is battered and permit prompt application of protective services to that patient.

John Hunter's Menagerie

Before going off to war, John made plans to start a menagerie for the study of all kinds of animals. He had leased two acres in Earl's Court in the village of Kensington where he proposed to build a house for his collection.

The design of the house was as unique as the idea of the menagerie was unorthodox. Over the door hung the head of a crocodile with gaping jaws. Four life-size statues of lions, two rearing and two crouching, were set on each side of the building. Back of the house was a den where real lions and leopards were chained. Over the den there was a mound of earth, topped with piles of seashells; in the shape of a little fort on which was mounted a small gun.

The strangest sight was the barnyard. Here all kinds of domestic and wild animals roamed in confusion. Rare birds and serpents, ostriches, geese, and pheasants mingled with buffalo and deer. Fowl and human teeth grafted on the combs, hens with roosters' feathers, goats and dogs were all there for some type of experiment. In a small fishpond Hunter bred eels, leechs, carp, and river mussels. Hedgehogs and other hibernating animals were kept in burrows to yield their secrets of winter sleep. No specimen was too bizarre for the surgeon-scientist to scrutinize. There were goose eggs for the study of embryology, pond water for fresh-water life, the skeleton of a giant dancing bear contracted for with a traveling gypsy when it was alive.

He frequented the pet shops, looking for strange creatures, and begged zoo keepers and members of expeditions for any rare beasts they might encounter. Dead animals were useful too. Certain parts he pickled in jars, others he dried. The rest were boiled down in a copper vat and the skeletons preserved.*

Advice from a Medieval Physician

And of those things which are incumbent on the student of this Art (Medicine) are that he should constantly attend the hospitals and sick-houses; pay unremitting attention to the conditions and circumstances of their inmates, in company with the most acute professors of Medicine; and enquire frequently as to the state of the patients and the symptoms apparent in them, bearing in mind what he has read about these variations, and what they indicate of good or evil. If he does this, he will reach a high degree in this Art. Therefore it behooves him who desires to be an accomplished physician to follow closely these injunctions, to form his character in accordance with what we have mentioned therein, and not to neglect them. If he does this, his treatment of the sick will be successful; people will have confidence in him and be favourably disposed towards him, and he will win their affection and respect and a good reputation; nor withal will he lack profit and advantage from them. And God Most High knoweth best.*

*Ali ibnu 'l-Abbas, Persian physician.

History of Medicine

Wilford Hall USAF Hospital

Wilford Hall USAF Hospital is a modern 1,000-bed general hospital, consisting of one 500-bed unit put into operation in 1957 and a second unit completed in December 1960. This nine-story hospital is the largest single structure of its kind in the Department of Defense. Only an extremely farsighted person could have predicted in 1942 that from the newly opened hospital adjacent to Kelly Field would come this giant of the United States Air Force Medical Service.

Wilford Hall USAF Hospital traces its ancestry back to June 15, 1941, when the first shovel bit into the clay-like San Antonio earth and broke ground for the Station Hospital, a unit of the San Antonio Aviation Cadet Center. Officially opened on June 8, 1942, the facility offered the usual services and included a fully equipped dental clinic. A secondary mission consisted of the conduct of a limited training program for selected medical officers from the School of Aviation Medicine and the operation of a Medical Training Center School for enlisted men.

By 1943 the hospital had expanded to 1,200 beds, and its principal functions were the medical processing of aircrew candidates and aviation cadets, corrective surgery on aircrew candidates, and operation of a School of Aviation Medicine branch.

On February 1, 1946, the Station Hospital became the Army Air Forces Regional and Convalescent Hospital. In mid-June 1950 the hospital was redesignated a United States Air Force Infirmary. This status was short-lived, however, for soon thereafter redesignation instructions were received from the Secretary of Defense to reopen the facility as a 100-bed hospital.

Cancellation of the infirmary status was accidentally prophetic, for a military incident put the hospital back on a fully operational basis; the North Koreans had invaded South Korea. Six weeks after the start of hostilities, the medical group (designated the 3700th Medical Group at that time) was authorized to set up a 475-bed hospital, which became known as the 3700th USAF Hospital. On December 11, 1950, Lackland Air Force Base was designated a major port of debarkation for American military men returning from Korea. The hospital, which had been providing temporary treatment for Korean War casualties, was ordered to increase its capacity to 1,000 beds, including 500 beds allocated for wounded servicemen.

Construction of the present facility began on October 11, 1954, and was completed in mid-1957. Patients were transferred to the new building during the latter part of September, and the official dedication was held on November 16, 1957. The new facility opened with 500 beds, but it was built on a 1,000-bed chassis. When the Aerospace Medical Center was established at Brooks Air Force Base, Texas, in October 1959, the hospital and the School of Aviation Medicine became two of its components. This Center was the first Air Force medical organization to provide comprehensive facilities for clinical therapy, research, and education. In 1960 completion of the teaching wing added another 500 beds and classroom space for the training of residents, interns, nurses, and medical technicians.

The following year Wilford Hall USAF Hospital was selected to aid the nation's space program when the National Aeronautics and Space Administration (NASA) requested clinical medical support for the first suborbital space flights of Project Mercury. Medical personnel were made available for the entire Mercury series of space probes. In 1961, also, the Aerospace Medical Division was created in order to provide medical support to the rapidly expanding field of aerospace development and operations in the United States. Wilford Hall USAF Hospital and the other units that formerly constituted the Aerospace Medical Center were absorbed by the new unit on November 1, 1961. The Division was established as part of the Air Force Systems Command.

Significant achievements were made in many areas. The open heart surgery program, begun in 1962, advanced through countless refinements. The team approach, together with standardization of techniques and simplified equipment, made it possible to operate successfully on complex cardiac conditions, including multiple valve replacements. Wilford Hall USAF Hospital, being the only Air Force cardiac surgical center, began to perform routinely three or four cardiac procedures a week. This program continues to be important.

On March 2, 1963, the hospital was named for Major General Wilford F. Hall, a former surgeon of the Air Materiel Command, a distinguished flight surgeon, and a recognized clinical specialist. General Hall, who died in 1962, made numerous contributions to the Air Force Medical Service. Renaming the hospital for a deceased officer changed the Air Force custom of giving each medical facility a numerical designation or the name of the installation on which it was located. Commensurate with advances in medicine, the hospital continued to increase its capabilities. The MacKown Dental Clinic was added to the growing complex in June 1965. Replacing six dispersed dental units on Lackland Air Force Base, this modern clinic consisted of treatment rooms, a library, classrooms, laboratories, a conference room and other facilities.

The United States Air Force Central Eye Bank was established in 1965, and by the middle of 1966 it was in full operation, supplying military and civilian hospitals with fresh or preserved eye tissue. On December 15, 1967, an agreement was signed between the University of Texas Medical School at San Antonio and Wilford Hall USAF Hospital to permit the interchange of the medical staff of both institutions as consultants and teachers, of interns and resident physicians for training purposes, and of the research staff; the establishment of cooperative research studies; and the teaching of medical students.

In 1967 the United States Air Force Central Tumor Registry was established at Wilford Hall USAF Hospital in order to have all tumors that were diagnosed in Air Force medical facilities registered at one institution, no matter where the Air Force personnel might have moved. Records of therapy, complications

Endocrinology	1966	1	1

and progress were established for all known patients and provisions made for adding new ones as they were identified.

Present Operation

Since 1957 Wilford Hall USAF Hospital has been characterized by steady growth in the number of patients treated, personnel assigned, workload capacity, research projects, and educational programs. The hospital furnishes full-scale medical care not only to the military population, dependents, and retired personnel in the San Antonio area, but also to patients with complex diagnostic and treatment problems referred from Air Force installations all over the world. It has three closely related missions: (1) patient care, (2) medical education, and (3) clinical research. A tremendous wealth of clinical material is available to the interns, residents and teaching staff. Table 1 indicates the workload for the most recent representative year (1 July 1966 to 30 June 1967).

Recognized as the leading medical center of the United States Air Force, the hospital has a large, competent staff that includes many members who are recognized nationally in their particular specialty. The present staff consists of:

Physicians	122
Dentists	53
Administrative and allied services	94
Airmen	1,368
Nurses	
Military	262
Civilian	57
Other civilian employees	474
Red Cross	18
Red Cross volunteers	85

All postgraduate training is under the supervision of diplomates of the various specialty boards, and all teaching programs are fully approved by the Department of Graduate Medical Education of the American Medical Association and the appropriate specialty boards. Table 2 shows the internships, residency programs and fellowships that are offered at Wilford Hall USAF Hospital.

Physicians of Wilford Hall USAF Hospital take an active interest in the welfare of San Antonio citizens by serving as consultants to Santa Rosa Medical Center, Robert B. Green Hospital, and the San Antonio State Tuberculosis Hospital. They also serve as visiting professors to six universities. The University of Texas Dental Branch at Houston is also affiliated with Wilford Hall USAF Hospital for teaching purposes. The civilian consultant program provides the hospital with the services of 121 civilian consultants, including 72 professors at university medical schools throughout the United States.

Wilford Hall USAF Hospital has a clinical research laboratory that is engaged in human research studies as well as animal studies. The main function of this laboratory is to support the research interests of the teaching and resident staff. During the past year, many members of the staff have presented papers at local, state, and national scientific and technical meetings and have been authors of papers published in various medical journals. As a result of the excellent reputation of the hospital, the patient population has continued to increase. Therefore, plans for updating and increasing the number of operating rooms, outpatient clinics, and educational and research facilities already exist; these planned improvements are scheduled to begin in 1969. After completion of this construction program, it is anticipated that Wilford Hall USAF Hospital will continue to maintain the reputation for excellence in patient care, medical education and clinical research established during earlier years.

Classified Advertisements

Classified advertising rates are twenty (20) cents a word; minimum monthly charge $5.00; key number, fifty (50) cents additional.

Replies to advertisements with key numbers should be mailed in care of Minnesota Medicine, 375 Jackson, St. Paul, Minn. 55101.

BENSON & ASSOCIATES: Business & Professional Collection Specialists. No charge if no collection made. Pho: 888-2242, 8601 Nicollet Ave., Bloomington, Minn.

WANTED: G.P. to join clinic serving population area of 12,000. City has new hospital, new clinic building, two nursing homes, new Jr-Sr high school, new swimming pool, rich farming area. Fishing and hunting nearby; metropolitan city close by. Salary open and partnership if interested. Write Minnesota Medicine-423; 375 Jackson, St. Paul 55101.

GENERAL PRACTITIONER wanted to join well-established practitioner. New clinic building—90 miles east of St. Paul—city of 14,000. Early partnership with full hospital facilities. Ideal location. L. W. Picotte, M.D.; Chippewa Falls, Wisconsin.

ASSOCIATE urgently needed in busy general practice. Excellent clinic and hospital facilities. Salary open. Partnership after 1 year. Klefstad Clinic, Greenbush, Minn. Call collect: Lloyd H. Klefstad, M.D., Tele. 218—782-5275 or 4725.

INTERNIST: Board certified or eligible. 269-bed General Medical and Surgical Hospital in Michigan's Upper Peninsula. Licensure any state, salary dependent upon background and qualifications. Excellent benefits for retirement, vacations, sick leave, and professional improvements. Non-discrimination in employment. Contact Chief of Staff, VA Hospital, Iron Mountain, Michigan 49801.

SECOND GENERAL SURGEON needed by busy twelve man specialty group in attractive Minnesota community of 15,000; unique industrial, business and recreational center close to the Twin Cities; ideal family environment with all cultural and recreational facilities available; new clinic and new hospital; weekend coverage assured; terms negotiable; paid interview. Write or call collect: Administrator, The Interstate Medical Center, P.A., Red Wing, Minn. Tel. No. 388-3503.

THREE MAN group in North West Wisconsin Resort, State Conservation and Retirement Area needs two more physicians adequately to serve their practice. Facilities offered are three-room physician suites, X-ray and lab under AMT technician, RN-only nursing personnel. New accredited thirty-two bed hospital and forty-six bed nursing home. Deer and duck hunting, fishing within five minutes of town. Internist most needed; generalists welcomed. Will meet any reasonable salary request. Partnership after one year. Write: MINNESOTA MEDICINE—365; 375 Jackson St., St. Paul 55101.

RESIDENTS IN PSYCHIATRY: Vacancies for July 1, 1969. Three years approved eclectic residency program with emphasis on community psychiatry, milieu, individual and group therapy. 350 inpatients; large outpatient dept.; children's unit; excellent senior staff; affiliation with University of Iowa. Stipend $15,000 for residents with Iowa license or immediate eligibility for regular license. Stipend for foreign graduates who must have ECFMG, $12,240. Federal stipend available to physicians with four years non-psychiatric training or experience following internship amounting to $15,000 annually, of which $3600 is tax exempt. Enthusiastic and dynamic training and treatment programs that are best understood by a personal visit. Write or call W. C. Brinegar, M.D., Supt., or William Blyth, M.D., Mental Health Institute, Cherokee, Iowa.

NINETEEN-MAN Wisconsin group located in college community of 40,000 with excellent hospital facilities is seeking additional associates in the following areas: (1) Internal Medicine, (2) General Practice, (3) Pediatrics and (4) Orthopedics. For further information please contact D. R. Griffith, M.D., Midelfort Clinic, Eau Claire, Wisconsin 54701.

WANTED: General practitioner to join two young general practitioners in well-established practice in suburban St. Paul. Excellent office space with lab, x-ray, and emergency room. Salary negotiable, with an association leading to early partnership opportunity. Write MINNESOTA MEDICINE 412, 375 Jackson St., St. Paul 55101.

EXPANDING EIGHT-MAN CLINIC IN NORTHWESTERN WISCONSIN has immediate openings in General Practice, Internal Medicine and Urology. New clinic building; three accredited hospitals; large branch of the University of Wisconsin; population 33,000. Liberal first year salary, early partnership. Contact Milton Finn, M.D., 3600 Tower Avenue, Superior, Wisconsin 54880. Tel.: 715-392-8111.

GENERAL SURGEON interested in some general practice to associate with a 2-man partnership in a rich agricultural community in southern Minnesota. Modern hospital and new clinic building. Hunting, 9-hole golf course, swimming pool. Salary open and full partnership as soon as desired. Write: MINNESOTA MEDICINE—405, 375 Jackson, St. Paul 55101.

INTERNIST AND GENERAL PRACTITIONER wanted to join a five-man clinic group in Minneapolis. Complete laboratory and X-ray with board roentgenologist. Excellent hospital staff associations. Salary arrangement to start with, early partnership. Write MINNESOTA MEDICINE—289; 375 Jackson, St. Paul, 55101.

Abstracts, Briefs and Commentaries

PENETRATING WOUNDS OF THE HEART
AN ANALYSIS OF 459 CASES

Both the non-operative and operative methods for treatment of penetrating wounds of the heart have been proposed by numerous authors over the past 30 years. The present article summarizes the experience with 459 penetrating wounds of the heart, at Parkland Memorial Hospital during a nine-year period. Of the 373 who were dead on arrival, 80% had been injured by gunshot; in contrast, only half of the 86 patients admitted alive had been injured in this manner. The mortality rate for the seven years prior to 1966 was 36%, the cause of death in over half of these cases being attributed to recurrent cardiac tamponade.

Beginning in 1966, all cases of penetrating wounds of the heart were treated primarily by open thoracotomy methods with a significant reduction in mortality rate from penetrating stab wounds, but no significant reduction in wounds produced by gunshot. There was a striking contrast between the 43% mortality figure with pericardiocentesis therapy alone and the 16% mortality rate when open thoracotomy was performed. From autopsy data on the patients arriving dead at the hospital, the authors noted the left ventricle was involved in over half of the cases, but in only 3% of surviving patients. Interestingly, patients with injuries of only the left atrium survived; but three of seven patients with right atrial injuries succumbed in the hospital.

This report generated comments from five members of the audience, most of whom agreed that the more aggressive open thoracotomy approach to both stab wounds and gunshot wounds of the heart was indicated. It was also pointed out that the pump oxygenator was needed on standby to salvage those cases which had previously been irreparable.

SCAR CANCER OF THE LUNG

The authors discuss 20 operative cases of carcinoma developing in scars of the lung. The sex incidence was equal and the average age was 57 years. Seventeen cases were of the bronchiolo-alveolar type, which is the most common variety reported in similar series; one was anaplastic carcinoma and two were squamous cell carcinoma. The cause of the scar was determined in only eight of the cases, the remainder showing marked interstitial fibrosis of unknown etiology. Specific causes of the scar included tuberculosis in five, foreign body in one, infarct in one and bronchiectasis in one. Surgical treatment included either lobectomy or segmental resection. Hilar lymph nodes were involved in only five cases. Of the 16 cases followed for five years, eight remained free from disease.

The pathogenesis of carcinoma developing in pulmonary scar remains unknown, although invariably the carcinomas are associated with a predominantly interstitial type of fibrosis in which degenerative alveolar epithelial hyperplasia has occurred. From the standpoint of x-ray diagnosis, the authors point out that the presence of calcification is of no significance, since it may have been present in the pre-malignant scar. They also question the conclusion drawn in reports dealing with lung cancers of assumed long standing. Rather than an earlier film showing early signs of cancer, they suggest that such cases might, instead, represent pulmonary scars which later develop carcinomatous change.

The conclusion is drawn that these tumors tend to progress slowly and metastasize late and that scar cancers, in general, offer a much better prognosis than bronchogenic carcinoma of the usual type.

EXPERIENCE WITH AN IMPLANTABLE SYNCHRONOUS PACEMAKER IN CHILDREN

This article deals with five completely implantable synchronous pacemakers in children whose ages ranged from three to 15 years. The etiology of the heart block was surgical in four cases and unknown in one.

The authors recommend the use of an implantable synchronous pacemaker in childhood for persisting postsurgical heart block of at least three to four weeks' duration, regardless of symptoms, and also in the symptomatic child with congenital complete heart block.

It is the authors' opinion that synchronous pacemakers are superior because of their ability to increase cardiac rate in response to the patient's activity, assuring a more normal cardiac function. The ability of the synchronous pacemaker to function as a standby unit if normal sinus rhythm returns is an additional benefit and prevents the bizarre rhythms of pacemaker competition. A further advantage of the synchronous pacemaker is that with battery depletion, the unit converts to a fixed rate, thus preventing recurrent complete heart block, as may occur with battery exhaustion in fixed rate units.

One of the problems which arise in treating heart block in children is the finding of a satisfactory site in which to implant the pacemaker unit, since all of the presently available instruments are relatively large.

Five sites were utilized in this series. When the left posterior, inferior intrathoracic space was used, replacement was somewhat more difficult and required general anesthesia. For this approach, a new thoracotomy incision was made directly over the unit without entry into the free pleural space, since a firm fibrous pocket had developed about the instrument. The unit has been replaced twice in this position.

Another approach also involved a left thoracotomy; but, in order to facilitate replacement, the diaphragm was separated from the costal arch at the posterolateral margin. In this case, the pocket was fashioned extrapleurally with displacement of the spleen anteriorly and the kidney somewhat medially. This extrapleural, retroperitoneal position was somewhat easier to re-enter than the foregoing with incision through the bed of the 12th rib.

A third method involved creation of a retroperitoneal pocket adjacent to the left ileum through a transverse incision made over the iliac crest. This site proved very protective to the unit with less danger of skin breakdown than might occur when the instrument is placed in a subcutaneous position.

Alternative standard methods included subcutaneous implantation on the anterior abdominal wall, which is quite satisfactory in adults and older children; and anterior chest wall placement beneath the pectoralis major muscle. However, the latter approach produced an unsightly bulge as well as atrophy of the overlying tissue.

Paleolithic Man's Endurance Test

Primitive man was close to nature, but the fallacy of his medicine was its interference with nature. He regarded health and disease as a constant conflict between good spirits and bad spirits, each battling for victory.

The sick person was thus denied rest and quiet, for the disease-demons must be allowed no peace: they must be frightened away by terrifying masks and grimaces; by strange howls, noises, dances; they must be made uncomfortable by beating, biting, pinching, kicking, strangling their host; they must be smoked out by unbearable smells and fumigations. If they were strong enough to endure all this, then by sorcery they must be lured elsewhere, to take their abode in some scapegoat—an animal, or the patient's enemy, or an inanimate object. If they were too clever to be fooled, then they must be appeased with sacrifices and precious gifts. The medicine-man's treatment was so heroic that often he looked as ill and gaunt as his patient, but he never gave up. Even when the struggles of the patient ceased and the soul left his body, the medicine-man would try to blow it back through the various orifices—the mouth, the ear, the anus. Many patients died in their prime, but this merely meant that the demons had conquered—perhaps the deceased had been disrespectful. On the other hand, the medicine-man had many remarkable cures to his credit, and if he kept testimonials, his medicine-bag must have been full of them. In primitive medicine, as in modern, the patient's faith and the physician's personality are important factors in the cure, and often both are the victims of ignorance and suggestion.*

WANTED: Young physician for association leading to partnership with four well established General Practitioners in fast growing suburb of St. Paul. Excellent clinic facilities in nearly new, partnership owned, well equipped, medical center building. Write: Minnesota Medicine-421, 375 Jackson, St. Paul 55101.

WANTED. General practitioner wanted to join three-man group in a fast-growing area just 30 minutes south of the Twin Cities. You will practice in a new clinic, hospital and nursing home. A complete resume of facilities, practice and area is available. Contact M. H. Hunter, M.D., River's Edge Medical Clinic, Farmington, Minnesota. Telephone 612-463-7181.

OXBORO MEDICAL CLINIC BUILDING (only) for sale in Bloomington, Minnesota's third largest city. Earn attractive return while current lease expires in four years. Clinic comfortably houses 11 doctors, each with 3½ examination rooms. Central air conditioning, adequate parking, and much more. Contact Towle Real Estate Co., 333-2445, Area Code 612. James R. Bingham.

DIRECTOR OF HOUSE SERVICE—An ideal position for someone in family practice who wants a less strenuous life in a stimulating medical environment. Excellent annual fee, plus fringe benefits. Located in Minneapolis, known nationally as an ideal city for family living. Every possible professional, educational, cultural and recreational opportunity. Teams in all major league sports. Write of your interest and come for an expense-paid visit. Write: Minnesota Medicine-422, 375 Jackson, St. Paul 55101.

OB-GYN—Join group of 4 GP's. Immediate work load. Time off assured. Early partnership opportunity. Well equipped clinic, established in 1962, recently expanded, in growing community of 7,000, 30 minutes from downtown Minneapolis-St. Paul. Fully accredited 116 bed. hospital in community. Call or write J. E. Ponterio, M.D. (612) 445-1305. Shakopee Medical Center, Shakopee, Minnesota.

GENERAL SURGEON, board certified or eligible wanted for 5 man group practice community sponsored prepayment plan in Northeastern Minnesota area of 14,000 located on Lake Superior 20 miles from Duluth. Anesthesia by physicians. No general practice. Accredited hospital with radiologist and pathologist services next door to modern clinic. Good schools with swimming pool and indoor ice arena, golf, hunting, fishing. Liberal salary, full partnership 6 months. Write Medical Director, Community Clinic, Two Harbors, Minnesota.

CANOE TRIPS—Complete relaxation in the Quetico-Superior Wilderness. Cruise, fish and explore, or base camp on remote lakes. Paddle, motor or fly in. Bring your family—return home completely rested. Cost only $9.00 per diem, $7.00 under 12. Write: Bill Rom, Dept. MM, Canoe Country Outfitters, Ely, Minnesota.

GENERAL PRACTITIONER urgently needed with two man partnership in Northern Minnesota County Seat Community has modern accredited hospital, stable industry, fine schools and excellent hunting and fishing. Contact Administrator, Roseau Area Hospital, Roseau, Minnesota. Telephone No. 218-463-2500.

MEDICAL ILLUSTRATOR—M.G.H. graduate, worked in hospital, medical school; experienced in surgical drawings, book illustrations, charts and teaching aids. Will work in my Edina home. 941-4499.

BURNSVILLE, NEAR Hwy. # 13 & 35 W. spacious suite in new office bldg., partitioned for medical offices. Over 500 or 1000 sq. ft. Doctors urgently needed for this area. Reasonable rent. Tel. 454-1233.

EXCELLENT OPPORTUNITY for one or two general practitioners. Deer River, Minnesota will be needing one or possibly two physicians by June 1, 1969. The present partnership has an extremely busy practice with higher than average income. An equipped ten room clinic in the hospital is available. For further information contact David McClure, Administrator, Community Memorial, Deer River, Minn. Call collect (218)-246-8245 weekdays or 246-8274 evenings or weekends.

WANTED: Young General Practitioner to join 5 man general practice group. Services of General Surgeon and Radiologist immediately available. College town serving population of 22,000, 30 miles from Twin Cities. Contact Roland M. Hammer, M.D., River Falls Medical Clinic, River Falls, Wisconsin. Phone 425-5322.

LAKE SHORE PROPERTY FOR RENT: For rent July, August, either/or, completely equipped 3-bedroom home on beautiful Lake Sylvan near Brainerd adjacent to the Pine Beach golf courses, 200 feet private sandy beach, screened patio, garden, walkout basement, fireplace. $800 a month. References required. Jerry Vessels, Route 6, Brainerd, phone 829-2065.

GENERAL PRACTITIONER WANTED to join well-established three man group in Twin City area. Starting salary $20,000.00 to $25,000.00 range with opportunity for early partnership; or, will negotiate. Write: Minnesota Medicine-424, 375 Jackson, St. Paul 55101.

TEN MAN MULTISPECIALTY group needs an ophthalmologist and another pediatrician. New clinic building, complete laboratory and x-ray facilities. 180 bed modern hospital across street from clinic. Early share-holders status. Salary open. Write or call the Lenont-Peterson Clinic, Ltd., C. A. Tietz, M.D., area code 218, 741-4292, Virginia, Minnesota 55792.

LONG LAKE NEEDS DOCTOR. Professional Bldg. for sale or rent. Has waiting room with reception counter, two toilets, lab-darkroom, large X-ray room plus five other rooms. Picker 100-100 Century available. Sublease area has large room and toilet, suitable for dentist or other Professional with shared waiting room. All new modern interior. Wide open; no Doctor in town. Jay R. Kallestad. A.C. 612-920-7687.

GENERAL PRACTICE—Excellent opportunity to join General Practitioner in western South Dakota community. Philip is located in the middle of rich ranching country. The community has modern 20 bed hospital with nursing home under construction. Modern clinic adjacent to the hospital. Tentative plans are to open day clinic in neighboring community of Wall, home of the famous "Wall Drug." Good hunting and fishing opportunities and within short drive of the beautiful Black Hills. For more information, write or call G. J. Mangulis, M.D., Philip, South Dakota or Mr. Ted Hustead, Wall, South Dakota.

Special Article

Value of Graphic Methods

in a Teaching Hospital

JOHN L. WANAMAKER, Lt. Colonel, USAF, MC*
Washington, D. C.

As a part of the program for teaching physical diagnosis to interns and residents during their tour on the Cardiology Service at Wilford Hall USAF Hospital, phonocardiograms and indirect pulse tracings have been recorded on a wide variety of patients. Since July 1965 approximately 1,200 graphic studies have been made on both ward and clinic patients. In this paper an attempt is made to evaluate the role of this method of study in the teaching program.

Recording Technique

The technique used at this hospital does not differ significantly from that of others[1] and will be described only briefly. The phonocardiogram is recorded in the four classical auscultatory areas with breathing suspended. Another recording is made during normal breathing with the pick-up in the pulmonic area in order to define the mobility of the two main components of the second heart sound. An indirect carotid pulse tracing is recorded simultaneously to permit study of its form and for timing of the phonocardiographic events. An apex cardiogram is recorded by placing the pulse pick-up over the point of maximum apex impulse; generally, it is obtained most readily by turning the subject from the supine to a more lateral position. The apex tracing is used to time the phonocardiographic events recorded at the mitral area. When indicated, other arterial pulse waves or the jugular venous pulse are recorded. An electrocardiogram lead is recorded simultaneously for an additional reference point for timing.

Using this technique, 90% of the tracings are recorded satisfactorily for interpretation. An illustrative study in which the phonocardiogram has been recorded in the mitral area is presented in Figure 1. The electrocardiogram can be recognized as the lower tracing; the apex cardiogram is directly above it. After

*Present address: Department of Medicine, Malcolm Grow USAF Hospital, Andrews Air Force Base, Washington, D. C.

atrial excitation, an outward movement of the apex is recorded. Attributed to presystolic left ventricular filling caused by atrial contraction, this movement is termed the A wave. The major outward movement of the apex is seen next; it begins slightly after ventricular excitation. This movement is believed to represent isometric left ventricular contraction, which ends with the onset of ventricular ejection—an event that corresponds to the E point on the ACG. During the remainder of left ventricular ejection and relaxation, the predominant motion of the cardiac apex is away from the chest wall. This withdrawal is arrested at 0, an event that times closely with mitral valve opening. Ventricular filling occurs in three phases: first, rapidly (RFW), then slowly (SFW), and finally, in the previously mentioned A wave resulting from atrial contraction.

The normal carotid pulse record shows a smooth rapid upstroke that rises to a single dominant peak: the percussion wave. The dicrotic notch, which is seen as a sharp indentation on the downslope, is very useful for identifying aortic closure and estimating the duration of left ventricular ejection.

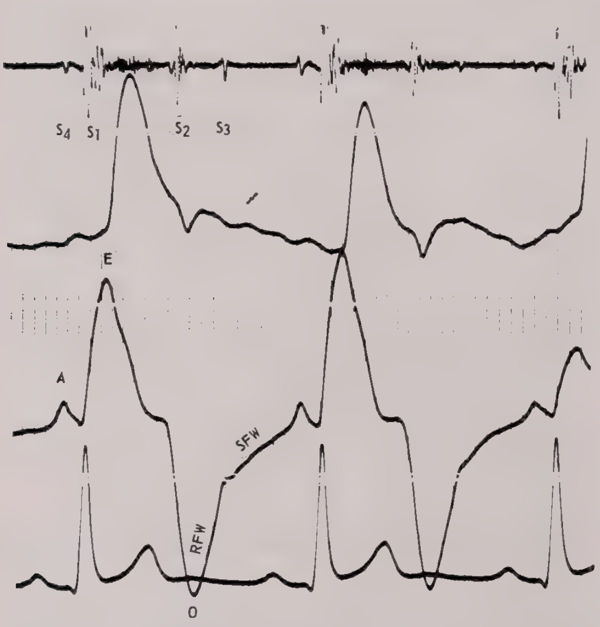

Fig. 1—A Typical Graphic Study. Lower tracing, lead II of electrocardiogram. Second tracing, apex cardiogram. A, E, O, RFW, and SFW refer to specific reference points as explained in text. Third tracing, carotid pulse. Top tracing, phonocardiogram: S_1, S_2, S_3, and S_4 refer to first heart sound, second heart sound, etc. A faint systolic murmur is present.

The phonocardiogram shows the four numbered heart sounds and their temporal relationships. The various portions of the study will be described in more detail later.

Benefits

With the possible exception of some low-frequency vibrations, it must be emphasized that the recording apparatus does not sense anything beyond the range of the physician's eyes, ears, and fingers; however, the tracings are objective and unbiased by historical, x-ray, or other data. One of the early benefits was to stimulate more careful physical examination and recording of findings, for the threat of being "scooped" by the recorder is ever present.

Separation of Cardiac Events

One major virtue of the graphic recordings is the ability to separate the various cardiac events into the proper time sequence. This ability is an inherent property of the recorder, but it can be developed in physicians only by experience and correlation with some reference point. The records provide a reliable point of reference.

Accurate timing of the events around the two heart sounds is essential for making judgments about disordered hemodynamics. Several of these events are shown in Figure 2. Splitting of the first heart sound is presumed to result from asynchronous closure of the mitral and tricuspid valves and is considered normal. Both of these sounds occur after the Q wave of the electrocardiogram and prior to the onset of the carotid upstroke. An ejection click focuses attention on one of the great arteries, or its semilunar valve. Both appear at a longer distance from the initial vibrations of the first sound and, if aortic in origin, they correspond to the onset of the carotid upstroke.

Hypertrophied Ventricle

A fourth heart sound, or atrial gallop, occurs during the P-R interval of the electrocardiogram. When this sound originates in the left ventricle, it is usually associated with a large A wave on the apex cardiogram. Physiologically the sound suggests a hypertrophied ventricle with elevated end-diastolic pressure[2]. . . . Occasionally a mid-systolic click can be confused with an ejection click. The phonocardiogram ends the confusion and indicates a change in the implication from one of great vessel disease to considerations of previous pericarditis or mitral regurgitation.[3,4]

Left Bundle Branch Block

Reversed splitting of the second heart sound may be difficult to identify at the bedside without considerable experience. The phonocardiogram with a carotid pulse for timing can make this phenomenon obvious. The reversed splitting of the second heart sound (Figure 3) was recorded from a patient with left bundle branch block. Although the reversed split is a common and reliable diagnostic feature of this conduction abnormality, it can be helpful for evaluating other problems. The presence

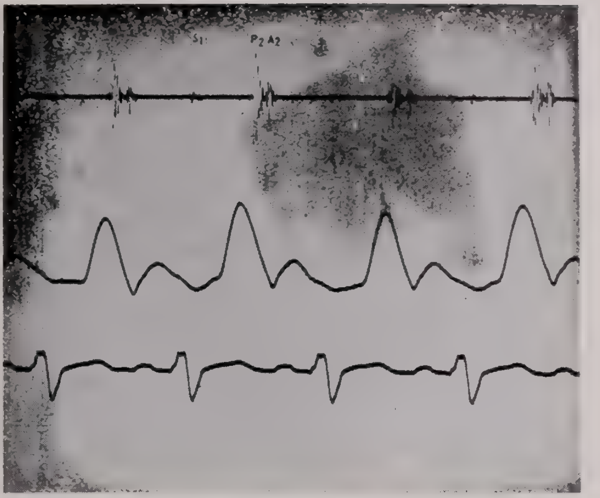

Fig. 3—Reversed Splitting of Second Heart Sound. Close temporal association of A2 with dicrotic notch on carotid pulse tracing identifies it as aortic closure. Occurrence of pulmonic closure prior to aortic closure establishes diagnosis of reversed splitting of second sound. Left bundle branch block is noted on accompanying electrocardiogram.

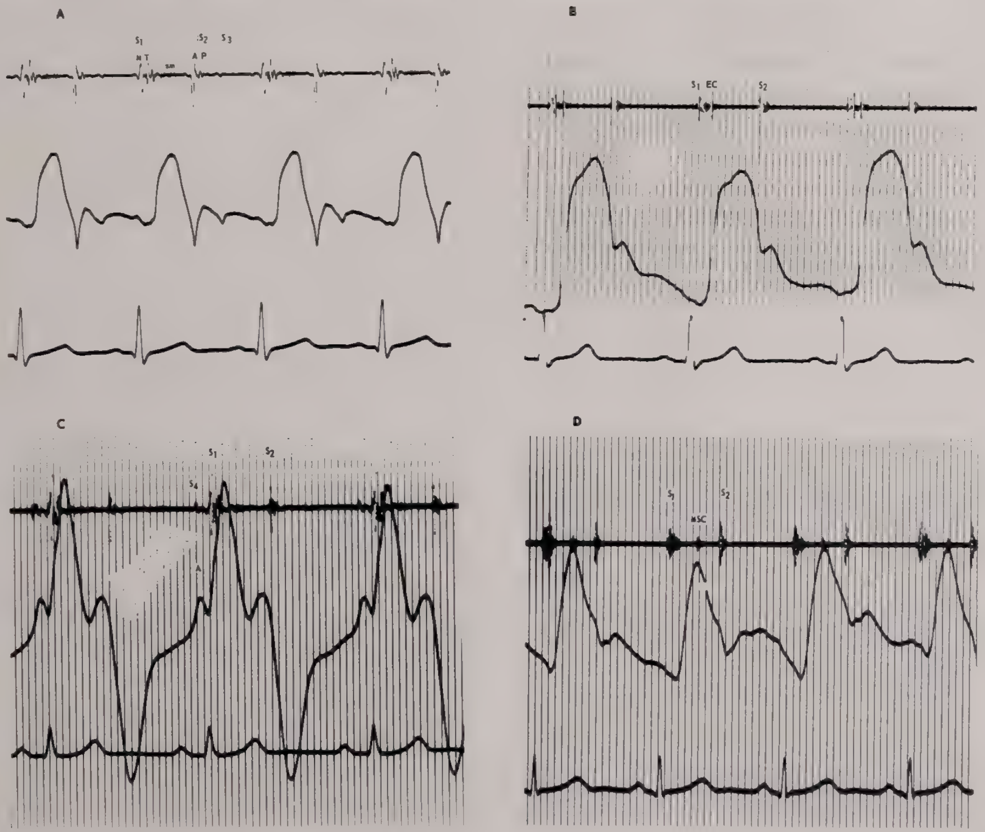

Fig. 2—Auscultatory Events Around First Heart Sound. (A) Split first sound. Separation between mitral (M) and tricuspid (T) is observed. Both occur after onset of QRS in electrocardiogram and before upstroke of the carotid pulse. (B) Aortic ejection click appears somewhat later and corresponds to upstroke of carotid pulse. (C) Fourth heart sound (S_4) on the phonocardiogram corresponds to A wave of apex cardiogram and occurs during the P-R interval of electrocardiogram. (D) Mid-systolic click (MSC) on phonocardiogram occurs well after onset of carotid pulse upstroke and well after QRS on electrocardiogram.

of this feature during an attack of chest pain can aid in establishing the diagnosis of ischemic heart disease.[5]

Specific Diagnoses

Some cardiovascular abnormalities have rather characteristic constellations of physical findings that lend themselves well to graphic analysis. In addition to aiding in clinical diagnosis, recordings of these abnormalities can serve as permanent displays in which the salient features can be emphasized for teaching purposes.

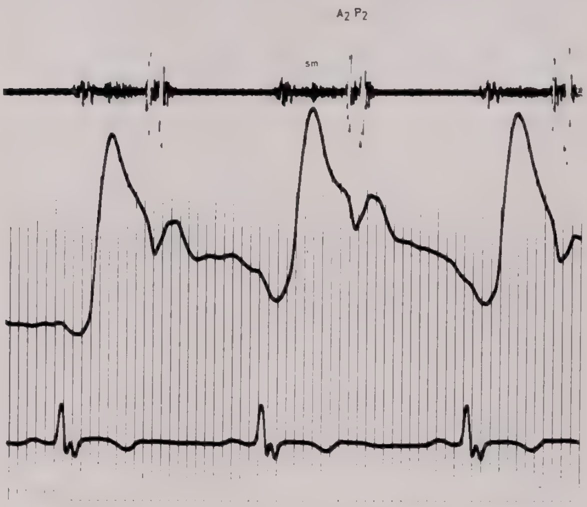

Fig. 4—Atrial Septal Defect. Phonocardiogram: systolic ejection murmur (SM), wide fixed splitting of S_2, accentuated pulmonic closure (P_2). Electrocardiogram: right ventricular conduction defect. Carotid pulse allows accurate timing of semilunar closure.

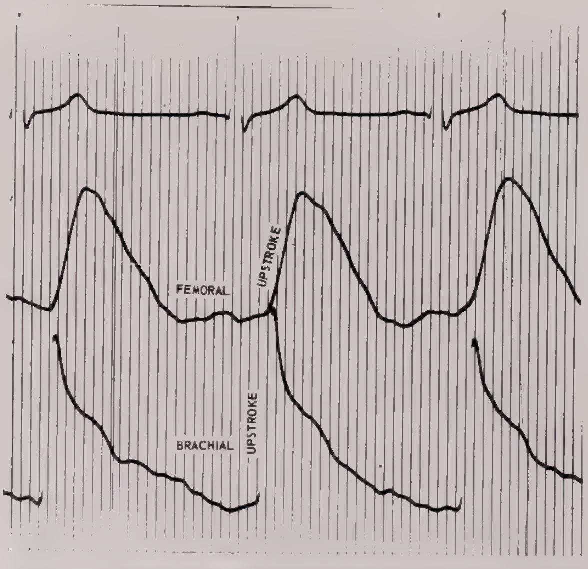

Fig. 5—Aortic Coarctation. Marked slowing of the upstroke is noted in the femoral pulse tracing. Brachial upstroke is normal.

Atrial Septal Defect

Figure 4 demonstrates the classic findings in the pulmonic area with an atrial septal defect, i.e., the systolic ejection murmur; the split second heart sound, which does not vary with respiration; and the prominent pulmonic closure. Many young men with systolic murmurs are evaluated annually in the Cardiac Clinic. The phonocardiogram has become a valuable screening tool for determining whether fixed splitting of the second heart sound is present in these patients.

Aortic Coarctation

Aortic coarctation is a curable form of hypertension that is frequently misdiagnosed. Simple palpation of the brachial and femoral pulses will allow one to make this diagnosis, for the difference in speed of the upstroke between the two pulses is quite striking. After seeing an example such as Figure 5, a physician is not apt to neglect examination of the femoral pulses in a hypertensive workup.

Patent Ductus

Another pathognomonic cardiovascular sign is the continuous murmur of patent ductus arteriosus, which may often be confused with the combined systolic and diastolic murmurs of aortic stenosis and aortic regurgitation. This is especially true if an adult presents with a previous diagnosis of aortic valvular disease and signs of a marked aortic run-off, like a recent patient at this hospital. Even after careful examination, several members of the staff were swayed into describing separate systolic and diastolic murmurs. The phonocardiogram (Figure 6) shows the continuous nature of the murmur with its peaking around the second heart sound and confirmed a central arteriovenous shunt.

Tricuspid Stenosis

At times, graphic methods may help to separate coincident lesions, as in the study of the young woman with rheumatic heart disease, as illustrated in Figure 7. Mitral stenosis was known to be present, but diagnosis of possible tricuspid involvement remained a problem. Inspiratory augmentation of the presystolic murmur at the tricuspid area, with simultaneous diminution in the one recorded at the mitral area, justified the diagnosis of tricuspid stenosis as a second lesion. The prominent A wave on the jugular venous pulse tracing was confirmatory. These diagnoses were documented at cardiac catheterization and surgical attack on both valves was successful.

As mentioned earlier, many Air Force recruits are screened in the Cardiology Clinic for systolic murmurs, many of which are presumed innocent in the absence of other cardiovascular abnormalities. Occasionally the

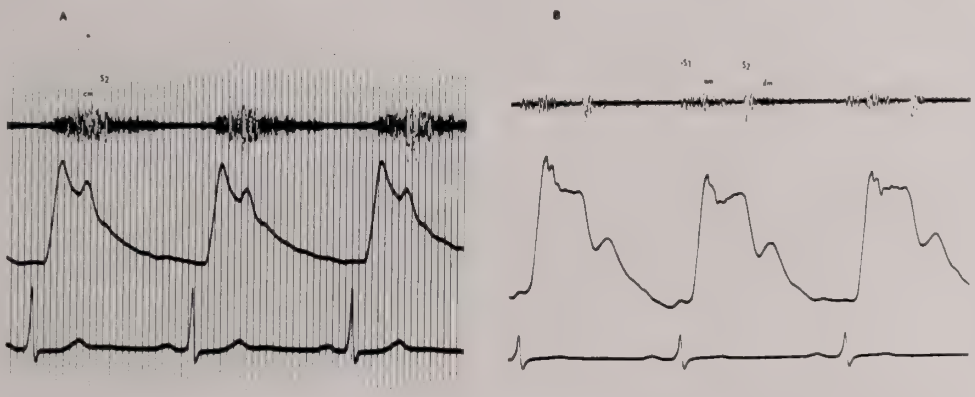

Fig. 6—(A) Patent Ductus Arteriosus. Phonocardiogram displays continuous murmur (cm) which peaks around second sound (S_2). It extends into mid-diastole. Carotid pulse tracing shows bisferiens nature characteristic of aortic run-off. (B) Combined aortic valve lesions. Systolic ejection murmur (sm) of aortic stenosis ends well before second sound (S_2). Semilunar diastolic murmur (dm) begins with S_2. Bisferiens carotid pulse noted.

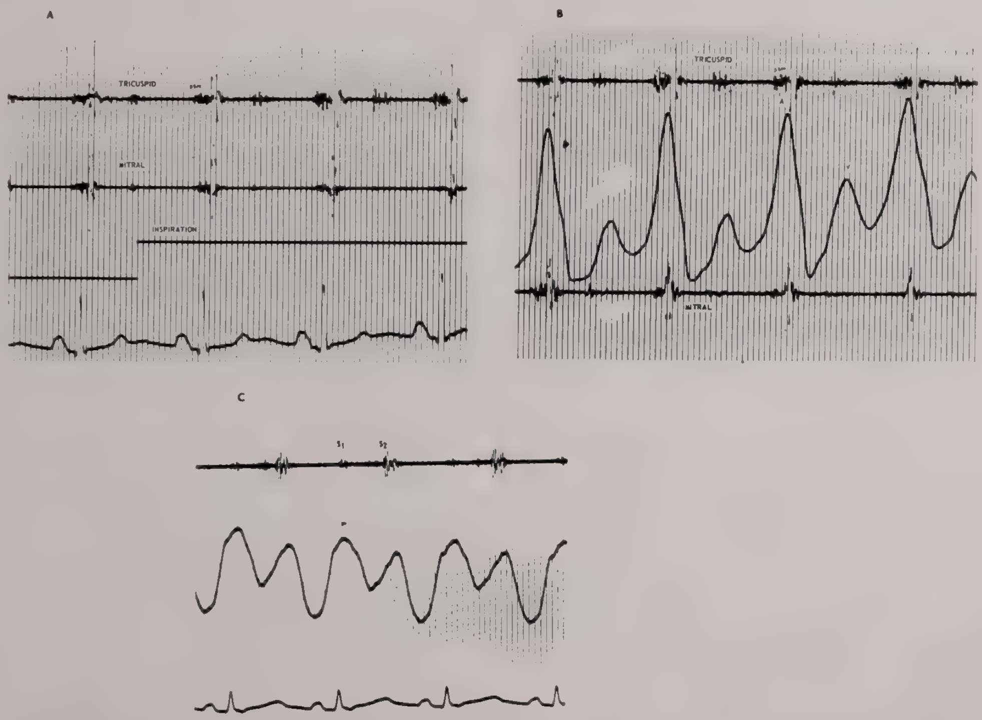

Fig. 7—Tricuspid and Mitral Stenosis. Inspiration increases amplitude of presystolic murmur (psm) in tricuspid phonocardiogram. The murmur of mitral stenosis is diminished with inspiration. (B) Very prominent A wave on jugular venous pulse from same case. (C) Postoperative tracing from same case. Diminution in height of A wave on jugular venous pulse. Reduction in presystolic murmur.

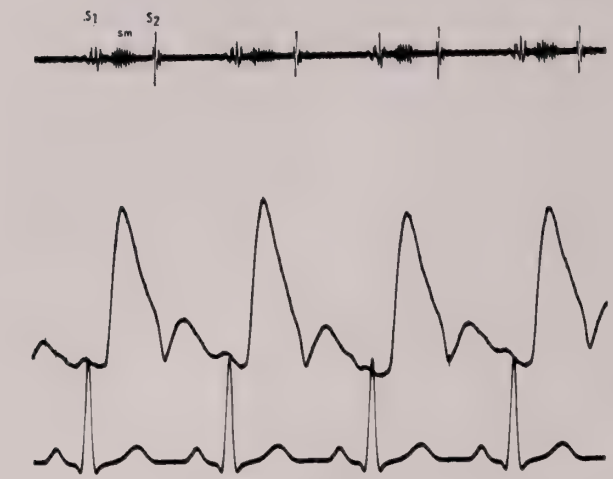

Fig. 8—Innocent Systolic Murmur. Systolic murmur (sm) with pure tone or vibratory quality.

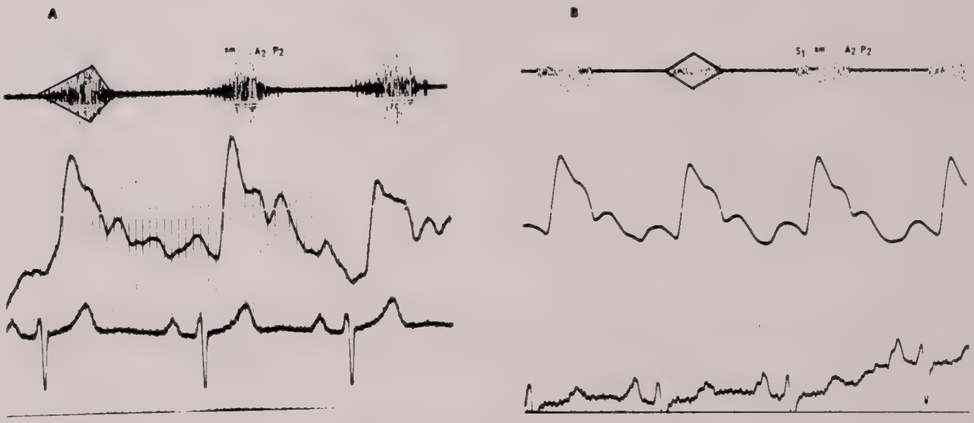

Fig. 9—Valvular Pulmonic Stenosis with Intact Ventricular Septum. Systolic murmur (sm) peaks late, partially obscures aortic closure (A_2), and persists beyond aortic closure. Wide split of second sound with delayed pulmonic closure (P_2). (B) Postoperative tracing from same case. Systolic murmur (sm) is shorter and peaks earlier than preoperative.

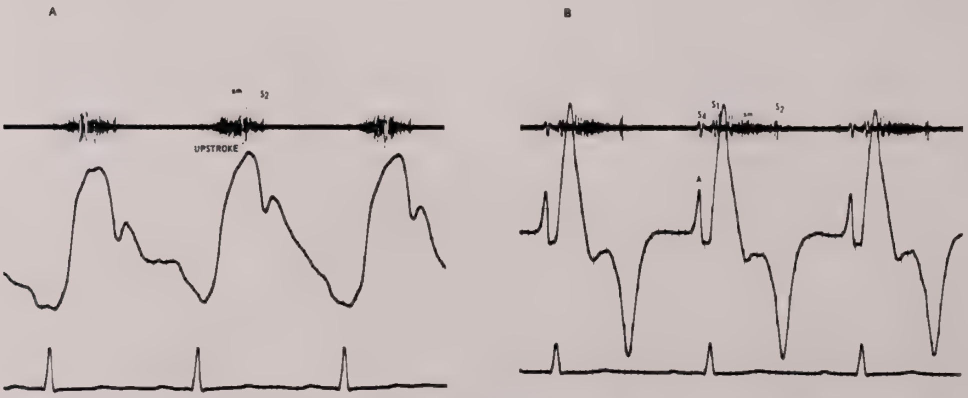

Fig. 10—Valvular Aortic Stenosis. (A) Phonocardiogram: systolic ejection murmur. Carotid pulse tracing: delayed and rounded upstroke. (B) Phonocardiogram: atrial gallop (S_4) corresponding to large A wave on apex cardiogram.

appearance of the murmur on the recording is characteristic of a pure tone or vibratory nature, and is useful in confirming its innocent origin.

Assessing Severity of Lesions

Pulmonic Stenosis

The severity of many cardiovascular lesions can be estimated quite accurately from the physical findings. Semi-quantitative evaluation of certain lesions may be made by analyzing graphic methods. A lesion of this type is pulmonic stenosis. Good correlation has been noted between the form and duration of the systolic murmur, the split second heart sound, and the peak systolic right ventricular pressure found at catheterization.[6] The recording of a patient with moderate pulmonic stenosis, a peak right ventricular pressure of 140 mm Hg and a gradient of 100 mm Hg across the pulmonic valve is shown in Figure 9. The murmur extends beyond aortic closure and peaks late, and the second sound is widely split in the preoperative recording. After successful surgery, the murmur is shorter and peaks earlier, and the split of the second sound is narrower.

Aortic Stenosis

Aortic stenosis differs slightly from pulmonic stenosis. Although the duration of the murmur may be of some help, it is often misleading when assessing the degree of obstruction. Narrow or reversed splitting of the second sound may be more helpful in evaluating prolongation of left ventricular ejection, or a fourth sound may indicate elevated left ventricular end-diastolic pressure. The most useful findings are those in the carotid pulse.[7] The slowed upstroke, systolic thrill, and prolonged ejection time can be appreciated at the bedside. On the indirect carotid pulse tracing they can be measured and the gradient estimated. Figure 10 illustrates the significant features in a patient with valvular aortic stenosis and a transaortic gradient of 80 mm Hg. Estimation of the severity of aortic stenosis is particularly important, because it may facilitate a decision regarding catheterization in this disease—a procedure that is attended with increased risk resulting from the need for some form of arterial puncture.

Mitral Stenosis

In some instances, cardiac catheterization may be impractical and even contraindicated. Graphic studies provide quantitative data under such circumstances. The example in Figure 11 is taken from a study of a 22-year-old woman in the first trimester of pregnancy who presented with symptoms of pulmonic congestion. The possible risk of irradiation to the fetus during catheterization was considered a relative contraindication to that procedure. The information presented in this illustration was sufficient for a diagnosis of mitral stenosis of surgical severity and led to successful commissurotomy.

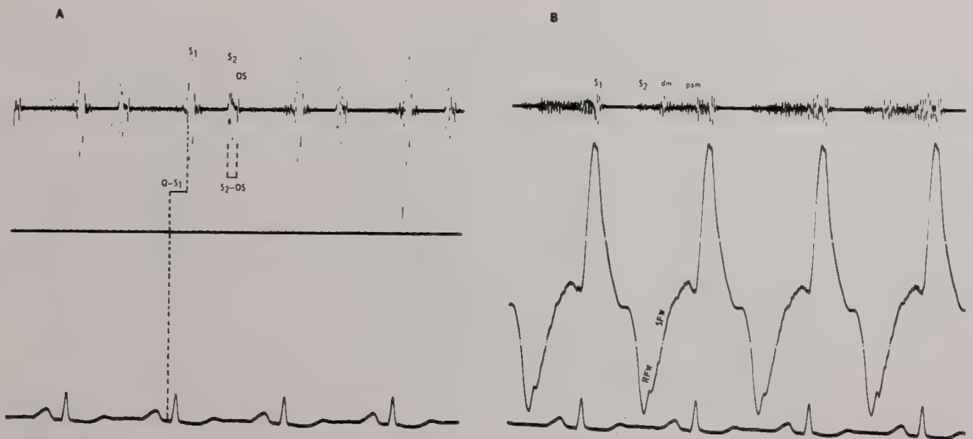

Fig. 11—Mitral Stenosis. (A) Method of determining Q-S_1 and II-OS intervals. Phonocardiogram is recorded in mitral area. (B) Phonocardiogram: diastolic murmur (dm) and presystolic murmur (psm). Apex cardiogram: blending of rapid filling wave (RFW) and slow filling wave (SFW) into single gradual diastolic wave.

Previous studies have established the prolongation of the Q-S_1 interval and the shortening of the II-OS interval in association with left atrial hypertension, secondary to the mitral obstruction.[8,9] When the Q-S_1 exceeds the II-OS interval, usually critical mitral stenosis is present. In this patient the II-OS interval is 0.05 seconds, and the Q-S_1 interval 0.09 seconds.

Another measure of mitral block is the alteration in the left ventricular filling pattern observed with this condition.[10] The apex cardiogram includes a gradual filling wave that does not show the usual neat separation between the rapid and the slow-filling phases. It is well illustrated in Figure 11, which also shows the typical opening snap and the diastolic murmur of mitral stenosis.

Evaluation of Therapy

Graphic studies can be used to evaluate the effects of treatment as well as to estimate the severity of certain lesions and follow their progression. The reappearance of a rapid filling wave on the apex cardiogram is a convenient method of assessing the hemodynamic benefit of mitral commissurotomy. Preoperative and postoperative tracings of a 35-year-old woman are shown in Figure 12. The transition from the gradual filling slope to one with distinct rapid and slow filling phases is apparent and indicates effective relief of the mitral obstruction.

Another example of serial tracings (Figure 13) pertains to a patient who had mitral valve surgery. The preoperative tracing made with

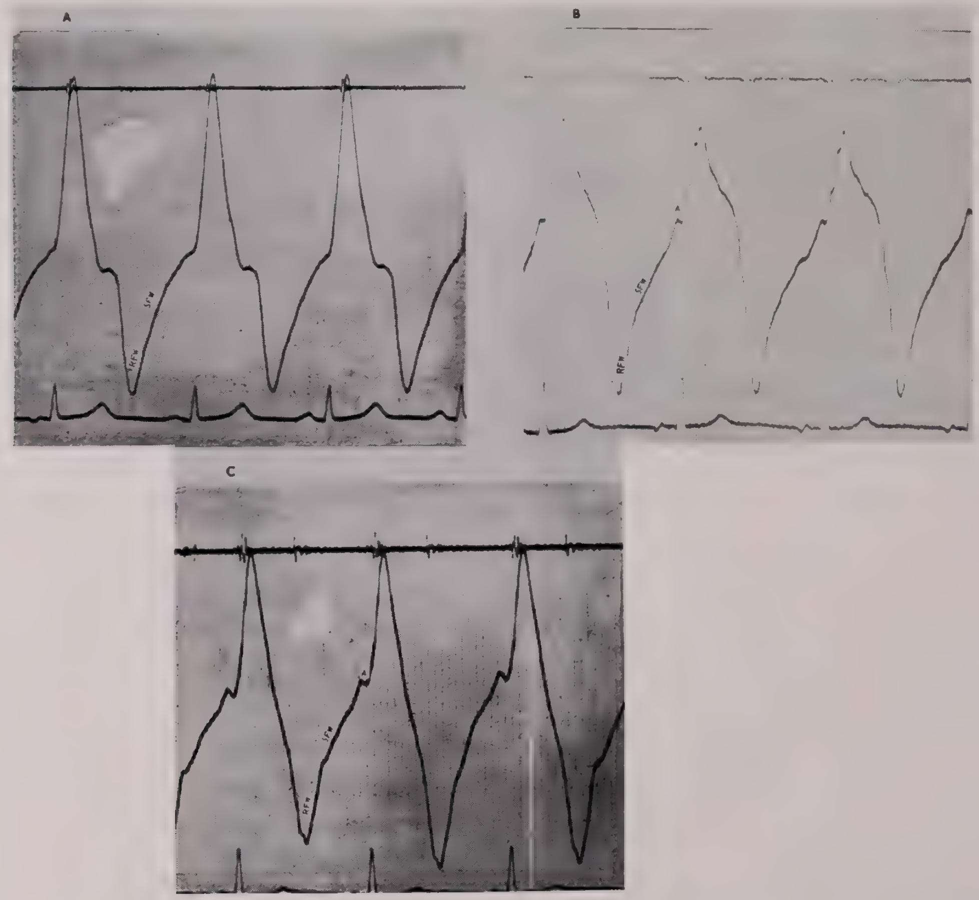

Fig. 12—Mitral Stenosis. (A) Preoperative tracing. Apex cardiogram: no recognizable separation between rapid filling wave (RFW) and slow filling wave (SFW). (B) Phonocardiogram and apex cardiogram three weeks postoperatively. Distinction between RFW and SFW now apparent. Return of A wave. All are evidence of relief of obstruction. (C) Tracing six weeks postoperatively; better definition of RFW, SFW, and A waves.

the phonocardiogram recorded in the mitral area shows the typical systolic regurgitant murmur, the mitral opening snap, and the ventricular gallop corresponding to the top of an accentuated rapid filling wave on the apex cardiogram that comprise the diagnostic findings of mitral regurgitation. The ventricular gallop is followed by a short flow rumble, which attests to the hemodynamic significance of the mitral leak. The postoperative study shows the sharp clicks associated with the closing and the opening of the mitral prosthesis. The systolic murmur is markedly diminished; the ventricular gallop and diastolic flow murmur are no longer present; and the diastolic motion of the apex is more nearly normal.

Some Surprises

Although we have emphasized that all of the information on the graphic recordings is available at the bedside, sometimes it is neglected or misinterpreted by the physician. On these occasions the tracings can teach the important lesson of humility and serve as a valuable supplemental method of study. Two examples are presented to illustrate this. The first tracing (Figure 14a) was made to evaluate chest pain and an atypical systolic murmur

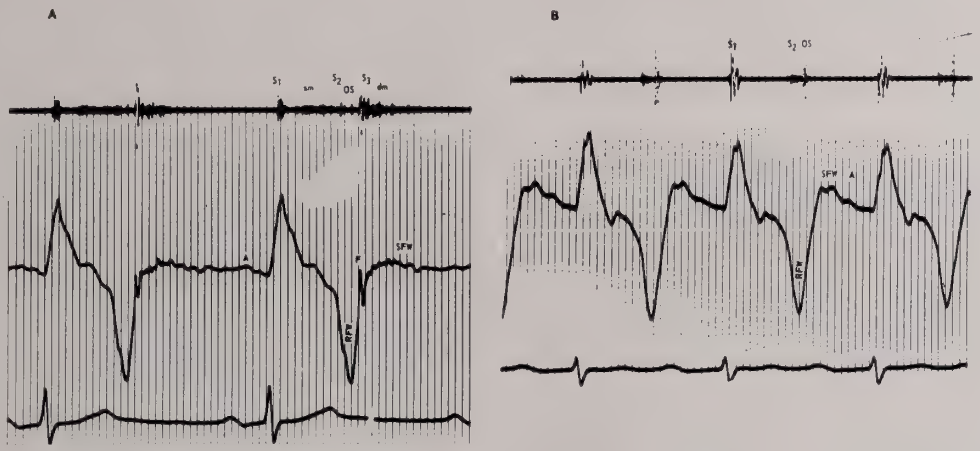

Fig. 13—Mitral Regurgitation. Preoperative tracing. Phonocardiogram: systolic murmur (sm), opening snap (os), ventricular gallop (S_3), and diastolic flow murmur (dm). Apex cardiogram: accentuated rapid filling wave (RFW) with significant peak (F), corresponding to ventricular gallop. (B) Postoperative replacement with Starr-Edwards prosthesis. Phonocardiogram: augmented opening sound of prosthetic valve (OS). Absence of previous murmurs. Apex cardiogram: disappearance of (F) wave and more normal behavior of RFW and SFW.

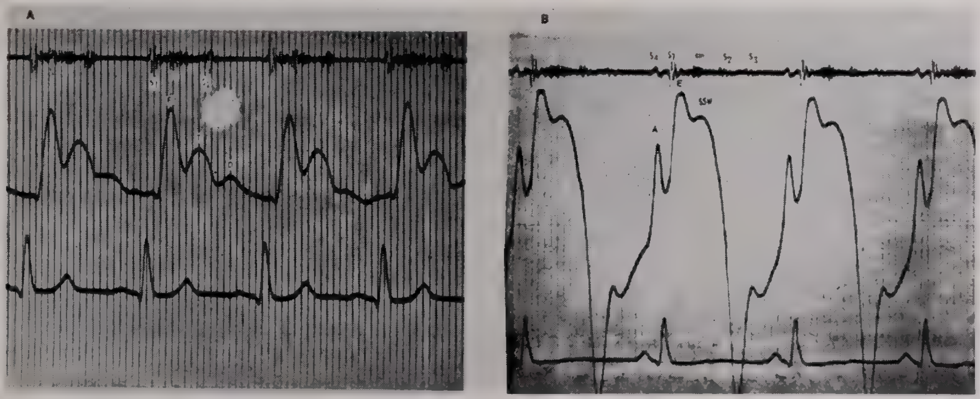

Fig. 14—Muscular Subaortic Stenosis. Phonocardiogram: systolic ejection murmur (sm). Reversed split of second sound (S_2). Carotid pulse tracing: prominent tidal wave (T) in combination with percussion wave (P) and dicrotic waves (D) produce typical m shape of carotid pulse. (B) Phonocardiogram at apex: atrial gallop (S_4) and ventricular gallop (S_3) corresponding respectively to augmented A wave and top of rapid filling wave on apex cardiogram. Apex tracing also shows second systolic bulge (SSW), another characteristic of this lesion.

in a young man. During a cardiology teaching conference, at which his case was presented, the physical examination was conducted by an experienced cardiologist, but no definitive diagnosis was made. Perusal of the carotid tracing later disclosed the typical m-shape curve[11] that is characteristic of muscular subaortic stenosis. This diagnosis was confirmed at cardiac catheterization. The atrial and ventricular gallops, which can be part of this syndrome as well as the characteristic second systolic wave on the apex tracing, are seen in Figure 14b.

Figure 15 illustrates the use of graphic studies for indicating the presence of unusual physiology, which is not always appreciated clinically. The patient was a 26-year-old woman who had undergone successful mitral replacement with a Starr-Edwards prosthesis in 1966. On a routine follow-up two years later, she was believed to be suffering from mild digitalis toxicity. An indication of this condition is the markedly prolonged P-R interval on the electrocardiogram. However, the unusual sound pattern of the prosthetic valve was not appreciated clinically. The first sound, which is very faint, lacks the prominent high frequency component that is characteristic of prosthetic valve closure. On the other hand, a prominent opening click occurs at the appropriate time in diastole. A similar click that occurs somewhat later in diastole suggests a prosthetic origin.

Examination of the electrocardiogram and the apex cardiogram indicates that atrial contraction must occur at about the time that the prosthesis opens. Early ventricular filling is then accomplished both passively and by active atrial contraction. It was thought that the combined mechanism of ventricular filling was effective in raising left ventricular pressure above left atrial pressure prior to the onset of left ventricular systole and led to premature closure of the prosthetic valve. Unfortunately, this speculation remained untested, for digitalis had been stopped and the patient had returned to her home before this fascinating graphic study was analyzed. This study illustrates again how use of the Graphic Laboratory can reveal previously overlooked, but significant physical findings and how careful analysis of the tracing can contribute to an understanding of the disordered hemodynamics.

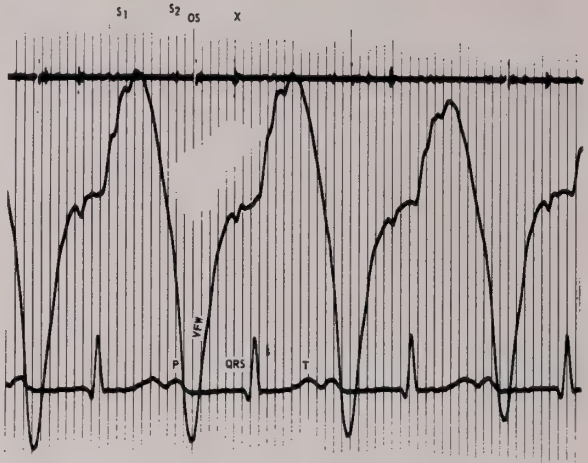

Fig. 15—Starr-Edwards Prosthesis with First Degree Heart Block. Phonocardiogram: first sound (S_1) is reduced in amplitude. The opening sound (OS) of the prosthetic valve corresponds to the 0 point on the apex cardiogram. High frequency sound (X) occurs in mid diastole at the top of ventricular filling wave, (VFW), of accompanying apex cardiogram. Electrocardiogram documents prolonged atrioventricular conduction with P-R interval 0.36 sec.

Summary

A review of about 1,200 graphic studies of the cardiovascular system has indicated their value in teaching physical diagnosis. The tracings serve as a reference that the physician can consult in checking his findings. Some types of cardiovascular lesions have graphic representations that are sufficiently characteristic for making the diagnosis as well as giving instruction on the typical findings. An analysis by graphic methods also permits semi-quantitation of the lesions, and this information is valuable in deciding whether to do a cardiac catheterization or surgery if a catheterization is not feasible. The physician also can follow the progress of some lesions and assess the effectiveness of the surgical treatment. On occasion, these studies have indicated diagnoses not previously apparent. Graphic methods are not only safe and easy to use, but also of considerable value to the teaching program at Wilford Hall USAF Hospital.

Acknowledgment

To the following people: TSgt Dale Gindlesperger and Mrs. Beatrice Hays, whose diligence and technical skill produced the recordings; Mrs. Lydie Dyer, whose facility with language transformed the manuscript into English; and Mrs. Mary L. Richardson, who coordinated the effort and carried it through to completion, most sincere appreciation and gratitude are extended.

Book Reviews

Books are the compasses and telescopes and sextants and charts which other men have prepared to help us navigate the dangerous seas of human life.—Jesse Lee Bennett

RECENT ADVANCES IN MEDICINE—Edited by Baron, Compston and Dawson. 433 pages. Published by Little, Brown & Co., 34 Beacon Street, Boston, Mass., 15th Edition, June 1968. Price $15.50.

This is the 15th edition of a well established review book, first published in 1924. The editors state in their foreword, "The chapters are intended to be readable and critical surveys of important subjects and are written by authors actively working in those fields. Once again they are designed for undergraduate and postgraduate students, as well as for consultants and general medical and scientific readers, rather than for specialists in their respective fields."

This volume succeeds beautifully in the stated aims and covers the following topics: Computers in Medicine, Diseases of Muscle, Coagulation Disorders, Poisoning, Disorders of the Adrenal Cortex and Pituitary Gland, Iron Metabolism, Clinical Pharmacogenetics, Systemic Mycoses, Hypertension, Leukemia, Temperature Regulation and Its Disorders, Environmental Factors in Disease, and Cardiac Infarction and Cardiac Resuscitation. Sixteen distinguished contributors have produced brief, concise readable reviews which are noteworthy for their crisp styling and clever phrasing. While all the chapters are well done, the essays on Computers in Medicine, Poisoning, Clinical Pharmacogenetics, Temperature Regulation and Environmental Factors in Disease are worthy of special comment.

One cannot help but compare this review with its American counterparts, namely, the Annual Reviews of Medicine and the Advances in Internal Medicine. It is regrettable that certain subjects, such as the treatment of newer diuretics, transplantation immunology, polypeptide hormone assays and recent advances in pharmacology, such as the development of propanolol and newer antibiotics, have been omitted from the British volume.

This book makes up for any deficiencies in editorial selection of titles by its beautiful prose style, clarity and brevity. The volume is handsomely bound and deserves a place on the bookshelves of practitioners and consultant physicians alike.

Steven C. Beering, Lt. Colonel, USAF, MC, F.A.C.P.
Chief, Internal Medicine Service

COOPERATIVE STUDY ON CARDIAC CATHETERIZATION. By E. Braunwald, M.D., Professor and Chairman, Department of Medicine, University of California, San Diego School of Medicine, La Jolla, California; H. J. C. Swan, M.B., Ph.D. Director, Department of Cardiology, Cedars Sinai Medical Center, Los Angeles, California; American Heart Association, Inc., New York, 1968; 113 pp., $2.25.

Between the covers of this imposingly titled book is data on the mortality and morbidity of cardiac catheterization based on analysis of 12,367 procedures performed in 16 laboratories between 1 November 1963 and 31 October 1965. Today, with catheterization a widely used diagnostic tool and with many physicians performing similar procedures, e.g., central venous pressure monitoring, this type of information is of inestimable value.

The book is a compilation of statistical data with case reports to illustrate specific points. Each chapter is complete in itself and has been written by one or more of the six collaborating physicians. Chapters deal with design and data handling incident to the study; with specific complications, e.g., arrhythmias; with specific groups, e.g., infants; and with specific procedures, e.g., coronary arteriography.

Although not included in the purpose of the study, I would have liked some concrete suggestions to minimize the complications reported. A chapter, "Alterations in Catheterization Techniques During the Course of the Study," only hinted at this. The group of outstanding cardiologists who conducted this study are uniquely qualified to draw such conclusions on the basis of their data.

All in all, this book contains a wealth of statistical data and is well worth the $2.25 out of any physician's pocket.

Eliot Schechter, Lt. Colonel, USAF, MC
Chief, Cardiology Service

Hot
under
the collar...
high under
the cuff.

Sometimes
he forgets he has hypertension, gets hot under the collar. . .high under the cuff.

For such
patients, consider **Regroton®**

chlorthalidone	50 mg.
reserpine U.S.P.	0.25 mg.

To lower blood pressure
and allay anxiety in hypertension.

For brief summary of prescribing information, see next page.

RE-6392

Regroton®

Geigy

chlorthalidone 50 mg.
reserpine U.S.P. 0.25 mg.

the once-a-day tablet for anxious hypertensives

Regroton is a combination of two basic antihypertensives designed to lower blood pressure and allay anxiety in hypertension. With Regroton he can keep his shirt on and you can keep his blood pressure down.

Before prescribing, please review carefully the indications, contraindications, warning, precautions, adverse reactions and dosage information below.

Regroton®
Each tablet contains:
chlorthalidone 50 mg.
reserpine U.S.P. 0.25 mg.

Indications: Hypertension.
Contraindications: History of mental depression, hypersensitivity, and most cases of severe renal or hepatic diseases.
Warning: With the administration of enteric-coated potassium supplements, which should be used only when adequate dietary supplementation is not practical, the possibility of small-bowel lesions (obstruction, hemorrhage, and perforation) should be kept in mind. Surgery for these lesions has frequently been required and deaths have occurred. Discontinue coated potassium-containing formulations immediately if abdominal pain, distention, nausea, vomiting, or gastrointestinal bleeding occur. Discontinue one week before electroshock therapy, and if depression or peptic ulcer occurs.
Use in pregnancy: Because chlorthalidone may cross the placental barrier and appear in cord blood and thiazides may appear in breast milk, this drug should be used with care in pregnant patients and nursing mothers. When used in women of childbearing age, the potential benefits of the drug should be weighed against the possible hazards to the fetus. Use of chlorthalidone may result in fetal or neonatal jaundice, thrombocytopenia, and possibly other adverse reactions which have occurred in the adult. Increased respiratory secretions, nasal congestion, cyanosis and anorexia may occur in infants born to reserpine-treated mothers.
Precautions: Antihypertensive therapy with this drug should always be initiated cautiously in postsympathectomy patients and in patients receiving ganglionic blocking agents, other potent antihypertensive drugs, or curare. Reduce dosage of concomitant antihypertensive agents by at least one-half. To avoid hypotension during surgery, discontinue therapy with this agent two weeks prior to elective surgical procedures. In emergency surgery, use, if needed, anticholinergic or adrenergic drugs or other supportive measures as indicated. Because of the possibility of progression of renal damage, periodic kidney function tests are indicated. Discontinue if the BUN rises or liver dysfunction is aggravated. Hepatic coma may be precipitated. Electrolyte imbalance, sodium and/or potassium depletion may occur. If potassium depletion should occur during therapy, the drug should be discontinued and potassium supplements given, provided the patient does not have marked oliguria.
Take particular care in cirrhosis or severe ischemic heart disease and in patients receiving corticosteroids, ACTH, or digitalis. Severe salt restriction is not recommended. Use cautiously in patients with ulcerative colitis or gallstones (biliary colic may be precipitated). Bronchial asthma may occur in susceptible patients.
Adverse Reactions: The drug is generally well tolerated. The most frequent side effects are nausea, gastric irritation, vomiting, diarrhea, constipation, muscle cramps, headache, dizziness and acute gout. Other potential side effects include angina pectoris, anxiety, depression, bradycardia and ectopic cardiac rhythms (especially when used with digitalis), drowsiness, dull sensorium, hyperglycemia and glycosuria, hyperuricemia, lassitude, restlessness, transient myopia, impotence or dysuria, orthostatic hypotension which may be potentiated when chlorthalidone is combined with alcohol, barbiturates or narcotics, leukopenia, aplastic anemia, skin rashes, thrombocytopenia, agranulocytosis, nasal stuffiness, increased gastric secretions, nightmare, purpura, urticaria, ecchymosis, weakness, uveitis, optic atrophy and glaucoma, and pruritus. Eruptions and/or flushing of the skin, a reversible paralysis agitans-like syndrome, blurred vision, conjunctival injection, increased susceptibility to colds, dyspnea, weight gain, decreased libido, dryness of the mouth, deafness, anorexia, and pancreatitis when epigastric pain or unexplained G.I. symptoms develop after prolonged administration. Jaundice, xanthopsia, paresthesia, photosensitization and necrotizing angiitis are possible.
Average Dosage: One tablet daily with breakfast.
Availability: Pink, single-scored tablets in bottles of 100 and 1000.

Electroencephalography Course

A Course in Current Problems in Electroencephalography: Advances toward their Solution; Date: March 13-15, 1969, Place: Houston, Texas. Sponsors: The American Electroencephalographic Society and Baylor University College of Medicine. For further information contact: Dr. Peter Kellaway, Baylor University College of Medicine, Texas Medical Center, Houston, Texas 77025.

Minnesota Heart Association Seeks Young Scientists

Applications are now available for two months of study at either the Mayo Graduate School of Medicine or the University of Minnesota, through the MHA high school summer fellowship program.

Twenty students will be chosen and assigned projects with heart researchers. In addition, they will be awarded a $400.00 stipend. Students selected from outside the Twin Cities or Rochester areas will be given an additional $200.00 for room and board.

Those interested in applying should consult their high school counselor or write the Minnesota Heart Association, 1821 University Avenue, St. Paul, Minnesota 55104.

Deadline for applications is April 1, 1969, and notification of the scholarship awards will be made by April 30, 1969.

the thousandth teaspoonful

Peptic ulcer patients find the thousandth dose of this antacid as effective and easy-to-take as the first!

Optimal neutralization[1] — provided by the combination of aluminum and magnesium hydroxides.
Unfailing good taste — confirmed by 87.5% of 104 patients in one study, after a total of 20,459 documented days on Mylanta Liquid or tablets.[2]
Concomitant relief of G. I. gas distress — provided by the proven antiflatulent action of simethicone[3].

Dosage: One or two tablets (well chewed or allowed to dissolve in the mouth); one or two teaspoonsful to be taken between meals and at bedtime, or as directed by physician.

DECLOSTATIN® 300

Demethylchlortetracycline HCl 300 mg
and Nystatin 500,000 units
CAPSULE-SHAPED TABLETS Lederle

b.i.d.

To guard susceptible patients against intestinal monilial overgrowth during broad-spectrum therapy—the protection of nystatin is combined with demethylchlortetracycline in DECLOSTATIN.

For your susceptible candidates, prescribe DECLOSTATIN—the broad-spectrum therapy that prevents monilial overgrowth.

Effectiveness: Because its antibacterial component is DECLOMYCIN Demethylchlortetracycline, DECLOSTATIN should be equally or more effective therapeutically than other tetracyclines in infections caused by tetracycline-sensitive organisms. The antifungal component, Nystatin, protects against superinfection by antibiotic-resistant fungal overgrowth (particularly monilia) in the intestinal tract.

Contraindication: History of hypersensitivity to demethylchlortetracycline or nystatin.

Warning: In renal impairment, usual doses may lead to excessive accumulation and liver toxicity. Under such conditions, lower than usual doses are indicated, and, if therapy is prolonged, serum level determinations may be advisable. A photodynamic reaction to natural or artificial sunlight has been observed. Small amounts of drug and short exposure may produce an exaggerated sunburn reaction which may range from erythema to severe skin manifestations. In a smaller proportion, photoallergic reactions have been reported. Patients should avoid direct exposure to sunlight and discontinue drug at the first evidence of skin discomfort. Necessary subsequent courses of treatment with tetracyclines should be carefully observed.

Precautions: Overgrowth of nonsusceptible organisms may occur. Constant observation is essential. If new infections appear, appropriate measures should be taken. In infants, increased intracranial pressure with bulging fontanels has been observed. All signs and symptoms have disappeared rapidly upon cessation of treatment.

Side Effects: Gastrointestinal system—anorexia, nausea, vomiting, diarrhea, stomatitis, glossitis, enterocolitis, pruritus ani. Skin—maculopapular and erythematous rashes; a rare case of exfoliative dermatitis has been reported. Photosensitivity; onycholysis and discoloration of the nails (rare). Kidney—rise in BUN, apparently dose related. Transient increase in urinary output, sometimes accompanied by thirst (rare). Hypersensitivity reactions—urticaria, angioneurotic edema, anaphylaxis. Teeth—dental staining (yellow-brown) in children of mothers given this drug during the latter half of pregnancy, and in children given the drug during the neonatal period, infancy and early childhood. Enamel hypoplasia has been seen in a few children. If adverse reaction or idiosyncrasy occurs, discontinue medication and institute appropriate therapy. Demethylchlortetracycline may form a stable calcium complex in any bone-forming tissue with no serious harmful effects reported thus far in humans.

Average Adult Daily Dosage: 150 mg q.i.d. or 300 mg b.i.d. Should be given 1 hour before or 2 hours after meals, since absorption is impaired by the concomitant administration of high calcium content drugs, foods and some dairy products. Treatment of streptococcal infections should continue for 10 days, even though symptoms have subsided.

Morton Salt introduces will power in a shaker

HALF/SALT MIXTURE
MORTON
HALF/SALT
MIXTURE
NET WT. 3½ OZ.

You probably know how hard it is for your patients to stay on a low-sodium diet. They try, but simply can't cut out salt completely. Now there's a product that's far more dependable than will power: New Morton Half/Salt Mixture™.

It contains half the sodium of table salt but gives your patients all the satisfaction of true salt flavor. If your patients think low-sodium diets are hard to swallow, let them use new Morton Half/Salt Mixture. It's a happy compromise.

Meet the Chairman

...you have a lot going for you in the wide range of bacterial infections.

PRESCRIBING INFORMATION. For complete information consult Official Package Circular. **Indications:** Infections due to susceptible strains of Gram-negative bacteria (including Shigellae, *S. typhosa* and other Salmonellae, *E. coli*, *H. influenzae*, *P. mirabilis*, *N. gonorrhoeae* and *N. meningitidis*) and Gram-positive bacteria (including streptococci, pneumococci and nonpenicillinase-producing staphylococci).

Contraindications: A history of allergic reactions to penicillins or cephalosporins and infections due to penicillinase-producing organisms.

Precautions. Typical penicillin-allergic reactions may occur, especially in hypersensitive patients. Mycotic or bacterial superinfections may occur. Experience in newborn and premature infants is limited and caution should be used in treatment, with frequent organ function evaluations. Safety for use in pregnancy is not established. In gonorrheal therapy, serologic tests for syphilis should be performed initially and monthly for 4 months. Assess renal, hepatic and hematopoietic function intermittently during long-term therapy.

Adverse Reactions: Skin rash, pruritus, urticaria, nausea, vomiting, diarrhea and anaphylactic reactions. Mild transient elevations of SGOT or SGPT have been noted. Black tongue has been noted in some patients receiving the Chewable Tablets.

Usual Dosage: Adults—250 or 500 mg. q. 6 h. (according to infection site and offending organisms). Children—50-100 mg./Kg./day in 3 to 4 divided doses (depending on infection site and offending organisms). Bacterial meningit
—150-200 mg./Kg./day in 6 to 8 divided dose

Chairman's Letter

Eighteen Years of the Physicians' Assistance Committee

THE PHYSICIANS' ASSISTANCE COMMITTEE of the Minnesota State Medical Association has the duty of caring for elderly physicians in Minnesota who have come upon evil days. Most members of the Association are completely unaware of the fine work being done by this industrious committee in their behalf. It is felt that the labor of this devoted group is worthy of note on completion of eighteen years of quite effective effort.

It has long been recognized that physicians were especially prone to be lax in retirement planning. Of all the learned professions the physician generally prospered best and planned the least. He planned to practice forever, and even today physicians find it hard to believe that they may some day not be fit mentally or physically to continue seeing patients. The number of truly needy elderly physicians was never great and generally of local interest only.

Nationwide, twenty-five medical societies, either state or county, have permanent assistance committees with planned income almost always from dues. The Philadelphia Medical Society Assistance Committee was formed in 1778 and is the largest and most successful. They operate on a budget of about $36,000 a year, half from funds contributed yearly and half from interest on invested capital of several hundred thousand dollars.

The late Dr. Wade Humphrey of Stillwater saw the chaos in the multiplicity of plans and thought at first that a committee could function with voluntary donations. He went to the Council in 1951 and was given a committee who sent an appeal to all members of the Association. The results were sickening! This sad response served the purpose of igniting Dr. Humphrey, and he appeared before the House of Delegates hopping mad in the memorable and acrimonious session in Duluth in 1953. His eloquence prevailed and the delegates voted a special $10.00 per member assessment to put the Physicians' Assistance Committee in business; $26,708.00 was collected and the Physicians' Assistance program was off and running.

The basic policy has been that no physician or his widow should draw direct relief or O.A.A. monies. The Committee in 1956 requested a yearly dues raise of $4.00 per member with the money ear-marked for Physicians' Assistance. Many of those in need have some small income and need supplementary help. The largest grant to an individual has been $160.00 monthly, and some have received as little as $25.00. Cases come to the attention of the committee by communication to a county medical society from a member. Mr. Harold

Hodgkin's Disease

Current Views on Management

Y. MARUYAMA, M.D.*
Minneapolis, Minnesota

HODGKIN'S DISEASE is a disease involving lymph nodes and lymphoid tissue. Because it forms tumor masses, can be progressive and can lead to a fatal outcome, it is considered a malignant condition. However, the histological picture is extremely complex with a heterogeneity of cell types including lymphocytes, fibrosis, eosinophils, and large multinucleate giant cells. These last, known as Reed-Sternberg cells, are the *sine qua non* for the histopathological diagnosis. However, the disease may not be truly neoplastic, as commonly understood; indeed, profound lymphocytopenia and immunological deficiencies are regularly associated with it.

Treatment of Hodgkin's is presently based upon clinical staging, and this method of classification has been shown to correlate with prognosis. Classification based on histopathological features of biopsy specimens has generally been less satisfactory. However, the recently proposed criteria of Lukes and Butler[1] appear to offer useful histological criteria and another parameter to assess prognosis. They are: (1) lymphocytic predominance, (2) nodular sclerosis, (3) lymphocytic depletion, and (4) mixed cellularity. Keller et al.[2] recently reported a five-year actuarial survival of 90-100% for disease with histologic features of lymphocyte predominance. Similarly nodular sclerosis, although less favorable than the above, showed twice the survival rate of lymphocyte depletion or mixed cellularity at five years. For anatomic stage I and II disease both lymphocyte predominance and nodular sclerosis carry excellent five-year prognoses. Because of rapidly changing views regarding the disease, it is timely to review current theories regarding staging, therapy, and prognosis.

Clinical Staging

Management and treatment of Hodgkin's

---

Aided in part by USPHS grants CA 05-190, CA 08-832 from the National Cancer Institute.

disease depend on the number of sites of glandular involvement by the disease process. Proper clinical management is dependent on accurate staging of the state of the disease. The treatment and prognosis are based upon staging of the clinical extent of disease, as recently modified[3] from the original staging system proposed by Peters and Middlemiss.[4]

Stage I

Disease limited to the lymph nodes of one anatomic region (I_1) or two contiguous anatomic regions (I_2) on the same side of the diaphragm.

Stage II

Nodal disease of more than two contiguous anatomic regions or in two noncontiguous regions on the same side of the diaphragm.

Stage III

Disease on both sides of the diaphragm but not extending beyond the involvement of lymph nodes, spleen or Waldeyer's ring* (limited to lymphatic tissues).

Stage IV

Disease involvement, in addition to lymph nodes, spleen or Waldeyer's ring of the bone marrow, lung parenchyma, pleura, liver, kidneys, gastrointestinal tract or any tissue or organ (extralymphatic sites).

These are further divided into A or B by the presence or absence of systemic symptoms such as fever, night sweats, pruritis, or weight loss in excess of 10 percent of normal weight. The designation of "B" is for the presence of systemic symptoms and is one of the most unfavorable of the prognostic indicators. It should be noted that disease of non-lymphoid organs cannot be staged by this scheme; in fact, a single extranodal site may be involved without lymph node disease and still carry an excellent prognosis (e.g., gastrointestinal tract[5] or lung).

Clinical Evaluation

The importance of accurate clinical staging requires that clinical evaluation be complete and accurate. Accurate staging requires careful history taking with particular attention to the systemic symptoms noted above. Physical examination should include palpation of all lymph node sites, visualization of the tonsillar fossa and nasopharynx, and examination for the presence or absence of an enlarged liver and spleen. Radiographic studies should include a chest and bone survey, intravenous

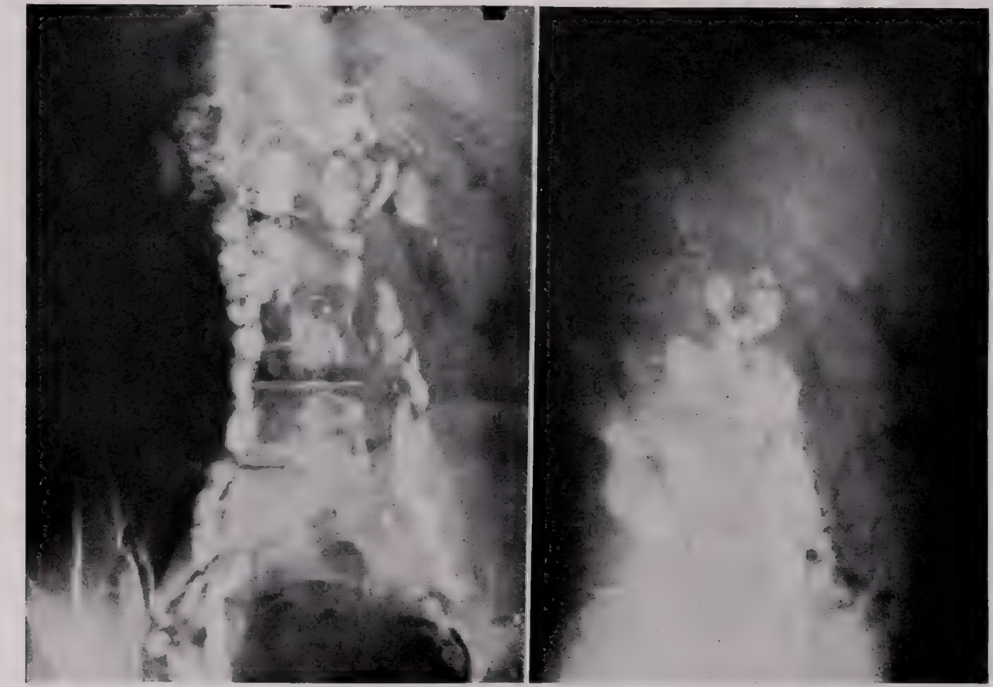

Fig. 1—Lymphangiogram showing extensive lymphomatous involvement of retroperitoneal nodes. The patient was asymptomatic and presented with a single enlarged gland in the cervical region.

---

*See Test Your Word Score Page 672.

pyelography, and bilateral foot lymphangioadenography (LAG) to evaluate the retroperitoneal lymph nodes. The latter study has been found to be associated with little hazard when properly done,[6] and provides valuable information regarding the position and extent of involvement of these poorly accessible structures.

At one time clinical evaluation was based on physical findings, chest x-ray and clinical chemistry; at the present time, it cannot be considered complete without complete radiographic evaluation. Lee[7] found that lymphadenopathy in the groin (in the absence of other adenopathy) was nearly always associated with radiographically abnormal retroperitoneal nodes (Figure 1). Similarly, most patients with systemic symptoms ('B') may have abnormal retroperitoneal nodes. Thus, accurate clinical staging requires lymphangiographic study and evaluation of retroperitoneal lymph nodes.

From the history, physical examination, x-ray and clinical chemistry studies, preliminary staging can be made. Biopsy of accessible nodes will provide the histopathological diagnosis. Additional studies of great value are tomography of the lung and mediastinum, and needle biopsy of the liver, bone marrow or other organs, if under suspicion of involvement.

Accurate clinical evaluation and staging will permit appropriate therapeutic management.

Therapeutics of Hodgkin's Disease

David Karnofsky, the eminent chemotherapist, has succinctly stated the case for the choice between radiotherapy and chemotherapy: *"Radiotherapy has the first priority in planning an appropriate therapeutic program."* Nevertheless, chemotherapy has acquired an important role in the management of advanced, disseminated, and symptomatic Hodgkin's disease, and has greatly improved the general status of the patient with active Hodgkin's disease.

However, the view that radiotherapy has first priority must not ignore the fact that the quality of the therapy must also be top rate to obtain optimal results. Many radiologists would treat these tumors with small doses and small irradiation fields, following the earlier view that the disease is widespread and multi-focal at the time of clinical diagnosis, and that radiation can therefore only palliate an ultimately fatal disease. Moreover, the rapid shrinkage and response to radiotherapy had led to the view that the tumor was "radiosensitive" and therefore required only small radiation doses. (An example of response of a mediastinal mass to radiotherapy is shown in Figure 2). *This view is now regarded as incorrect.*

Stenstrom of the University of Minnesota early adopted the view that extended field therapy and large treatment doses might cure some of the patients afflicted with this condition. Hence the University of Minnesota in

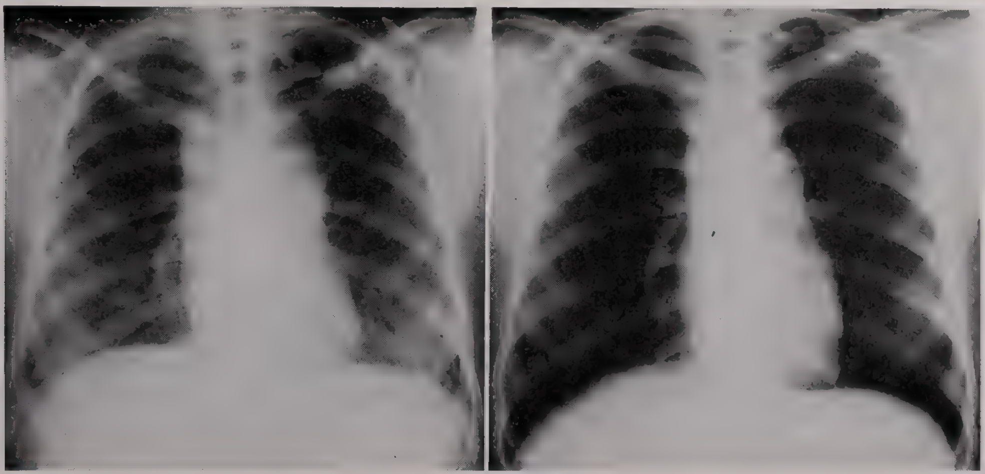

Fig. 2—Mediastinal mass and left supraclavicular lymphadenopathy shown by contrast medium following lymphangioadenography study (left). Following radiotherapy, mass and nodes show marked shrinkage with moderate (3500 rad) radiation dose.

1954[8] was able to report a series of patients treated with the intent to cure. In Stage I and II disease that aim was achieved in 90 percent for a five-year period (for Stage I, 17/20 and Stage II, 18/20). In Stage I, 77 percent (10/13) were surviving 10 years after treatment. This represents one of the outstanding therapeutic experiences reported for this disease. Extremely important to these results is the relationship to clinical staging as shown in Figure 3. For Stage III disease 10 percent (17/168) survived five years and 2 percent (3/143) for 10 years.

For Stage I and II (localized) disease the aim of therapy is cure. The best means to achieve this aim is with radiotherapy. Such treatments are best given with megavoltage equipment to large fields, shielding with lead blocks normal structures such as lung and spinal cord (Figures 4 and 5). Treating a single large field is generally more satisfactory than the practice of treating multiple small fields, the junctions of which may under- or overlap, leading to uncertain tumor doses in the junctional zone.

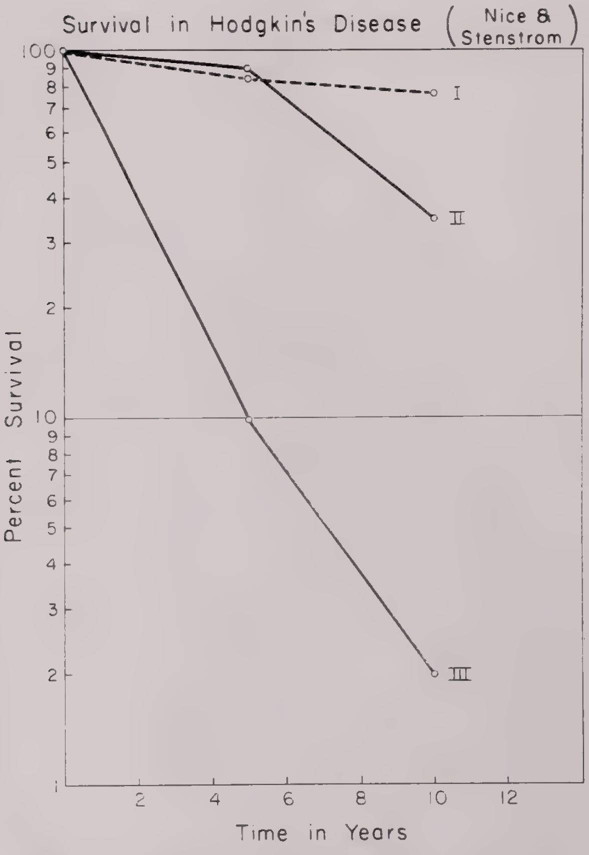

Fig. 3—Survival curve for Hodgkin's disease as a function of stage of disease based on older Peters[4] classification. Extent of disease (stage) correlates with survival following radiation therapy (from Nice and Stenstrom).

If the localized disease is in the upper half of the body, Kaplan[9] advocates treating essentially all the supradiaphragmatic nodes (mastoid, cervical, supraclavicular, mediastinal, and axilla) in a single field ("mantle") with the same therapeutic dose. The efficacy of this approach for Stage I disease is presently being compared with the localized field approach in a randomized national study which should in time provide additional relevant information. In Stage II (supradiaphragmatic) disease, the "mantle" approach is undoubtedly the most satisfactory form of therapy.

If localized disease appears below the diaphragm, an inverted "Y"-shaped field is used to treat all subdiaphragmatic nodes. Fields are shown in Figure 4. The therapy is directed to the entire para-aortic, iliac-pelvic, and groin nodes. Treatment of the stomach, spleen or retroperitoneum should also include appropriate adjacent regions and is best guided by chest radiography, lymphangiography, IVP and, if necessary, abdominal exploration. Whether to irradiate, or to remove the spleen surgically for subdiaphragmatic disease is still an open question.

Stage III disease and its proper management is presently highly controversial and under active investigation. Staging of early cases by means of lymphangioadenography permits early diagnosis, and megavoltage equipment facilitates aggressive and wide-field, high-dose radiation therapy. The general view has been well stated by Aisenberg of the Massachusetts General Hospital: "Radiation should not be withheld if the known disease can be encompassed within reasonable treatment fields." Since it had been shown that Hodgkin's disease is curable by radiation,[10] such a view is entirely a reasonable one, especially if the patient lacks constitutional symptoms, and provided his physical constitution would appear to tolerate the treatments. Although the feeling in the past had favored chemotherapy, recent experience reported by Kaplan[11] indicates that the disease-free period may be much increased if radiotherapy is directed to the entire supra- and infradiaphragmatic lymph node regions. The final answer to this approach will await further clinical experience and results from randomized clinical trials.

The efficacy of radiation for Hodgkin's disease is illustrated by representative examples described below.

Case Reports

Case 1

An example of a prolonged disease-free period following radiation therapy. A 37-year-old white male was found to have right supraclavicular adenopathy in 1949. No symptoms of fever, itch or night sweats were noted. Chest x-ray was normal and no additional adenopathy was noted (Stage I A). Radiation therapy was given to the entire right neck to a dose of 2,000 rad in two weeks time. At the present time, 20 years later, he is alive and remains free of evidence of disease.

Case 2

An example of a prolonged disease-free period following radiotherapy of recurrent disease. A 23-year-old white female presented in 1943 with mediastinal and left supraclavicular adenopathy (Stage II A). After radiation therapy the disease sites regressed completely (3500 rad/3 weeks). Twelve years later in 1955 she appeared with a 3 cm submental node and a mediastinal recurrence by x-ray. The mediastinum was re-treated and the submental node treated with x-rays. Both cleared completely. In 1968 she is well and remains free of evidence of disease (25 years), but was recently diagnosed to have peripheral neuropathy secondary to her prior radiotherapy.[12]

Even under circumstances where the disease is advanced (Stage IV) and hope of cure is

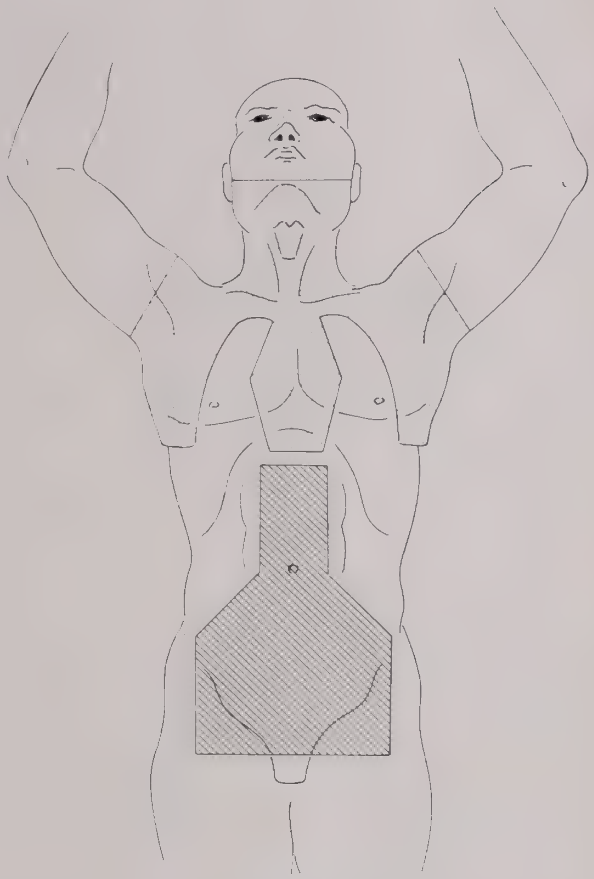

Fig. 4—Treatment fields presently advocated for radiotherapy of Hodgkin's disease. Upper shaded field ("mantle"), lower shaded field, or both may be treated, depending on stage of disease. The spleen may also be included in the lower mantle.

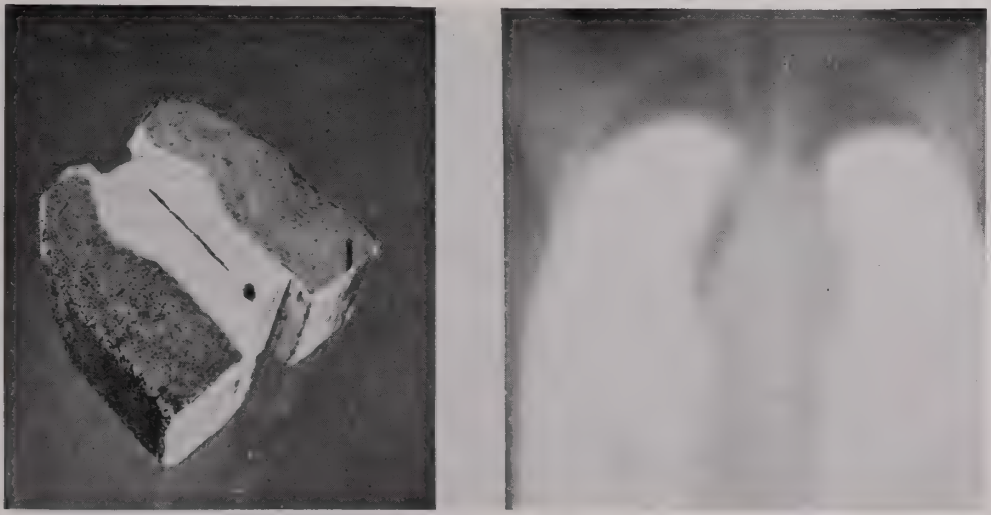

Fig. 5—Individualized lung shields are made for each patient treated to the supradiaphragmatic field (left). The protected regions are evident on the port radiograph routinely obtained on every patient treated (right). The lung shields are made in polyethylene cutout molds in which lead shot is embedded in Rigidax compound (method of Maruyama, Moore, Burns, and Hilger).

slim, radiation by virtue of its efficacy against local deposits represents a therapeutic modality which may be applied effectively at any time in the disease. Thus, while chemotherapy is necessary to control systemic symptoms, radiation by small-field techniques may be used for palliation of even advanced stages of the disease. Examples include:

1. Symptomatic adenopathy.
2. Superior vena caval or mediastinal obstruction.
3. Spinal compression (done carefully, this may spare a patient a surgical laminectomy).
4. Unhealing ulcerations.
5. Extranodal masses.
6. Symptomatic hepatosplenomegaly.
7. Pulmonary infiltration.

Case 3—Mass, Cranial Nerve Palsy and Unhealing Ulcerations Associated with Adenopathy in Advanced Disease.

A 53-year-old white male had known Hodgkin's disease of five years' duration. He had received many courses of x-ray therapy to small fields. However, there was progression of his disease and he was referred to the University Hospitals with advanced disease. He had a left temporal mass, and a large 8 x 8 x 4 cm mass of matted nodes in the right groin. Four courses of chemotherapeutic agents were attempted over a period of several months. Temporary response followed each course but was followed in turn by regrowth and progression. The right groin mass became secondarily infected and required incision and drainage. The incision site subsequently failed to heal, fungated through the skin, drained continuously, and progressively enlarged.

The patient then developed obstructive lymphedema of the right foot and leg. The left temporal mass extended to involve the left orbit with a resultant VIth cranial nerve palsy and diplopia. At this point radiation therapy was considered. Treatment of the right groin and pelvis and of the left temporal-orbital region was recommended and carried out with Cobalt 60 and localized beam therapy. In both sites, mass regression was evident after four to five treatments and complete regression was ultimately produced. The ulcerative groin mass healed completely and the left temporal mass regressed entirely, with restoration of normal eye motion and of normal vision.

Although the patient ultimately expired from advanced disease, these distressing symptoms were effectively and completely ameliorated.

Case 4—Therapy of Spinal Compression in Advanced Disease.

A 36-year-old white female was diagnosed with Hodgkin's disease in 1956 when she appeared with anemia, pruritus and left cervical adenopathy. Biopsy of the cervical nodes established the diagnosis. Over the next several years it became apparent that her disease was widespread. Multiple courses of various chemotherapeutic drugs, steroids and localized field radiotherapy maintained her symptom-free.

In 1967 she appeared, complaining of excruciating lumbar back pain. Diagnostic x-rays revealed osteolytic lesions of the vertebral bodies of D 12 and L 1. Physical examination showed hypalgesia of the lower extremities and depressed deep tendon reflexes. A sensory level was noted at the D 12 level. Some decrease in anal sphincter tone was present although bladder and bowel control were intact. The patient refused myelograms and surgery. Therefore, Cobalt 60 treatments were cautiously and deliberately delivered to the lumbodorsal region concurrently with large doses of steroids. About ten treatments and 2500 rad led to complete relief of back pain, restoration of normal neurological status, and reossification of the bone lesions. Two years later she is active and symptom-free and does her own housework for her family. No laminectomy was necessary.

Case 5—Mass, Leg Edema, and Blocked Urinary Tract in Advanced Disease.

A 71-year-old white male was found to have left leg edema. Admission evaluation disclosed several small nodes in the left neck and a matted 3 x 4 cm left inguinal mass. Biopsy of the left neck nodes disclosed Hodgkin's disease. Lymphangiography disclosed blocked lymphatics on the left side with abnormal periaortic nodes. An intravenous pyelogram was normal at this evaluation. He was considered Stage III A disease. Chemotherapy was started and a course of oral drugs given. Initial partial response was followed by marked regrowth and progression three months later. He was therefore admitted to the hospital and intravenous alkylating agents were given in high dosage. Again partial response was followed in two months by regrowth. Continuous oral cytotoxic therapy was therefore administered and was followed by incomplete regression.

During this time left leg edema (2^+ - 3^+ pitting) was continuously present. The left groin nodes were 3 x 3 x 5 cm in size. During this time a large left iliac fossa mass became apparent as well as partial blockage of the left urinary tract by intravenous pyelogram. At this point, radiotherapy consultation was requested. Treatment of the left groin, left iliac and para-aortic chain led to complete regression of the adenopathy and masses. Urinary tract obstruction was relieved and the left leg edema cleared. The patient eventually expired from advanced disease, but no further problems with leg edema, left inguinal nodes or the urinary tract ensued during his subsequent clinical course. The recent experience of Kaplan[11] with Stage III A disease suggests that initial management should have been radiotherapeutic.

For Stage III B and IV, the aim is often not to cure, but to produce patient comfort. It is in this category that chemotherapy has been so effective in improving the general status of the patient with active disease, and it is undoubtedly responsible for the improved quality of survival in many patients. Here, the aim of management is to restore a sense of well-being and free the patient of systemic symptoms. Blood transfusions, antibiotics, and general supportive measures are essential. Careful judgment in the choice and use of chemotherapeutic agents can bring about gratifying periods of remission while avoiding undue bone marrow toxicity.

Localized field radiotherapy can be used for the management of localized, symptomatic areas. Because the deposits are radioresponsive, relatively few treatments are usually required to achieve the aim of effective amelioration of symptoms and patient comfort. Moreover, the duration of response of localized deposits to irradiation is often much longer than for chemotherapeutic agents, which may be of short duration.

Conclusions

The view that Hodgkin's disease is a relentless and incurable disease is incorrect and unduly pessimistic. Early-stage disease may be cured by radiotherapy; advanced disease may be managed by chemotherapy combined judiciously with radiotherapy to maintain patient comfort. Radiation therapy should be delivered by competent specialists with meticulous attention to detail in the early or 'A'-stage patients. Large individually tailored fields are presently recommended to achieve the aim of cure. Use of unwarranted chemotherapy in early stages may further depress an already impaired immunological reactivity and competence of patients with Hodgkin's disease. It may further limit the adequacy and dosage possible with later radiation therapy by reducing normal tissue tolerance. Accurate staging correlates well with prognosis; and intensive radiotherapy in early Stage I and II disease and probably III A disease is the treatment of choice. In advanced disease, radiation represents a powerful adjunct to a comprehensive chemotherapeutic-medical program to maintain patient well-being and comfort and to ameliorate symptomatology.

The evaluation of stage in Hodgkin's disease is essential to its correct management and should be carried out by physicians with an interest in the disease, making use of all available techniques for its full evaluation. Accurate diagnosis, staging and appropriate therapeutics have been shown to alter the course of a disease previously regarded as ultimately fatal to one now considered potentially curable by proper therapy.

Ranula—from Latin *rana* (a frog)

WHAT'S YOUR DIAGNOSIS?

A 64-year-old white female, a known diabetic for eleven years, with a nephrotic syndrome secondary to Kimmelstiel-Wilson and atherosclerotic coronary heart disease, was admitted because of multiple medical problems. She had been in chronic heart failure for several years but reported increasing pedal edema over the past six weeks and recent shortness of breath. While sleeping or relaxing, she usually lay on her left side.

The pertinent physical-finding examination revealed a suspicious mass in the left breast. The breasts were pendulous, the left larger than the right. Bilateral axillary nodes were thought to be palpated, and thickening of the skin in the upper quadrant of the left breast was found by all examiners. Thus a mammogram was performed.

The pertinent laboratory findings revealed an alkaline phosphatase of 19 and 28; a liver scan demonstrated a slightly enlarged liver with no filling defects. The bromsulphthalein was 22.

The mammogram was interpreted as being normal on the right. On the left, marked thickening of the skin was seen to involve the entire breast, but no mass could be detected. Carcinoma of the breast was a major consideration (Figures 1A and B). The suspected diagnosis of inflammatory carcinoma could not be maintained due to the lack of clinical manifestations of inflammation in the breast. A metastatic bone survey was negative. A chest radiograph revealed an enlarged heart, with bilateral pleural effusion, secondary to failure (Figure 2).

What is your diagnosis? (See page 594.)

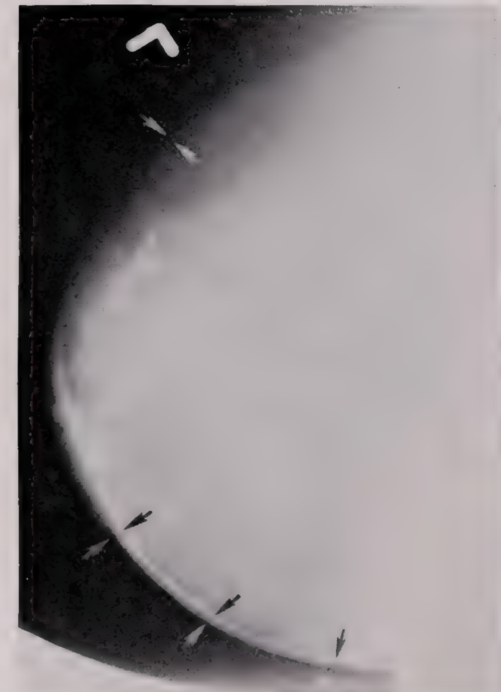

Fig. 1A—Mediolateral projection of the left breast demonstrating marked diffused skin thickening of the breast.

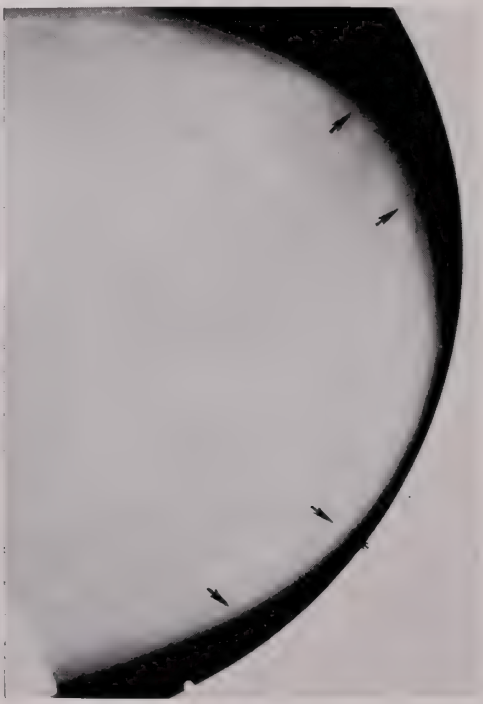

Fig. 1B—Craniocaudad projection of the left breast demonstrating with greater detail the skin thickening.

An Unusual "Complication" of A Duodenal Diverticulum

Report of A Case

JONATHAN A. van HEERDEN, M.D., CH.B.*
JAMES T. PRIESTLEY, M.D.†
Rochester, Minnesota

Sir William Osler[1] was the first to describe a duodenal diverticulum in the American literature in 1881. Since that time many series elucidating the surgical and pathologic aspects of this entity have been reported.

It has been stated[2] that almost any complication one could imagine has been reported with diverticula of the small bowel. This certainly holds true for duodenal diverticula, as exemplified by this brief case report.

Duodenal diverticula are found in approximately 1% of patients undergoing upper gastrointestinal x-ray examination.[3] About 95% of these diverticula are found on the concave aspect of the duodenal loop, usually in the second portion near the papilla of Vater, and most are of the extraluminal type.[2] This anatomic site is one of the factors resulting in the high operative mortality, which varies from 8 to 18%[2] in reported series. We could not find a complication such as ours recorded in the current literature.

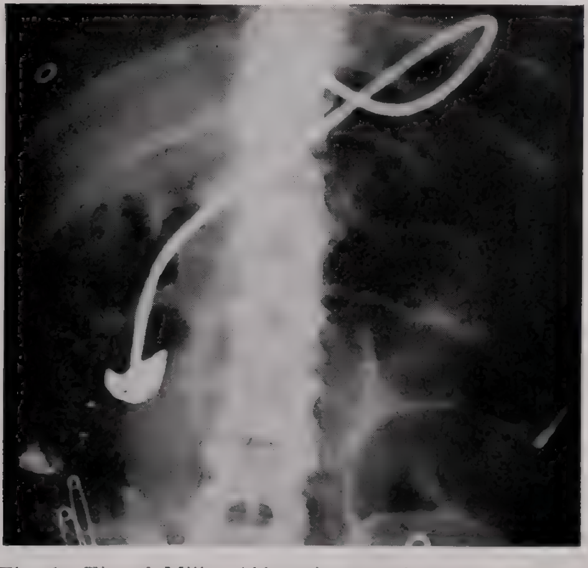

Fig. 1—Tip of Miller-Abbott in second portion of duodenum.

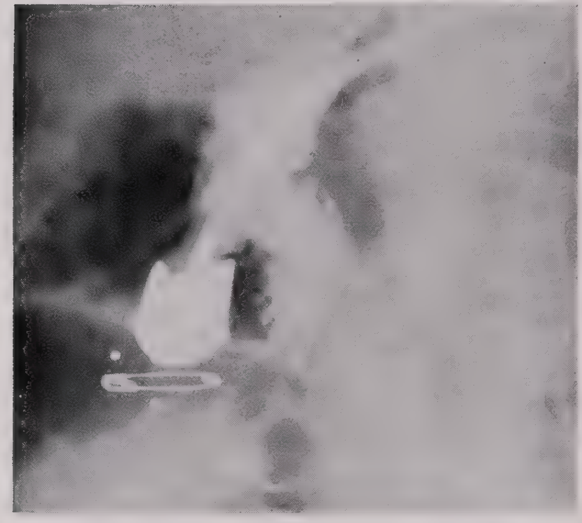

Fig. 2—Tip of Miller-Abbott tube lodged in duodenal diverticulum.

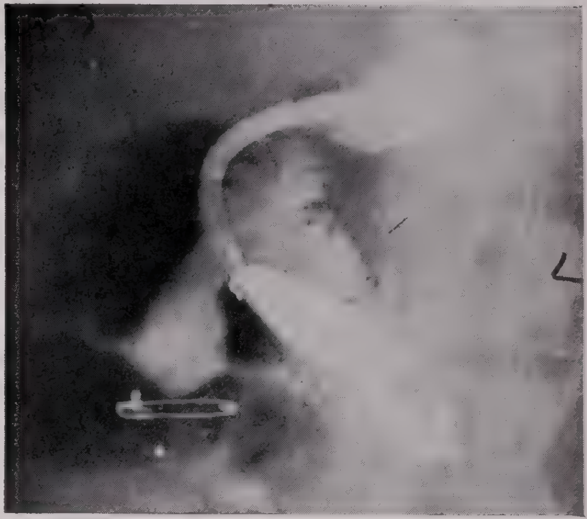

Fig. 3—Tube after manipulation, showing wide-necked duodenal diverticulum.

Report of Case

Recently a 67-year-old white man underwent routine cholecystectomy for cholelithiasis as well as excision of an incidentally found Meckel's diverticulum of the ileum. Partial obstruction of the small bowel became clinically evident on the fifth postoperative day. As this was suspected to be due to a soft adhesion, we elected to pass a Miller-Abbott tube for intestinal decompression. Under fluoroscopy the tip of the tube was easily passed through the pylorus into the second portion of the duodenum. Despite repeated tube manipulation, the tip of the tube would not advance beyond this point even with good drainage over a period of 48 hours (Figure 1).

At this stage it was decided to inject 37% meglumine diatrizoate (Gastrografin) into the tube and visualize the position of the tip under fluoroscopy. When this was done the tip was found to be lodged firmly in a wide-necked duodenal diverticulum lying on the convex aspect of the second portion of the duodenum (Figure 2). With correct positioning and manipulation the tip was easily passed beyond this diverticulum, whence it rapidly progressed distally (Figure 3). After decompression the tube was removed and the subsequent hospital course and convalescence were uneventful. As is our practice, we did not advise surgical removal of this diverticulum.

Summary

A patient had an asymptomatic and unsuspected diverticulum on the lateral (convex) portion of the second part of the duodenum. A Miller-Abbott tube became lodged in this diverticulum and caused a temporary diagnostic dilemma because of its failure to progress further.

Harley Street

Every year the Medical Directory undertakes a counting of heads, and according to the current account there are 789 doctors with Harley Street addresses. To paraphrase Edsel Ford's after-dinner speech when the ten-millionth Ford rolled off the production line, "Whichever way you look at it, 789 is a lot of doctors." The lot includes forty-two women, one lord, fourteen knights, and twenty-three hyphenated names. The current range is from Abel to Zezi and includes, democratically enough, a Smith, a Jones, and a Robinson. You can pay your money and take your pick, and, unless you choose one of the three or four complete outsiders, you will have available to you all the resources of the best of British medicine, which is still better medicine than is practiced anywhere else in the world.*

Mediastinoscopy

AYDIN M. BILGUTAY, M.D.*
NATHAN KENNETH JENSEN, M.D.
W. ROBERT SCHMIDT, M.D.
JOSEPH J. GARAMELLA, M.D.
MICHAEL F. LYNCH, M.D.
WILLIAM D. KELLY, M.D.
Minneapolis, Minnesota

MEDIASTINOSCOPY is a method of exploring the superior mediastinum with minimal surgical trauma. It provides a means for direct vision, palpation and biopsy of mediastinal lymph nodes and the other tissues of the mediastinum for diagnosis and prognosis. With mediastinoscopy, information about the nature and extent of many diseases of the lung and mediastinum can often be obtained without resorting to exploratory thoracotomy.

Mediastinoscopy was first introduced in Sweden in 1959 by Carlens.[1] It was not until 1966 that we began to occasionally utilize it; but as our experience increased and we learned its value, our indications for the procedure broadened. We now employ the technique with increasing frequency; as of May 1968 we have used it in 100 cases, 80 of them during the past year. This report presents a review of the technique of mediastinoscopy as we use it and the results.

Technique of Mediastinoscopy

Mediastinoscopy is carried out under general anesthesia with endotracheal intubation. The patient is positioned supine with his neck slightly hyperextended over a pillow beneath his shoulders. The anesthetist assumes his place at the side of the table while the surgeon works from the head of the table as in bronchoscopy.

Through a curvilinear incision of three or four centimeters in the suprasternal notch, the skin and platysma are divided (Figure 1). The strap muscles are separated longitudinally by dividing the fascial layer between them. The dissection is then carried through the pretracheal fascia and extended beneath it to and beyond the tracheal bifurcation, exposing the anterior and lateral walls of the trachea and both main bronchi. This dissection is performed digitally with the index finger (Fig-

P.A. = pulmonary artery
In.A. = innominate artery

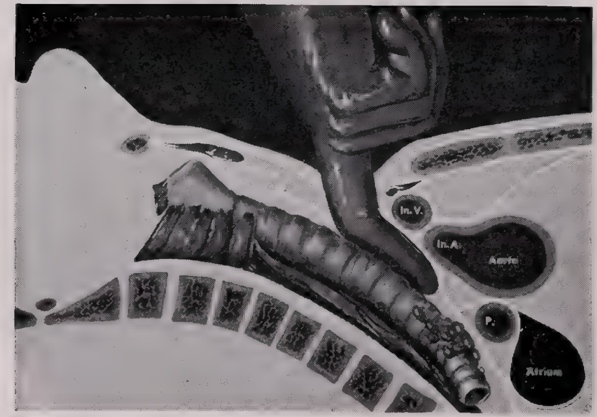

Fig. 3—Digital dissection down behind the pretracheal fascia.

ures 2 and 3). The aorta and innominate artery can be palpated anteriorly. Posteriorly the trachea and lymph node areas along each side of the trachea are felt (Figure 4). Palpation also gives valuable information about the consistency of the upper lobes and presence of tumor in the adjacent areas of lung and mediastinum which are useful in determining the sites for biopsy.

The mediastinoscope* is then introduced behind the pretrachea fascia and advanced to the carina, inspecting each side of the trachea, the carina, and the right and left main bronchi for two or three centimeters from their origins (Figures 5 and 6). The subcarinal region and the proximal portions of each bronchus may be freed from further areolar tissue with the help of blunt dissection with a long biopsy or dissection forceps.† Approaching the subcarinal nodes over the left bronchus avoids injury to the azygos vein. The lymph nodes are first freed from their surrounding tissues and then excised or biopsied. If there is any doubt as to the nature of tissues, as in differentiating the lymph nodes from vascular structures, a test puncture with a long 20-gauge needle may be performed. Large nodes, especially those encountered in sarcoidosis, can be enucleated with the finger. If no lymph nodes are identified, biopsy of mediastinal connective tissue is advisable. It is advisable to explore both sides of the trachea and carina, both for diagnosis and to determine the extent of the lesion. Closure of the wound is effected by catgut stitches for the muscle layers and subcuticular stitches for the skin.

Selection

In this series, selection of patients for mediastinoscopy has been prompted by the presence of pulmonary or mediastinal lesions suggestive of primary or metastatic cancer of the lung, or by hilar or mediastinal changes suggestive of granulomatous or lymphomatous involvement. Mediastinoscopy in these patients was usually done following exhaustive studies including routine radiography, tomography, bronchoscopy and bronchography. Bronchial washings were obtained at all bronchoscopies, and bronchial biopsies were made of all sus-

---

*Made by Medical Products Co., distributed by V. Mueller Co.
†Pilling Company.

pected areas. Many patients had scalene node biopsies. When these were non-diagnostic, mediastinoscopy was then performed as the final step before undertaking exploratory thoracotomy for definitive diagnosis. In two patients where bronchial biopsies were positive, mediastinoscopy was performed to determine the extent of the lesion for prognostic information.

Contraindication for mediastinoscopy was evident in only one patient not included in this series. This patient had a metastatic lesion involving the fifth cervical vertebra and could not extend his neck. Therefore, Harken's[2] procedure under local anesthesia was performed, establishing the diagnosis in this patient.

Results

Mediastinoscopy was performed on 100 patients, aged from seven to 82 years. The majority were between 50 and 70 years old (Table 1).

TABLE I

Mediastinoscopy & Mediastinal Lymph Node Biopsy
Age and Sex Distribution

Age in Years	Men	Women	Total
0-9	1		1
10-19	1		1
20-29	4	2	6
30-39	4	1	5
40-49	10	5	15
50-59	17	6	23
60-69	28	5	33
70-79	11	4	15
80-89		1	1
Total	76	24	100

Forty patients had benign lesions, the remaining 60 malignant ones.

Benign Lesions

Thirty-four of 40 patients (85%) yielded positive findings at mediastinoscopy (Table 2). Eighteen of these 40 yielded mediastinal lymph nodes diagnostic of sarcoidosis. In 10 of these 18 patients prior scalene node biopsies had been performed with negative results; eight patients had not had scalene node biopsies. Thus with mediastinoscopy, all of the 18 patients had positive findings for sarcoidosis.

Nineteen patients had mediastinal lymph nodes which were interpreted on microscopic examination as normal or showing benign

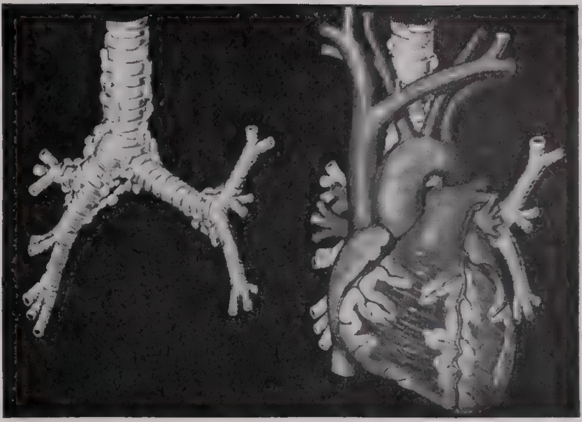

Fig. 4—Relation of mediastinal structures.

hyperplasia or nonspecific granulomatous reactions. Fifteen of these patients underwent thoracotomy, at which time they proved to have either non-specific granuloma, chronic infections or bronchiectasis with secondary chronic peribronchial lymphatic hyperplasia. In these patients mediastinoscopic findings correlated with thoracotomy findings. Two large lesions, one involving the anterior mediastinum and the other involving a peripheral subpleural location in the chest wall, proved to be lipomas at thoracotomy. In each, mediastinoscopy was negative.

One child with a mediastinal mass proved to have a vascular anomaly at mediastinoscopy, accounting for the x-ray picture suggesting tumor of the mediastinum.

Malignant Lesions

Sixty of the 100 patients studied had malignant lesions (Table 3). Fifty-one had primary cancer of the lung, five had metastatic lesions and four had lesions of lymphomatous origin.

In the 51 patients who ultimately proved to have cancer of the lung, 30 had positive findings at mediastinoscopy. Fifteen patients in this group had negative mediastinal lymph nodes at mediastinoscopy and were subjected to thoracotomy for diagnosis and treatment. In retrospect, another eight patients should have had positive nodes at mediastinoscopy, as thoracotomy revealed lesions in the mediastinal nodes within the reach of the mediastinoscope. From the anatomical evidence in these cases, it appears that the correct diagnosis could have been established in 38 of the 51 patients (by mediastinoscopy) or 74.5 percent.

All of these patients have had various diagnostic procedures as indicated in Table 4. It is interesting that of the 38 patients in this group who were bronchoscoped, only two had lesions amenable to bronchial biopsy which were diagnostic. In these two patients, mediastinoscopy was performed to determine the extent of the spread to mediastinal lymph nodes. However, these 38 patients who also had mediastinoscopy do not represent all the cases bronchoscoped. Those whose lesions were diagnosed by bronchoscopy alone are not included in this report; therefore these 38 patients represent a select group.

Bronchial washings were obtained in all of these 38 patients at bronchoscopy and were positive in 12. Positive bronchial washings were usually accepted as supportive but not considered as definite evidence of tumor.

Expectorated sputa were examined for malignant cells in 14 of these patients. In five they were reported as "atypical" or "suspicious." In two of these, mediastinoscopy was negative. Yet because of the patient's history and chest roentgen findings and clinical deterioration, carcinoma was accepted as the most likely diagnosis without thoracostomy.*

Four patients who had negative nodes on mediastinoscopy were discovered to have bone lesions, one in the iliac bone, three in the ribs. These were biopsied and metastatic carcinoma was found. Procedures which determined final diagnosis of cancer of the lung in 51 patients are summarized in Table 5.

It is interesting to compare three patients in whom carcinomatous nodes were found by mediastinoscopy and who were nevertheless subjected to thoracotomy with those who had negative mediastinoscopy and were subjected to thoracotomy. Two of the three patients with positive mediastinoscopy who were operated on were young, and the chest x-rays suggested that the lesions could be resected; while in the third case the thoracotomy was attempted despite the carcinomatous mediastinal lymph nodes to control infection in a cavitating cancer.

All three were found non-resectable because of tumor invasion of either the aorta, pulmonary artery or veins (Table 6).

Discussion

Mediastinoscopy is a simple and safe method of exploring the superior anterior mediastinum for diagnostic and prognostic purposes.

In this series, 30 of 51 cases of cancer of the lung were diagnosed and evaluated as non-resectable by mediastinoscopy; thoracotomy was thus avoided. In six additional cases, pelvic bone or rib biopsy or examination of sputa gave the final diagnosis and evaluation, although mediastinoscopy had failed to find malignant tissue. Positive mediastinoscopy in malignant disease usually signifies a poor prognosis. Patients with such findings are generally past the stage where they can be considered for curative resection. The presence of metastatic nodes along the trachea or direct invasion of the mediastinum with the tumor precludes curative resection in most cases.[3]

This is illustrated in the three patients who had positive mediastinoscopy and were subjected to thoracotomy because the outlook seemed favorable, yet all were found to be non-resectable. On the other hand, of the 15 patients with negative mediastinal lymph nodes, nine were found resectable at thoracotomy. This would indicate a 60 percent "resectability for cure" rate in otherwise favorable patients found free of mediastinal involvement by mediastinoscopy.

The follow-up on 27 patients with positive mediastinal nodes not subjected to thoracotomy did indeed suggest that the lesions would have been non-resectable by the very short downhill course that followed their diagnosis, despite irradiation or chemotherapy in some.

Summary and Conclusion

Technique of mediastinoscopy is reviewed and the results in our first 100 patients presented. There were no complications. Mediastinoscopy is a valuable adjunct for diagnosis and prognosis of lesions involving the mediastinal structure. In many cases, it provides information otherwise available only by thoracotomy.

TABLE 5

Procedures Which Determined Final Diagnosis of Cancer of the Lung in 51 Patients

TABLE 6

Thoracotomy Done Despite Positive Mediastinoscopy (Three Patients)

One had small cell carcinoma.
One had adenocarcinoma with invasion of mediastinum.
One had squamous cell carcinoma with abscess cavities.
All were non-resectable at thoracotomy.

---

*See Test Your Word Score Page 672.

In this series, exploratory thoracotomies for diagnosis were avoided in 18 of 18 patients with sarcoidosis. When all the benign lesions in this series are considered, exploratory thoracotomies were avoided in 23 of 40 (57.5 percent). As for malignant lesions, thoracotomies were avoided in 34 of 51 patients (not including those three who had thoracotomy despite positive mediastinoscopy), or 66.6 percent.

Addendum

Since submission of this paper our experience with an additional 40 cases supports the above conclusions.

Highway Safety

Doctors who care for the human wreckage from highway carnage know that positive steps are called for right now. A systems approach can be designed to cut in half today's mortality rate and to significantly reduce crippling injuries. The subsystems in this approach involve the *Driver,* the *Automobile,* and the *Medical Care.*

The Driver must be conditioned to slip into his safety harness every time he enters his auto—without fail. We know that wearing a seat belt has reduced accident mortality by 40 percent, and wearing a shoulder harness adds another 30 percent to probability of survival.

The drinking driver must be eliminated. If he will not assume responsibility, he must be subject to increasingly severe penalties under the law. The favorable Supreme Court decision on "stop and frisk" by police officers should have a salutary effect by permitting them to investigate suspects under reduced liability to themselves.

The Automobile manufacturers must continue improvement of vehicular crash design. This calls for universal energy-absorbing devices, such as collapsible steering gears, bumpers which give, and padded instrument panels. An improved shatterproof glass is now found on many cars—better than standard safety glass but not perfect as yet. Car frames should be strengthened, featuring impact protection from the sides as well as from the front and back.

Effective Medical Care requires rapid transport of accident victims. The mortality rate rises rapidly for each half-hour delay in serious accidents. Helicopters or medicopters should be considered for urban areas where rush hour traffic seriously hampers accessibility by ambulance.

A trauma unit should be included in all major medical centers. Although few trauma units exist currently, they hopefully will become as effective and common as recovery rooms. Such a special facility dictates responsive training of physicians and supporting personnel. Trauma patient care should be recognized as a subspecialty in its own right with careful attention paid to proper training of doctors, nurses, and technicians.

Taken as a total system—subject to concerted and continuing promotion—these three approaches could be expected to improve considerably the current intolerable record of U.S. highway safety.

Infarct of the Prostate Causing Pyohydronephrosis*

STANLEY J. ANTOLAK, JR., M.D.†
St. Paul, Minnesota

INFARCTION OF THE prostate is a well recognized entity; the diagnosis is usually made at autopsy or on sectioning the surgical specimen. Frequently there is no history to suggest any significant sequelae, but there are numerous reports of acute urinary retention secondary to prostatic infarction. An unusual complication of prostatic infarction is presented.

Case History

History and Physical Examination

A 73-year-old white male was transferred to the Minneapolis Veteran's Administration Hospital on December 7, 1967, because of anuria of two days' duration. He had previously been admitted to another hospital because of several syncopal episodes. He had last voided just prior to leaving for that hospital. Treatment had included intravenous fluids and intramuscular penicillin. There had been no abdominal or flank pain during this period and he denied voiding symptoms.

Past history included bilateral renal calculi since 1924, with a right nephrectomy in 1962. Apparently a left renal calculus had been present at that time. An enterocolostomy had been performed because of regional enteritis.

Examination revealed a lethargic elderly male in no distress and with no complaints. Blood pressure was 126/58 mm. Hg., pulse 96/min., and temperature 103 degrees (rectal). There was guarding in the left upper quadrant and mild left flank tenderness. The surgical scars were noted. The prostate was 2 plus enlarged with a firm rubbery consistency; it was not tender.

Laboratory Data

Initial laboratory data were: hemoglobin 10.5 gm.%, WBC 13,700 with 92% neutrophiles, BUN 58 mgm.%, sodium 129 mEq./L, chlorides 97 mEq./L, potassium 4.6 mEq./L, CO_2 combining power 19.5 mEq./L. KUB x-ray showed a staghorn calculus involving the left upper pole.

Hospital Course

Cytoscopy revealed a 5-cm.-long prostatic urethra with hyperemic mucosa and enlarged obstructing lateral lobes. The bladder mucosa showed evident cystitis. The left side of the trigone was elevated and edematous, and the left ureteral orifice was lateral to the expected position. No efflux‡ occurred. A #5 Fr. ureteral catheter was passed to 25 cm. and 30 cc. of purulent material was aspirated. A pyelogram showed the staghorn calculus and hydronephrosis (Figure 1). The renal pelvis was irrigated with neo-

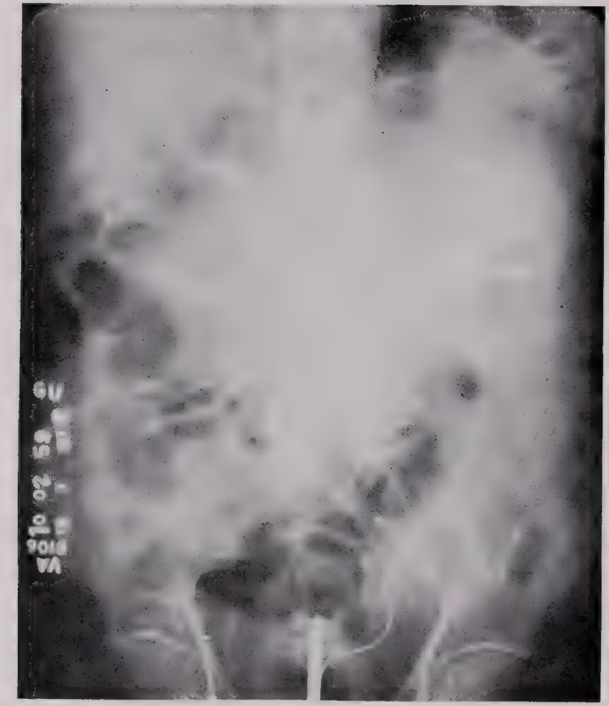

Fig. 1—Pyelogram after aspiration of 30 cc. pus.

mycin solution and the catheter left indwelling. Urine culture failed to grow any bacteria.

Treatment with intravenous Keflin and chloromycetin was started and the ureteral catheter irrigated with 1% neomycin solution every two hours. Because of repeated obstruction of the catheter by debris, a second catheter was passed on December 8, 1967. A withdrawal pyelogram showed complete filling of the ureter to the ureterovesical junction (Figure 2). The patient's temperature was normal on December 10, 1967, but because of intermittent obstruction of the catheters with recurrent fevers, a nephrostomy was performed two days later. His temperature became normal the following day. No attempt was made to remove the staghorn calculus which did not involve the lower pole calyx.

Five days after the nephrostomy the patient began to void small amounts of urine with a residual of 60 cc. A cine-pyelogram showed normal peristalsis along the entire ureter with complete emptying within 15 minutes. A sixteen-gram transurethral resection of the prostate was performed on December 29, 1967. The edema of the trigone was absent and the left ureteral orifice was in its normal position. During the resection the tissue from the posterior and apical areas of the left lobe was noted to be mottled dark brown. *This proved to be infarcted prostate.*

The nephrostomy tube was clamped and later removed, and the patient was voiding normally when discharged on January 8, 1968. In retrospect the changes at the trigone and orifice were secondary to the prostatic infarction and resulted in pyohydronephrosis. Acid phosphatase determinations had not been done because the infarct had not been suspected.

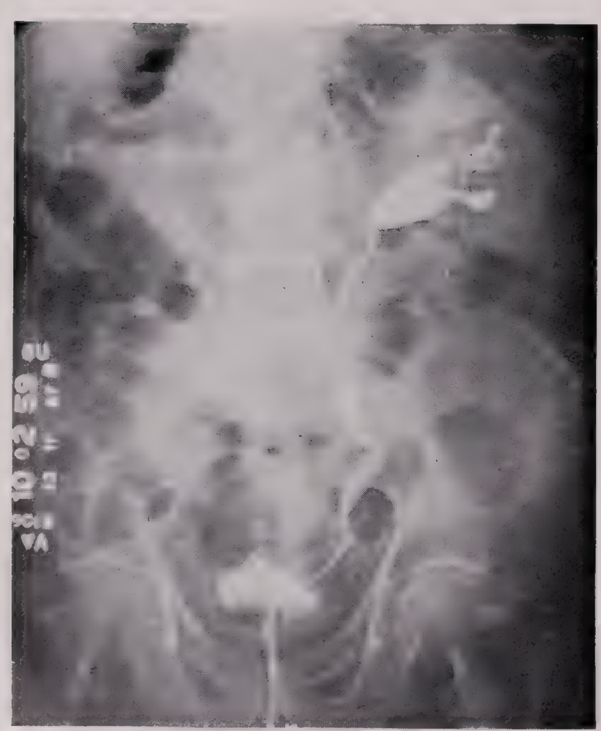

Fig. 2—Filling to ureterovesical junction on withdrawal of pyelogram.

Discussion

Since the report of Abeshouse in 1933,[1] which alerted urologists to this disease, there have been several papers dealing with prostatic infarction. From 8% to 25% of surgical or autopsy specimens have been found to contain areas of infarction.[3,8] Several causes have been proposed, including trauma (endoscopy, catheters, fecal impaction), infection, vascular compression by an adenoma within the relatively indistensible prostatic capsule, thrombosis of the periprostatic venous plexus, arteriosclerosis, and embolic phenomena.[6,7] Zufall reported a case of prostatic necrosis following repair of a ruptured aortic aneurysm.[10]

The usual clinical picture is that of prostatism, frequently with acute urinary retention. Some authors have described gross hematuria, but rarely is there any pain secondary to the infarct.[8]

The microscopic appearance of prostatic infarction is central infarction with peripheral hemorrhage and leucocytic infiltrate; later there is invasion by fibroblasts and new vessels and fibrosis.[4,7] Squamous metaplasia of surrounding acini is common and has been misinterpreted as adenocarcinoma of the prostate.[2,5] The only known biochemical change due to the infarction is transient elevation of the serum acid phosphatase.[9]

Postcholecystectomy Syndrome

This syndrome is characterized by the persistence after gallbladder removal of preoperative symptoms or by the initial appearance of similar symptoms after biliary tract surgery. Repeated attacks of biliary colic, perhaps with abdominal pain, bloating, nausea, and vomiting, are characteristic. Jaundice, chills, and fever may also be present. An unnecessarily long cystic duct stump, mechanical irritation, stenosis or obstruction of the common bile duct because of stone or stricture, cholangitis, functional spasm and incoordination or fibrosis of the sphincter of Oddi, or traumatic neuromas may be causative.

Determination of the postoperative pathologic process is difficult even with the aid of intravenous cholangiography. McClenahan and associates, in applying this technique in a series of 121 patients with persisting postoperative symptoms, demonstrated common bile duct abnormalities in 33 percent of patients. Pathology included cystic duct remnants in 16.5 percent, calculi in 9.1 percent, and stricture in 7.4 percent. Quite significant was his control study of 46 postoperative asymptomatic patients. In this series disorders of the common bile duct were demonstrated in 34.8 percent, cystic duct remnants in 28.3 percent, calculi in 4.3 percent, and strictures in 2.2 percent. These contrasting figures indicate the difficulty of relating postcholecystectomy symptoms to demonstrable pathology in the lower biliary tract.

Differential diagnosis should exclude functional disorders with gastrointestinal manifestations and organic disease outside the biliary tract. Surgical exploration is frequently necessary to determine and correct the causal factor.

Answer to What's Your Diagnosis?

(From page 582)

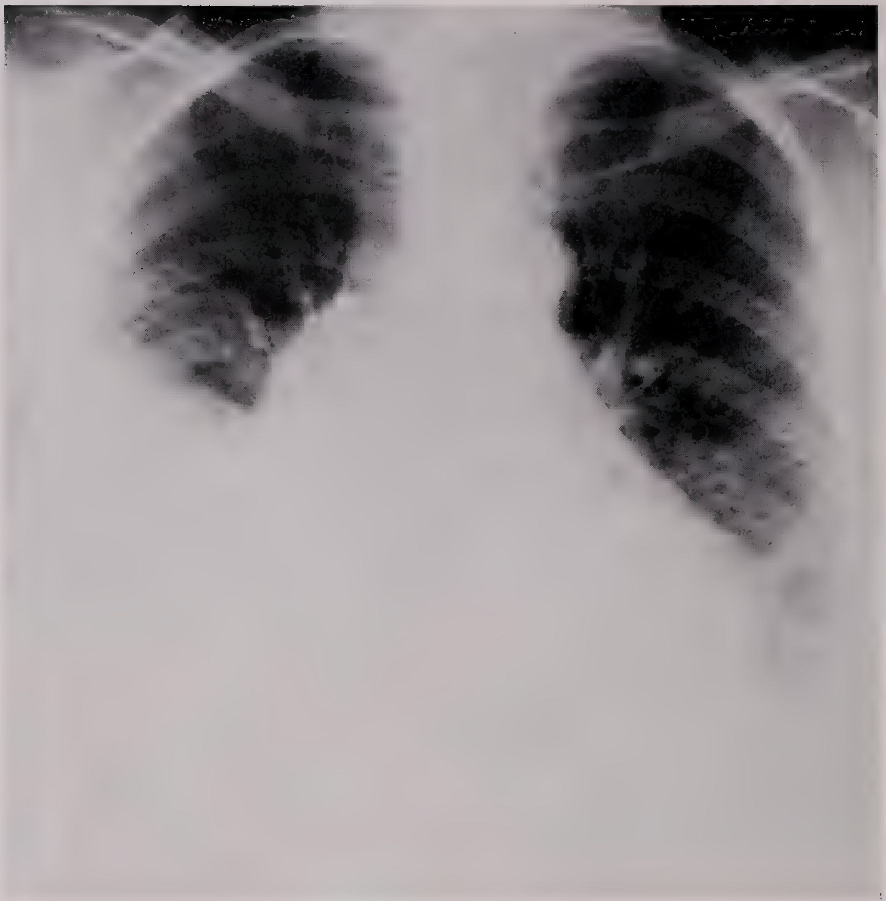

Fig. 2—Posteroanterior projection of the chest demonstrating bilateral pleural effusion due to cardiac failure.

The patient was treated with diuretics and bed rest, and lost 20 pounds in six days. With a decrease in the pedal edema, within 14 days the total weight loss was 43 pounds. The edema had disappeared completely.

A repeated mammogram revealed no thickening of the skin, and the major suspicion of carcinoma of the breast was abandoned. The alkaline phosphatase and the bromsulphthalein remained somewhat elevated, which was thought to be due to chronic, passive congestion.

It is now a well-known fact that early thickening of the skin is better evaluated radiographically than clinically.[2] The numerous etiologies for this occurrence have been described by Morrish.[3]

Thymoma with Myopathy

Report of A Case

JACQUES V. SOUADJIAN, M.D.*
LLEWELYN P. HOWELL, M.D.†
EDWARD H. LAMBERT, M.D.‡
Rochester, Minnesota

The role of the thymus in immunologic phenomena has recently been emphasized,[1] but the relationship between the thymus and autoimmune disorders is yet to be defined. There is suggestive evidence of an auto-immune mechanism in myasthenia gravis[2] and polymyositis[3]; remission of myasthenia gravis following thymectomy has been observed for years.[4,5] In 1964 Klein and colleagues[6] reported two patients with thymoma and polymyositis in whom the polymyositis remitted after treatment with glucogenic steroids; these patients developed clinical manifestations of myasthenia gravis soon after thymectomy. These authors suggest that there may be a relationship between myasthenia gravis and polymyositis—particularly in the presence of thymoma—on the basis of a common auto-immune mechanism in which thymic dysfunction plays a role. Others[7,8] have also suggested that there is a relationship between polymyositis and myasthenia gravis.

We are reporting a patient with thymoma and myopathy, in whom the myopathy decreased after thymectomy.

Report of Case

A 65-year-old farm wife and mother of five children came to the Mayo Clinic on December 14, 1964, on the advice of her physician who had discovered a mediastinal mass two weeks earlier. She had enjoyed good health all her life except for menorrhagia, which had been treated with intrauterine menopausal doses of radium in 1944, and varicose veins, which had been operated on in 1945. About the middle of October 1964 she requested a "flu shot" from her physician; this was given and, later the same day, she observed swelling in the arm that received the injection. Two days later, to the best of her recollection, she first noted swelling of her feet. Diuretics were prescribed without apparent benefit. She then began to have difficulty with phonation and swallowing, experienced feelings of "weakness and a little dizziness," and found that her "left little finger had curled up and the left hand felt stiff and tender."

*Mayo Graduate School of Medicine (University of Minnesota), Rochester: Resident in Internal Medicine.

†Mayo Clinic and Mayo Foundation: Section of Medicine.

‡Mayo Clinic and Mayo Foundation: Section of Physiology.

Physical Findings

On examination the patient weighed 165 lb (usual weight 160 lb). She had moderate pitting edema over the ankles in the presence of some lipedema. There was evidence of increased pressure in the external and internal jugular and the subclavian veins on the left side, but there was no evidence of increased pressure in the veins on the right side or over the abdomen and legs. The edge of the liver was palpable; the lungs were clear. A puddling of mucus in the pyriform sinuses at the introitus of the esophagus was seen; the larynx appeared normal.

Motor Function Tests

Testing of motor function revealed mild generalized weakness, especially in the pelvic girdle muscles. In tests of esophageal motility the contractions in the pharynx, pharyngoesophageal region, and throughout almost all of the esophagus were feeble. This abnormality was similar to that previously seen in patients with dermatomyositis and scleroderma and with the myasthenic syndrome sometimes associated with bronchogenic carcinoma.

Electromyographic studies revealed numerous fibrillation potentials in many areas of all the muscles that were examined, including the left biceps brachii, first dorsal interosseus, anterior tibial, and vastus medialis. The motor-unit action potentials during voluntary contraction were numerous. They were predominantly short-duration spikes and polyphasic potentials, especially in areas with fibrillation. The mean duration of motor-unit action potentials in the biceps brachii was 6.5 msec (range 3 to 10 msec, $n = 22$): significantly below the range of mean values (9.3 to 14.1 msec) for seven healthy persons of the same age. Thirty-five percent of the motor-unit action potentials were polyphasic, in contrast to values of less than 10% in healthy persons. The amplitude of the summated muscle action potential evoked by a single maximal stimulus to the ulnar, median, or peroneal nerve was low (25 to 60% of the normal mean), but study of the effects of repetitive stimulation failed to reveal any evidence of a defect of neuromuscular transmission. Conduction velocities of motor fibers of the ulnar, median, and peroneal nerves between elbow and wrist or knee and ankle were normal (65, 58 and 58 m/sec, respectively). The latency (distal latency) of the muscle action potential evoked by a maximal stimulus to the nerve at the wrist or ankle was in each instance in the midpart of the normal range. The action potential of large afferent fibers of digital nerves had a normal amplitude (14 μv) and latency (2.8 msec to negative peak, distance 13.0 cm). The pattern of abnormalities in the electromyographic and nerve-conduction studies was that of a myopathy. It was consistent with a diagnosis of polymyositis but not pathognomonic for this disorder.

Transaminase Activity

The serum glutamic-oxalacetic transaminase activity (SGOT) was 1.97 μmoles/hr/ml (normal up to 1.43 μmoles/hr/ml) and the serum creatine kinase activity was 17.46 μmoles/hr/ml (normal up to 3.27 μmoles/hr/ml). X-ray examination disclosed, in the anterior mediastinum, a large mass that extended into the left lung field.

Operation

On December 21, 1964, a median sternotomy was performed and a thymoma measuring 9 by 6 by 5 cm was excised. This was predominantly of the lymphocytic type. A specimen of the pectoralis major obtained at the same time revealed more than the usual variation in the diameter of muscle fibers. There were a few widely scattered basophilic fibers with large vesicular nuclei. Several intrafascicular blood vessels were surrounded by excessive fibroblasts. There was no significant perivascular accumulation of round cells. The abnormalities were considered to be consistent with myopathy of a nonspecific type. Postoperatively the patient did well and her strength increased, although she continued to have some dysphagia and hoarseness. Eight days after operation the serum creatine kinase activity had decreased to 5.64 μmoles/hr/ml.

When the patient returned in June 1965, at our request, she professed to be well and weighed 150 lb. The pitting edema of her legs was decreased. On close inquiry she admitted to some persistent weakness, hoarseness, and dysphagia. The electromyogram showed a marked decrease of fibrillation in the muscles tested. Only rarely during the examination were fibrillation potentials observed; however, abnormalities of motor-unit action potentials were still present. Serum glutamic-oxalacetic transaminase activity was 0.86 μmole/hr/ml of serum and the creatine kinase activity was 3.05 μmoles/hr/ml of serum. A communication from her in May 1966 indicated that she was still doing well.

Comment and Summary

A patient presented evidence of a generalized myopathy;* she had dysphagia, with abnormal esophageal motility, and muscle weakness, especially of the pelvic girdle muscles; serum glutamic-oxalacetic transaminase and creatine kinase values were increased; and the electromyogram showed fibrillation in resting muscles, decreased duration of motor-unit potentials, and an increase in the proportion of polyphasic potentials. Muscle biopsy showed abnormal but nonspecific changes. On removal of the thymoma the patient's strength improved; serum glutamic-oxalacetic transaminase and serum creatine kinase values decreased to normal, and electromyography showed marked reduction in fibrillation. To our knowledge this is the first report of a patient with thymoma and myopathy whose symptoms and findings diminished after thymectomy. Spontaneous remissions in polymyositis have been reported, but in this patient the possibility that the remission was related to thymectomy cannot be excluded.

A "cold" fact

20 ml. NTZ® N-627
Contains Neo-Synephrine® (brand of phenylephrine, USP) HCl 0.5%, Thenfadil® (brand of thenyldiamine, NF) HCl 0.1%, Zephiran® Cl (brand of benzalkonium Cl, USP) 1:5000. To relieve nasal congestion, spray once or twice into each nostril, with head up, every 3 or 4 hours as needed. See circular.
S001CA
Winthrop
NW 87 H

NTZ®
delivers relief of nasal symptoms

The *first spray*—1 or 2 squirts—of NTz opens the inferior part of the common meatus. The *second spray*, a few minutes later, shrinks the turbinates to promote adequate sinus drainage and ventilation—to help prevent sinusitis. Dosage may be repeated every three or four hours.

The fact is, NTz is more than a simple vasoconstrictor. It contains:

Neo-Synephrine® HCl 0.5%, a decongestant of unexcelled efficacy (in full adult strength) to shrink nasal membranes and allow comfortable breathing.

Thenfadil® HCl 0.1%, a topical antihistamine to help relieve itching and rhinorrhea.

Zephiran® Cl 1:5000, an excellent wetting agent and antiseptic preservative to aid rapid spread of components.

NTz, for temporary relief of nasal symptoms, is well tolerated, but overdosage should be avoided.

Available: NTz Nasal Spray in squeeze bottles of 20 ml.; NTz Solution in bottles of 1 oz. with dropper.

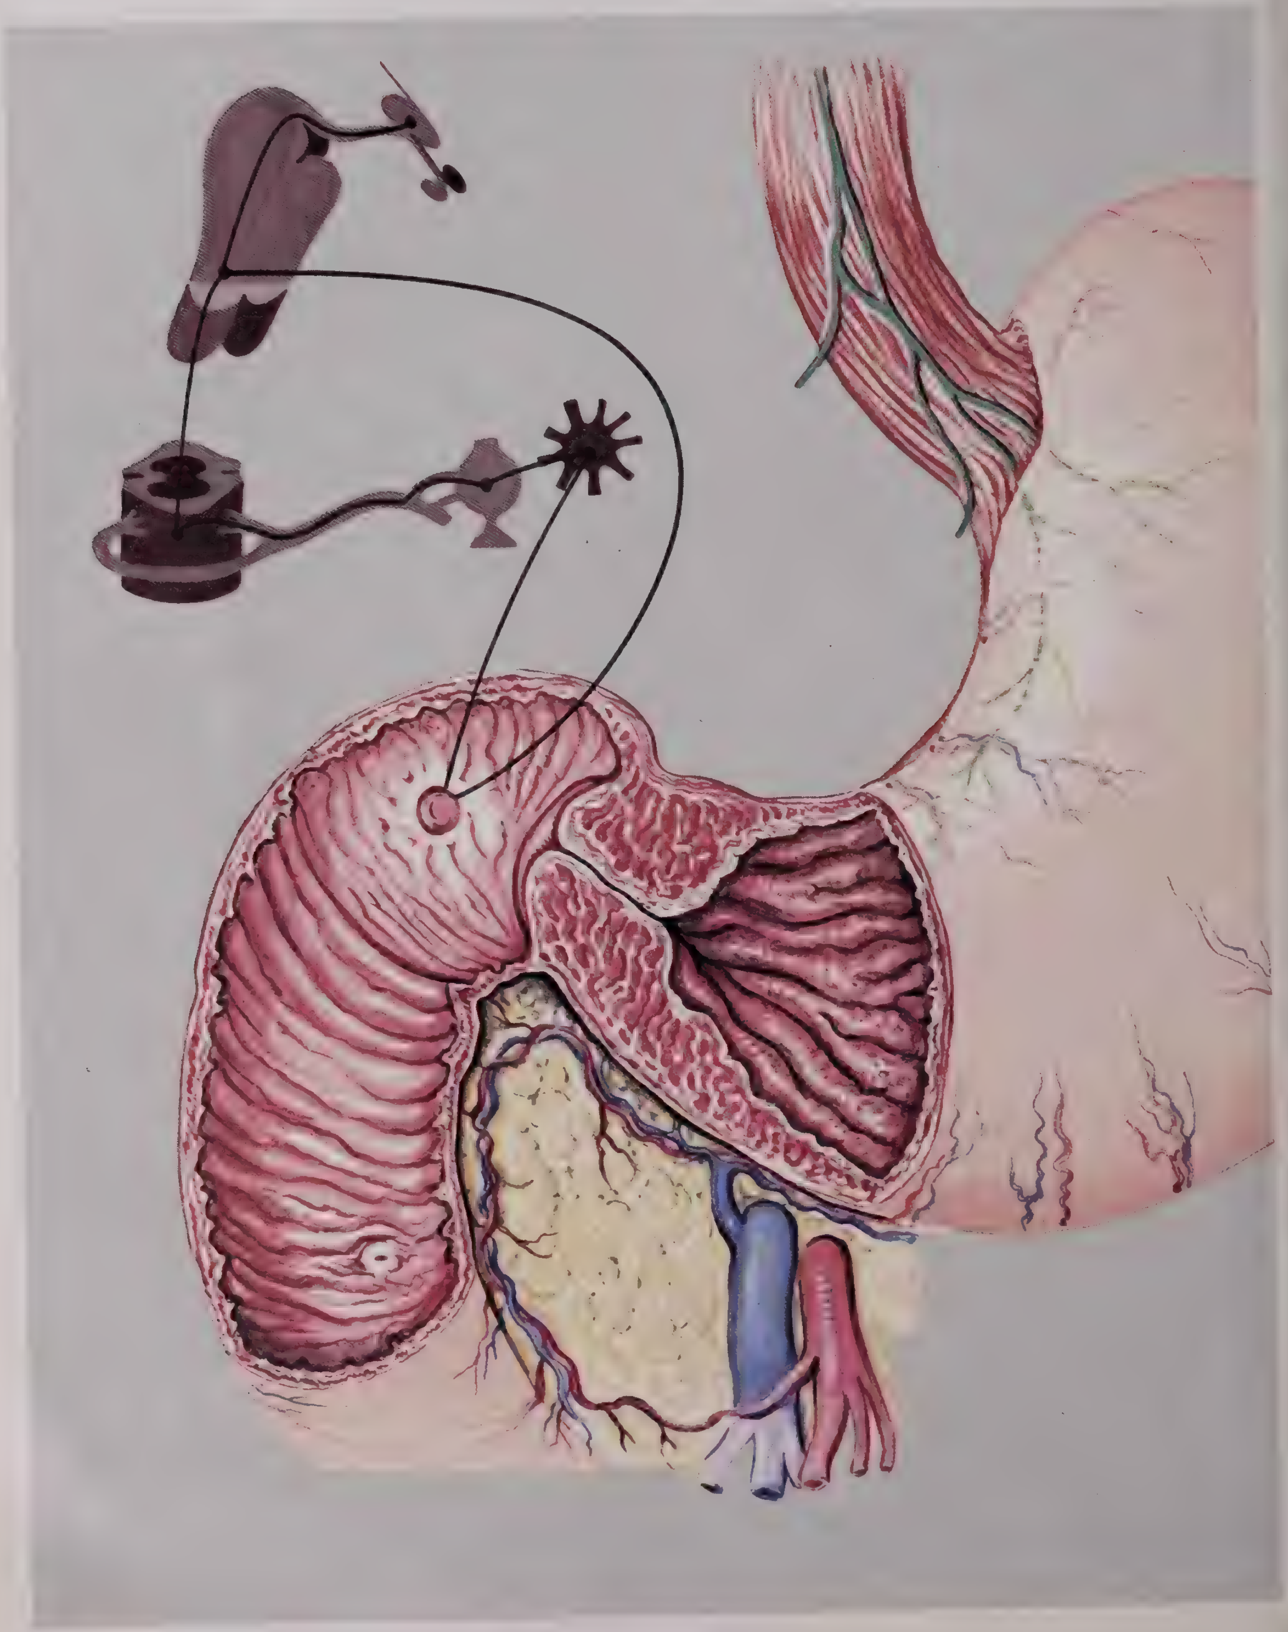
Healing the ulcer crater



Pro-Banthīne®

brand of
propantheline bromide

blocks ulcerogenic autonomic impulses

Therapeutic Activity—Pro-Banthīne blocks ulcerogenic impulses at both parasympathetic effector sites and ganglia and at sympathetic ganglia.

This dual action, a capacity quite beyond that of belladonna derivatives, has been shown repeatedly to reduce gastric secretion, to suppress gastrointestinal motility and to relieve ulcer pain.

Healing Environment—Thus, Pro-Banthīne, together with other standard measures, creates a favorable environment to hasten healing of the ulcer.

So widely is this ability recognized that for years Pro-Banthīne has been the most widely prescribed medication for treating peptic ulcer.

Indications: Peptic ulcer, gastroenteritis, pylorospasm, biliary dyskinesia, functional hypermotility and irritable colon.
Contraindications: Glaucoma, severe cardiac disease.
Precautions: Since varying degrees of urinary hesitancy may occur in elderly men with prostatic hypertrophy, this should be watched for in such patients until they have gained some experience with the drug. Although never reported, theoretically a curare-like action may occur with possible loss of voluntary muscle control. Such patients should receive prompt and continuing artificial respiration until the drug effect has been exhausted.
Side Effects: The more common side effects, in order of incidence, are xerostomia, mydriasis, hesitancy of urination and gastric fullness.
Dosage: The maximal tolerated dosage is usually the most effective. For most adult patients this will be four to six 15-mg. tablets daily in divided doses. In severe conditions as many as two tablets four to six times daily may be required. Pro-Banthīne (brand of propantheline bromide) is supplied as tablets of 15 mg., as prolonged-acting tablets of 30 mg. and, for parenteral use, as serum-type vials of 30 mg. The parenteral dose should be adjusted to the patient's requirement and may be up to 30 mg. or more every six hours, intramuscularly or intravenously.

hours*)

TUSSIONEX SUSPENSION/TABLETS: Each teaspoonful (5 cc.) or tablet of TUSSIONEX contains 5 mg. hydrocodone (Warning: May be habit-forming) and 10 mg. phenyltoloxamine, both as cation exchange resin complexes of sulfonated polystyrene.

Class B narcotic—oral Rx where state laws permit.

INDICATIONS: Coughs associated with respiratory infections including chronic sinusitis, colds, influenza, bronchitis, and cough resulting from measles, pulmonary tuberculosis, bronchiectasis, and bronchogenic carcinoma.

*DOSAGE: *Adults:* 1 teaspoonful (5 cc.) or tablet every 8-12 hours. *Children:* Under 1 year: 1/4 teaspoonful every 12 hours. From 1-5 years: 1/2 teaspoonful every 12 hours. Over 5 years: 1 teaspoonful every 12 hours.

SIDE EFFECTS: May include mild constipation, nausea, facial pruritus, or drowsiness.

For complete detailed information, refer to package insert or official brochure.

Management of Prostatic Infarcts

Elsewhere in this issue, Antolak* describes the successful management of a challenging patient with pyohydronephrosis secondary to prostatic infarction. The conservative approach to such a problem often results in a successful outcome, as dramatically outlined. Nephrostomy drainage in the face of a solitary kidney containing a calculus, with lower ureteral obstruction, was instrumental in achieving a rapid recovery. Roberts and Lattimer[1] have shown similar effective improvement in renal function by catheter drainage of prostatic obstruction as measured by 184% improvement in the creatinine clearance.

Also, in spite of a sterile urine culture, the utilization of antibiotics demonstrated judicious care, as the patient had previously received penicillin which may mask ongoing infection.

Improvement occurred with upper tract drainage, antibiotic therapy and time, and set the stage for treatment of the obstructive lesion.

The rather sudden onset of obstruction of the bladder outlet, and clinical findings suggest another fascinating, obscure condition—granulomatous prostatitis, which also presents in this manner. The necrotizing granulomata, as described by Kelalis, Harnson and Utz[2] may respond to bladder drainage and steroid therapy.

Enzymatic determinations as well as microscopic tissue verification may prove of value. In a series of 96 open prostatectomies for benign disease, Howard and Fraley[3] found elevation of the acid phosphatase in eight cases. All had microscopic infarction of the prostate.

The progression of infarct of the prostate to abscess formation can similarly lead to sudden obstruction of the ureters as well as the bladder outlet. Drainage by transurethral unroofing, or by spontaneous intravesicle rupture (autoprostatectomy) can be most dramatic.

Thus an aggressive, logical, staged approach (often the more conservative ultimately) may result in significant patient salvage—whether the correct diagnosis is made preoperatively or not.

Ambar No 2 Extentabs
THE Cost of AMBAR EXTENTABS IS APPROXIMATELY ONE-HALF THAT OF OTHER LEADING APPETITE SUPPRESSANTS.
AN IMPORTANT FACTOR IN LONG-TERM THERAPY!

CONTROL FOOD AND MOOD ALL DAY LONG WITH A SINGLE MORNING DOSE

AMBAR #2 EXTENTABS®

methamphetamine HCl 15 mg., phenobarbital 64.8 mg. (1 gr.)
(Warning: may be habit forming).

One Ambar Extentab before breakfast can help control most patients' appetite for up to 12 hours. Methamphetamine, the appetite suppressant, gently elevates mood and helps overcome dieting frustrations. Phenobarbital, the sedative in Ambar, controls irritability and anxiety... helps maintain a state of mental calm and equanimity. Both work together to ease the tensions that erode the willpower during periods of dieting.

Also available: Ambar #1 Extentabs®—methamphetamine hydrochloride 10 mg., phenobarbital 64.8 mg. (1 gr.) (Warning: may be habit forming).

BRIEF SUMMARY/**Indications:** Ambar suppresses appetite and helps offset emotional reactions to dieting. **Contraindications:** Hypersensitivity to barbiturates or sympathomimetics; patients with advanced renal or hepatic disease. **Precautions:** Administer with caution in the presence of cardiovascular disease or hypertension. **Side Effects:** Nervousness or excitement occasionally noted, but usually infrequent at recommended dosages. Slight drowsiness has been reported rarely. See package insert for further details.

Intrasynovial Corticosteroid Therapy*

INTRA-ARTICULAR INJECTION of hydrocortisone or its derivatives is a valuable adjunct to treatment in many rheumatic diseases. Such injections are usually of temporary benefit, however, and must be coordinated with the overall plan of therapy for each patient. All diarthrodial joints (true joints) except the spinal joints may be injected. The advantage of intra-articular injection over systemic administration is that a high concentration of the hormone, with its anti-inflammatory effect, may be given to a desired local area while the total injected dose is relatively low. When the proper dosage is injected, usually only a small amount of the drug is absorbed into the systemic circulation, and the potential hazard of suppression of pituitary-adrenal function is thereby avoided. In addition to their use in rheumatoid arthritis, steroids injected intra-articularly are often effective in degenerative arthritis, acute gouty arthritis, traumatized joints and arthritis associated with psoriasis, ulcerative colitis, and systemic lupus erythematosus.

With injection of hydrocortisone acetate or other similar steroid derivatives, decrease in pain and swelling may occur in 90% of patients within 24 hours.[1] But improvement often lasts only a week or less. When the t-butyl acetate group is substituted for the acetate group of hydrocortisone or its derivatives, the steroid becomes less soluble and is more slowly hydrolyzed by body tissues. The action is thus prolonged to two weeks or longer. The work of Bilka and of others[2] suggests that the effect of triamcinolone hexacetonide is also prolonged.

Often intra-articular injections of corticoids are especially helpful when one or only a few joints are inflamed, painful, or particularly bothersome because of one of the conditions previously listed. Intra-articular injections of corticoids may be helpful when given with systemic treatment or when treatment with other medications is contraindicated. After an injection, the patient should be cautioned about over-using the injected joint, as the clinical improvement may encourage abuse of the joint, thus shortening the duration of effectiveness of the injection and causing irreversible damage to the joint. This is especially true of the weight-bearing joints.

Rheumatoid patients are not usually helped by intra-articular injections of corticoids when there is marked widespread activity or severe joint destruction and deformity. Intrasynovial injections of corticoids are contraindicated when a specific infection is responsible for the inflammation of the joint or when an infection is present in a periarticular region. Roentgenograms of the joint should be taken before injection. Culture of synovial fluid prior to injection should be considered when the diagnosis is uncertain or an atypical clinical picture is present.

Some people are so sensitive that they feel snubbed if an epidemic overlooks them.—Frank Hubbard

Photo professionally posed.

No injection after all!

This penicillin produces high, fast levels—orally.

Pen•Vee® K is usually so rapidly and completely absorbed that therapeutic penicillin levels are attained within 15 to 30 minutes. Thus it can often obviate the need for penicillin injections. The higher serum levels produced generally last longer than with those of oral penicillin G.

Indications: Infections susceptible to oral penicillin G: prophylaxis and treatment of streptococcal infections; treatment of pneumococcal, gonococcal, and susceptible staphylococcal infections; prophylaxis of rheumatic fever in patients with a previous history of the disease.
Contraindications: Infections caused by nonsusceptible organisms; history of penicillin sensitivity.
Warnings: Acute anaphylaxis (may prove fatal unless promptly controlled) is rare but more frequent in patients with previous penicillin sensitivity, bronchial asthma or other allergies. Resuscitative (epinephrine, aminophylline, pressor amines) and supportive (antihistamines, methylprednisolone sodium succinate) drugs should be readily available. Other rare hypersensitivity reactions include nephropathy, hemolytic anemia, leucopenia and thrombocytopenia. In suspected hypersensitivity, evaluation of renal and hematopoietic systems is recommended.
Precautions: In suspected staphylococcal infections, perform proper laboratory studies including sensitivity tests. If overgrowth of nonsusceptible organisms occurs (constant observation is essential), discontinue penicillin and take appropriate measures. Whenever allergic reactions occur, withdraw penicillin unless condition being treated is considered life threatening and amenable only to penicillin. Penicillin may delay or prevent appearance of primary syphilitic lesions. Gonorrhea patients suspected of concurrent syphilis should be tested serologically for at least 3 months. When lesions of primary syphilis are suspected, dark-field examination should precede use of penicillin. Treat beta-hemolytic streptococcal infections with full therapeutic dosage for at least 10 days to prevent rheumatic fever or glomerulonephritis. In staphylococcal infections, perform surgery as indicated.
Adverse Reactions: (Penicillin has significant index of sensitization): Skin rashes, ranging from maculopapular eruptions to exfoliative dermatitis; urticaria; serum sickness-like reactions, including chills, fever, edema, arthralgia and prostration. Severe and often fatal anaphylaxis has been reported (see "Warnings").
Composition: Tablets—125 mg. (200,000 units), 250 mg. (400,000 units), 500 mg. (800,000 units); Liquid—125 mg. (200,000 units) and 250 mg. (400,000 units) per 5 cc.

ORAL **PEN•VEE® K**

(potassium phenoxymethyl penicillin) Wyeth

Tremetol Intoxication (Milk Sickness)*

The author is to be commended on a comprehensive description of a perplexing, frequently lethal, formerly common, but fortunately rare poisoning at the present time.

Tremetol intoxication may pose a challenging diagnostic problem to the physician who is confronted with a patient suffering from it, and it may be confused with severe diabetic acidosis or salicylate intoxication. These were the initial diagnostic impressions in the patients reported by Dr. Hartmann, Sr., et al., but a normal blood sugar and the absence of sugar in the urine precluded diabetes mellitus, and a normal or low serum salicylate quickly ruled out salicylate intoxication.

Characteristically, the acidosis (ketosis) of tremetol intoxication is resistant to fluid and alkali therapy, as exemplified by the cases reported by Dr. Hartmann, Sr. et al. The first case, a twelve-year-old girl seen in 1946, with an initial serum CO_2 content of 4 mEq/L, required 11.5 mM/kg. of sodium lactate, 32 mM/kg. of glucose, and 8 mM/kg. of hypotonic Ringer's solution administered over a 48-hour period in order to correct the acidosis. Most other types of acidosis respond to treatment in 12-24 hours. The second patient, a seven-month-old girl, was admitted in December 1962, with an initial serum CO_2 content of 4.8 mEq/L. She required 25 mM/kg. of sodium lactate, 10 mM/kg. of sodium bicarbonate, 90.5 mM/kg. of glucose, and 10 mM/kg. of hypotonic Ringer's administered over an 85-hour period to correct the acidosis. This is the most refractory case of acidosis in our records. The third case, a twenty-month-old girl (sister of Case 2), was admitted five days after her sister's discharge with an initial serum CO_2 content of 9 mEq/L. She responded to treatment in 24 hours with 17.5 mM/kg. of sodium lactate, 13 mM/kg. of glucose, and 6.25 mM/kg. of hypotonic Ringer's. The acidosis in this girl was due entirely to ketosis. Her serum ketone level was 15 mEq/L.

Unfortunately, tremetol poisoning may last a long time and may produce repeated bouts of acidosis, precipitated especially by infections in children. This happens even though the contaminated milk is removed from the diet. The twenty-month-old girl (Case 3 above) was readmitted two months after her first admittance with severe acidosis precipitated by measles (rubeola). Her seven-month-old sister (Case 2 above) was readmitted one year and eight months after her first admittance with severe acidosis precipitated by a respiratory tract infection. Both girls continued to develop ketosis with each respiratory infection up to the present time, four years after their first admittances.

The excellent work of Dr. Anna Pierce Bixby shows what an astute clinician on the battlefront of disease can accomplish without a great deal of laboratory assistance.

Adolescence*

The actions and problems of youth seem to be an eternal and persistent concern of those who are no longer young, and particularly so if one lives under the same roof with one or several adolescents. Problems among the young today may be either greater or only more widely publicized, and youth may, in effect, be libeled on the front pages of newspapers for every spectacular affront to our mores. These affronts may be all the greater because they often touch too transparently on the hypocrisies of those of us who have "settled down." Our outrage and our tendency to categorize acts in terms of crime and punish-

ment or of law and order make us overlook the need for justice and compassion.

Physicians, in particular, need to be aware that beneath those activities and mannerisms that seem obnoxious, there may frequently be issues that are not just matters of conflict between generations but represent the extremes of those persistent problems that all young people share in growing up. A central source of these problems is discussed at length in a scientific article found elsewhere in *Minnesota Medicine,* which speaks clearly to a central problem of a significant number of adolescents: a problem that may be obscured by the superficial manifestations or assertions of a particular youth. The medical issue that may be encountered most frequently, however hidden, is that of a depressive reaction, which may involve all the unique anguish of a given individual but may be masked by his automatic social efforts to overcome, deny, obscure his personal suffering.

The physician will usually be called upon by the parents, and their concerns may be couched in terms of the "incomprehensible" behavior of their sons or daughters. If the physician is aware of other possibilities, and if he can take a wise rather than an authoritarian stance and look beneath social manifestations, he will often find an adolescent in need of help and willing to receive it if it can be presented with dignity and compassion and without adverse or punitive responses.

Each problem will naturally have an individual stamp despite social or clinical similarities; hence one will have to seek individual approaches to treatment. Despite these variations, however, most of the difficulties will probably involve the basic issue leading to the common problem of depressive reaction: namely, the process of gradual emotional separation from one's parents in an automatic way. Many of the superficial, social trappings are only a part, and often an insignificant one, of the individual effort to assert that separation and independence and to deny that it is hurtful and difficult. If the physician can be aware of this and recognize it, he will be able to help with the problems that lie beneath the surface.

Mitral Valve Reconstruction

ONE OF THE MOST dramatic recent developments in the field of cardiac surgery has been the perfection of satisfactory prosthetic devices for total replacement of irreparably damaged cardiac valves. Many thousands of patients are now enjoying good health because of these advances. Nevertheless, it is always preferable to preserve the patient's own valve with reconstructive techniques, whenever this is possible. The long-term complications of the use of prosthetic valves, particularly that of thromboembolism, preclude unwarranted replacement of any damaged valve if reconstructive methods can provide good functional results. This philosophy has been emphasized recently by Drs. Kiser, Peterson, and Johnson in the July 1968 issue of MINNESOTA MEDICINE.*

In most cases, mitral stenosis without calcification and without appreciable mitral insufficiency can be very satisfactorily repaired, and rarely is mitral valve replacement indicated. There is no unanimity of opinion on whether the closed (non-bypass) or open technique should be used for the repair of mitral stenosis. With the perfection of safe methods of cardiopulmonary bypass, mitral stenosis is being repaired under direct vision by increasing numbers of surgeons. The open approach permits a more consistent division of both commissures and greater relief of subvalvular stenosis than closed techniques provide. Mitral regurgitation may be corrected when it is found or produced (as in Case 3 of Kiser and Johnson), and thrombi in the atrium may be completely and safely removed when they are unexpectedly encountered. The left atrial ap-

BRONCHIAL DISTRESS

mudrane

Emphysema, Chronic Bronchitis and Asthma are relieved in fifteen minutes by the fast-disintegrating, uncoated Mudrane tablet.

Checkpoints:

DILATES THE BRONCHI
DRAINS THE MUCUS
SEDATES MILDLY
SUSTAINED ACTION
SUPERIOR TOLERANCE

Each tablet contains:

POTASSIUM IODIDE	195 mg.
AMINOPHYLLINE	130 mg.
PHENOBARBITAL, Caution: may be habit forming.	21 mg.
EPHEDRINE HCl	16 mg.

FEDERAL LAW PROHIBITS DISPENSING WITHOUT PRESCRIPTION

Precautions: Usual for aminophylline-ephedrine-phenobarbital. Iodides may cause nausea, long use may cause goiter. Discontinue if symptoms of iodism develop. Iodide contraindications: tuberculosis, pregnancy.

DOSAGE: One tablet, with full glass of water, 3 or 4 times daily.

Dispensed in bottles of 100 and 1000 tablets.

pendage can be closed if desired to prevent further thrombus formation at that site.

The *open approach to the valve* is preferable in patients with combined mitral stenosis and insufficiency, because there is no satisfactory way to treat valve insufficiency by a closed procedure. Likewise, patients with calcification of the valves, previous embolism (the incidence of intracardiac thrombosis may be as high as 37% versus 19% in patients without embolism),[1] and clot in the left atrial appendage deserve the benefits of open surgery to decrease the incidence of embolic complications. Perhaps long-standing atrial fibrillation should also be included as an indication for open operation because of the much greater incidence of associated left atrial thrombi.[1]

The *mortality rate* for open operation on pure mitral stenosis with a pliable valve can be less than 2%[2,3] and is comparable to that for closed commissurotomy. Many surgeons have adopted open techniques for all patients with mitral stenosis and believe that their results have been improved by this change.[2,4,5] There is also the theoretical advantage that if the valve is opened completely and all insufficiency is repaired, the onset of re-stenosis and the need for re-operation may be either delayed or eliminated. While it is generally agreed that open surgery is indicated in complicated cases of mitral stenosis, its place as a routine procedure in all cases cannot be definitely defined until long-term results are evaluated.

Mitral insufficiency may result from malfunction of any of the four parts of the valve —the mitral annulus, the valve leaflets, the chordae tendineae, and the papillary muscles. Because the clinical picture of mitral regurgitation may result from a diversity of pathologic changes and since no single method of correction can be applied in all cases, open cardiac repair is necessary for uniform assessment of the pathologic anatomy of the diseased valve and application of the proper corrective operation.

Clefts, tears, or perforations of the leaflet may be seen in congenital cleft mitral valves, in traumatic insufficiency produced during the correction of mitral stenosis, and following cure of subacute bacterial endocarditis. These circumstances represent favorable lesions for treatment; and direct suture or patching of the defect, with or without concomitant annuloplasty,* has usually given an excellent result.

Insufficiency resulting from *rupture of chordae tendineae* may be corrected by a number of techniques. Successes have been obtained with the use of artificial chordae and with re-suture of the chordae (or free edge of the leaflet) to the normal point of attachment. We prefer plication of the valve in the area of absent chordae combined with a posterior annuloplasty.[6,7] Because the other portions of the valve are essentially normal, results of repair have usually been excellent.[7] Even though isolated patients may later develop evidence of recurrent mitral insufficiency, repair is generally preferable to replacement of the valve, particularly in younger patients.

In some cases, mitral insufficiency is caused by dilatation of the entire valve ring, and the valve tissue itself is only minimally deformed. Annuloplasty, a selective shortening of the mitral annulus, narrows the valve orifice and allows the valve leaflets to approximate. When applicable, this technique yields very satisfactory results and avoids the complications associated with valve replacement.

The main *disadvantage of annuloplasty* is the problem of late recurrence of mitral insufficiency—a difficulty which has led to the abandonment of the technique by some surgeons. The incidence of recurrence may be decreased by "overcorrection" and by proper placement of deep, strong sutures, preferably backed up with fabric pledgets to help prevent them from pulling through the myocardial tissues. The procedure is most successful in young patients with good tissues and in hearts of moderate size. In some instances, the basic pathologic process of annular dilatation continues and insufficiency recurs. This is more likely to happen with myocardiopathies, Marfan's syndrome, and coronary artery disease—conditions in which valve replacement may be preferable.

Valves that have lost significant leaflet substance and those that are damaged by extensive fibrosis and calcification cannot be restored to satisfactory function by valvuloplasty techniques; such valves must be excised and replaced with a prosthesis. Similarly, lesions of mixed mitral stenosis and insufficiency usually

require prosthetic replacement for best results.

Tricuspid insufficiency is frequently associated with mitral valve disease. It may be "functional" because of dilatation of the annulus secondary to an enlarged right ventricle, or it may develop from organic changes in the valve leaflets caused by rheumatic scarring. The leaflets are relatively normal in functional tricuspid insufficiency, although they exhibit some thickening and other minor abnormalities. Organic tricuspid insufficiency may be suspected if the right ventricular pressures are normal; but it is virtually impossible to differentiate organic from functional insufficiency by palpation alone, unless there is associated valvular stenosis. Because of the difficulty of assessing the tricuspid valve preoperatively, it is routinely palpated in every case of open mitral valve surgery.

Surgical correction of functional tricuspid insufficiency by methods other than valve replacement has met with varying success. In general, techniques of mitral annuloplasty cannot be transferred directly to the tricuspid valve, and attempts to do so have usually given poor results. We have had the greatest success with a type of annuloplasty which obliterates the posterior cusp, converting the valve into a bicuspid one. The heart is allowed to beat, the right ventricle is then filled with blood, and competency of the valve can then be inspected under direct vision. With few exceptions, functional tricuspid insufficiency can be completely corrected by this technique, and valve replacement may be avoided. It adds less than 10 minutes of bypass time, and the long-term results have been excellent.

A satisfactory tricuspid annuloplasty offers an alternative to valve replacement or a "do-nothing" approach.[8,9] We feel it is important to perform an annuloplasty in all cases where the insufficiency is of more than mild severity, even if it is deemed functional and reversible. Postoperative cardiac output is improved, and perhaps there are a few more survivors among patients who would otherwise die of "low-output syndrome." In addition, convalescence is speeded and fluid-retention problems are minimized. Finally, one avoids the situation of the occasional patient who has a disappointingly poor result from his mitral valve surgery because of failure of the tricuspid insufficiency to regress spontaneously.

The authors include two cases in which it was necessary to replace the aortic valve with a prosthesis. Our experience[10] and that of others[11] would indicate that the incidence of postoperative embolization is no greater for multiple valve replacement than for single valve replacement. Consequently it is less imperative that all attempts be made to preserve the mitral valve if other valves require replacement with prostheses. Certainly if there is any question about the functional result following valvuloplasty, replacement should be undertaken.

In addition to avoiding the postoperative complications of prosthetic valves, mitral valve repair by reconstructive techniques is accompanied by a lower operative mortality than valve replacement. The mortality for mitral annuloplasty in suitable cases is approximately half of that for valve replacement, and open mitral commissurotomy can be performed with only a fraction of the mortality of valve replacement. We therefore concur that the preservation of the patient's own tissues, if repair can be accomplished without compromise of the functional result, is far preferable to a replacement with any mechanical prosthesis now available.

The Editor's Soliloquy

Medical Education

THE SURVEY of Doctors I. J. Fahs and W. R. Miller* was gratifying to read, confirming the suspicion that a large percentage of doctors devote considerable time to keeping up with the advances of medicine by reading well-written current medical journals, books and other medical literature.

Classifying 13 sources of medical information they state that specialty societies, postgraduate courses, medical journals and medical books predominate in providing opportunity for advance and progressive medical education. County and national medical society meetings and the costly ($14,000) Minnesota television "Monday for Medicine" series rank very low, along with the teaching tapes and the courteous, gracious and welcome calls of the patient detail men, as the least valuable source of medical information.

According to Doctors Fahs and Miller's Survey, "Each physician works out his own unique way of striving to keep abreast of expanding medical information. He may thoroughly digest the contents of one medical journal to the exclusion of all others, he may concentrate on attending scientific lectures by selected experts, he may ingeniously 'pick his colleagues' brains' in informal contact, or he may utilize all of these and other methods to varying degrees."

Although the specialty medical societies are considered high on the list of those providing worthwhile continuing medical education, considerably above the state and national medical meetings, these latter organizations are most valuable in allowing doctors to renew their social acquaintances and thereby establish intimate and harmonious rapport. To be sure there is a very considerable amount of up-to-date medical knowledge available in the state and national meetings, but the majority of doctors do not consider this source to be as valuable as current medical literature which can be assimilated at their own private moments of relaxation.

Having an eye for economy and endeavoring to obtain the greatest value at the least expense, similar to what the Medical Association recommended to the Federal Government pertaining to Medicare, it is probable that this Association will discontinue the expensive Monday night television series, which ranks lowest in importance as a source of medical information for doctors.

Carl O. Rice, M.D.

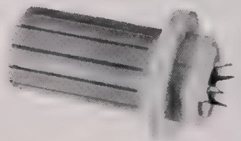
Stanley R. Maxeiner, M.D.

The Editors are pleased to publish the address given by Mr. George D. McConnell on the occasion of the presentation of the St. Barnabas Bowl Award to Dr. Stanley R. Maxeiner, Sr., January 15, 1969.

I AM SURE that most of you are familiar with the St. Barnabas Bowl Award. It was inspired by and made possible through the generosity of Mr. Charles Bolles Rogers, who was the President of the Board of Trustees of St. Barnabas Hospital from 1946 to 1951. It was designated to be given to the physician who, in the opinion of the members of the Hennepin County Medical Society, by reason of his professional contribution on the basis of medical research, achievement or leadership, has become the outstanding physician of this and other years. This award has been given since 1952, with the exception of three years when no selections were made. Of the 14 recipients of this award, eight are still living and four of these eight are with us tonight.

TB is still around.

In 1967 almost 45,000 new active cases were reported. Isn't that a good reason to make tuberculin testing with the white LEDERTINE™ Applicator a routine part of your physical examinations?



TUBERCULIN TINE TEST

Tonight's recipient of the 1969 St. Barnabas Bowl Award, Dr. Stanley R. Maxeiner, has served his profession through six decades. As he has won many previous honors, winning still another award is not new to him.

Dr. Maxeiner was born in Chippewa Falls, Wisconsin, in 1885 and grew up there. His first exposure to surgery came in a most personal way. When he was in high school he was detailed to hold a leg for an amputation while the local doctor cut it off. I suppose this had a great deal to do with the fact that Dr. Maxeiner later selected surgery as his life work.

In 1909 he achieved the M.D. degree from the University of Minnesota and entered internship at the Minneapolis General Hospital. This was the beginning of a long association with Dr. Robert Emmett Farr, the surgeon under whose preceptorship Dr. Maxeiner learned and contributed to the young specialty of surgery. General anesthesia in those days was an inexact and dangerous business. Dr. Farr had pioneered in the development of techniques of local and regional anesthesia; Dr. Maxeiner underlaid these techniques with research reported in Dr. Farr's classical textbook. His mastery of local anesthesia, and of the gentle surgical touch which must go with it, pervaded all his teaching to subsequent surgical generations.

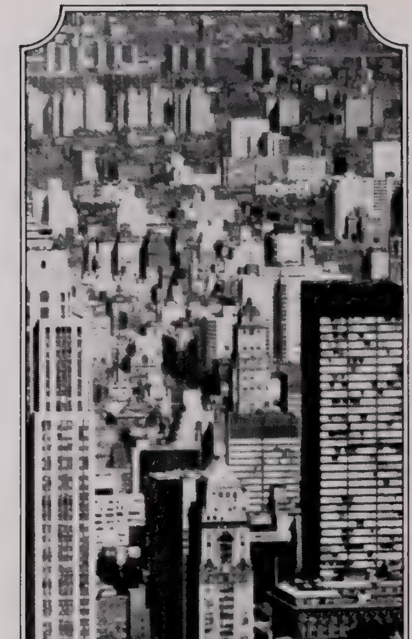
Dr. Maxeiner served as attending surgeon at the Minneapolis General Hospital. At the founding of the U. S. Veterans' Hospital in Minneapolis, he became attending surgeon and surgical consultant, where he worked and taught for over 35 years. He loved to teach as well as to work. He contributed extensively to surgical literature. His academic appointments to the Department of Surgery at the University of Minnesota reached the rank of Clinical Professor in 1949, from which he has now retired.

In 1917 and 1918 he served as a Captain in the Medical Corps. He was sent at once to France where he served in British trenches for 16 months and where he sustained a permanent hearing loss from shell-fire.

After resuming his practice, he became aware that he and his colleagues had common problems and common needs and that some kind of a forum or meeting ground was required to solve these needs. In 1922 he met with three other surgeons, Drs. Webb, Zierold and Dunn, and formed the Minneapolis Surgical Society. During the same year he contributed to the formation of the Minneapolis Clinical Club, which was designed to bring men of different specialties together for fellowship and for cross-pollination. This society became the Minneapolis Academy of Medicine. He served as president in the early years of both of these societies. He also became a member of the Minnesota Academy of Medicine, the Western Surgical Society, the American College of Surgeons, and the Founders Group of the American Board of Surgery. He has served both the Hennepin County Medical Society and the Minnesota State Medical Association as a member and as president. Privately he has served innumerable colleagues over the years as consultant, adviser, and friend. He can look back over the years and see the development of surgery into a science, a discipline, and a compartment of medicine.

Dr. Maxeiner is now retired. He shares his days now with his companion of 47 years, his wife Madeline. They like to travel, they like to grow roses, and he plays golf—the third love of his life.

His special joys, however, are the opportunities which he has to see his son, Dr. S. R. Maxeiner, Jr., working in the same vineyard, seeing patients whose lives are better for what he has done for them, and seeing surgeons



118th Annual Convention

AMA

NEW YORK CITY

JULY 13-17, 1969

The magnetism and the grandeur that characterizes New York City will provide a superb setting for AMA's 118th Annual Convention in July. Plan to attend now and look forward to five memorable and stimulating convention days in a city of unlimited excitement.

Continue your postgraduate education with a varied program of • four General Scientific Meetings on Chronic Pulmonary Insufficiency and Problems of Air Pollution, Human Sexuality, Impact of Medical Education on Patient Care, and Physical Fitness and Aging • 23 Section Programs • Color Television • Medical Motion Pictures • and over 700 scientific and industrial exhibits. The nation's outstanding medical authorities will lecture and discuss the significant advances in today's medicine.

In addition the AMA TV network will present more than 40 hours of convention programming.

Reserve now for the Scientific Awards Dinner in honor of the Scientific Award Winners—Wednesday, July 16, 1969. Since space is limited, we suggest you make your reservations before June 30, 1969. Tickets are $10.00 each, payable in advance.

The complete scientific program, plus forms for advance registration and hotel accommodations, will be featured in JAMA, May 26, 1969.

NEW YORK CITY, NEW YORK • JULY 13-17, 1969
AMERICAN MEDICAL ASSOCIATION'S 118th ANNUAL CONVENTION

who once listened to his teaching and are now making their own contributions to medicine and the community.

Dr. Maxeiner, your great passion for medicine and your compassion for your associates and your patients have earned you this award.

George D. McConnell
Board of Directors, St. Barnabas Hospital

Chairman's Letter

(Continued from page 571).

Brunn has been of tremendous help to the Committee in investigations and recommendations. The doctors previously given a grant are visited twice a year or oftener by a committee member and current reports are made at each meeting. Presently receiving grants are seven widows and no physicians.

Through the years the physician-in-need has been a fascinating subject to contemplate. These men are frugal, not demanding, grateful and fiercely proud and independent. They accept help from their colleagues but would starve before asking for government aid. Their honesty and integrity is demonstrated time and again. A recipient receiving $75.00 monthly wrote to tell us that he had finally outlived an insurance policy, that the insurance company would now send him $25.00 a month for life, and would we please reduce his draw to $50.00. A couple on a fund grant received a small bequest unknown to the Committee and returned our monthly check stating that they would let us know when the $5,000.00 was gone and when we should resume payments.

In a number of instances a widow of a physician has changed her will to leave properties to the Committee. No such bequests have been realized as yet.

If you know of a destitute physician or a widow of a physician in genuine need, call your county medical society secretary, Mr. Harold Brunn or me. We stand ever ready to don our shining armor, mount our milk-white steeds and gallop off to relieve distress and oppose the forces of evil, all with your money.

The Committee has an unparalleled and unmatched record for attendance at meetings. The diligence and devotion of these men make chairing this group my most enjoyable duty for the State Association. At the call of the Chairman they come from the far corners of the state in the foulest weather and despite impossible driving conditions. With the notable exception of the chairman, none of them are young.

Of the original eighteen-man committee under Dr. Humphrey, three are still serving; Dr. Paul Boman of Duluth, Dr. Herman Juergens of Belle Plaine, and the present chairman, Dr. James A. Blake of Hopkins. Meetings of the group are attended by fourteen or fifteen of the eighteen at all times, with occasional one hundred per cent turnouts.

What's Your Score in Alcohol?

Problem: A city street after midnight; a car and its driver; suddenly, a pedestrian off the curb and in the road; no time to avoid him; the walker is struck and killed. A common story. Chances are the pedestrian was "under the influence." True or False?

Answer: True. Studies show that 40% of pedestrian fatalities died with blood levels of 100 mg% of alcohol or more, a level which always impairs cerebral functions.

Problem: The police officer who interrogated the driver at the accident scene found him to be middle-aged, well dressed, employed, driving a late-model car, and residing in a comfortable home nearby. This driver, as a responsible citizen, can surely be assumed to have no drinking problem. True or False?

Answer: False. Only one alcoholic in ten is in skid row. Nine problem drinkers out of ten keep their places in society.

Problem: The police officer detected some odor of alcohol. However, the driver could stand steady and walk straight. The police officer could be sure the driver was not "under the influence." True or False?

Answer: False. He couldn't be sure, and neither could you. Tests show blood levels of 100 mg% commonly go unrecognized even by physicians. Degrees of intoxication obvious in a complex activity like driving may be inapparent in the simple tests usually performed for sobriety. The only meaningful test of intoxication is actual measurement of alcohol levels in blood, breath, or urine.

Problem: Despite obstacles, the police officer was able to secure a legal and valid determination of blood alcohol. The measured concentration was 120 mg%. State law defines 100 mg% or more as intoxication. The driver just had the bad luck to get caught. It takes only a few drinks or so to raise blood alcohol to this level. It could happen to anybody. True or False?

Answer: False. 120 mg% is not attained by ordinary drinking; it follows sustained, heavy intake. Blood alcohol concentration depends upon body weight, metabolic state, and span of time, as well as intake. It is therefore difficult to say how much drinking 120 mg% of blood alcohol may represent. One can estimate that a 150-pound man would require 8 ounces of hard liquor within an hour, or one highball every 10 minutes, steadily, one after the other. This amount of drinking doesn't "just happen" to anybody; it indicates a problem drinker.

Problem: It is not important for society to identify the problem drinker, for he (or she) knows his own problem and can seek help. True or False?

Answer: False. Typically the problem drinker is the last to know. Alcoholism becomes a disease when the patient can no longer control his drinking. He has slid into his affliction insidiously and has built up his deceptions step by step. He may not recognize them himself.

Problem: Recognition is still not important, for treatment doesn't make much difference anyway. True or False?

Answer: False. Alcoholism is a chronic disease with a high incidence of reactivation. It is difficult to treat *but not hopeless.* Non-medical therapists including alcoholics themselves have succeeded in thousands of cases. Unfortunately, interested physicians have been few. Medical research has concerned itself with the complications of alcoholism rather than the disease itself. Perhaps the trouble with treatment lies less in the disease and more in medical reluctance. Medicine must become willing to establish an early diagnosis, to be scientific and definitive in testing and therapy, and to join with other workers in this broad social problem.

Curbstone Consultation

Osteomyelitis

QUESTION: A 13-year-old girl sustained a relatively minor fracture of the posterior of the tibia and a short leg cast was applied. Three weeks later the leg was considerably swollen and six weeks later an obvious osteomyelitis was evident. Antibiotics were then given and the systemic symptoms subsided, but a sinus tract developed in the leg. Could this have been prevented?

ANSWER: Timing of antibiotic therapy is most important in the control of this condition. The antibiotic therapy may be effective in overcoming the systemic manifestations, but ineffective in overcoming the local lesion. Insofar as the lesion is concerned, the antibiotics must be administered in plentiful amounts before the lesion walls off. Otherwise, the antibiotics become ineffective. In this case, even with antibiotic therapy, the systemic manifestations subsided while the local symptoms increased. Early decompression of the involved area could probably have prevented the ischemic necrosis. There is still some disagreement as to the best time for surgical intervention. The timing is often quite difficult. After a few days, if the local symptoms do not subside, the area should be opened. A simple incision through the skin and several large drill holes or a window through the bone, is usually all that is necessary. The area is flushed with antibiotic solution, the window is closed, and antibiotic therapy is continued.

Vitamin B_{12}

QUESTION: Is vitamin B_{12} of value in the treatment of diabetic retinopathy?

ANSWER: There is no substantial evidence of vitamin B_{12} deficiency in diabetics or that such a deficiency plays a role in the etiology of diabetic retinopathy. Therefore, therapy with vitamin B_{12} would not seem to be indicated in the treatment of that condition.

Beware lest you lose the substance by grasping at the shadow.—Aesop

What's Your Score in Alcohol?

(Continued from page 620)

Problem: These criticisms of the medical community may not apply to you. For example:

a. You are alert to the early symptoms and signs of loss of control in alcoholism.

b. You can determine, in your regular medical laboratory, the concentration of blood alcohol in any patient at any time, just as you would determine the concentration of blood sugar.

c. You know where to secure for any alcoholic patient a balanced, long-term therapeutic effort by a treatment team in which a physician plays an appropriate, knowledgeable, and responsible part. True or False?

S. R. Maxeiner, Jr., M.D.*

All the King's Horses

Otto von Guericke, in studying air and its effects, created what is said to have been the first man-made vacuum. He made two halves of a heavy metal sphere, the parts that met having been machined so accurately that when put together they were air-tight. He also invented a stopcock through which he pumped out the air.

"Not all the king's horses can pull them apart," he said.

"They can't, eh?" said the King of Prussia. "Prove it."

So von Guericke attached strong handles to the hemispheres. Ten of the king's horses were hitched to each hemisphere. For an hour they pulled steadily and even jerked. The hemispheres could not be pulled apart. When all present admitted that even the twenty king's horses could not unlock the two parts, von Guericke turned the stopcock with one finger and let in the air. Instantly the two parts fell apart.*

Prescription for Youth

1. Avoid fried meats which angry up the blood.
2. If your stomach disputes you, lie down and pacify it with cool thoughts.
3. Keep the juices flowing by jangling around gently as you move.
4. Go very light on the vices, such as carrying on in society—the social ramble ain't restful.
5. Avoid running at all times.
6. Don't look back—something might be gaining on you.

Satchell Paige

The true value of a human being is determined primarily by the measure and the sense in which he has attained liberation from the self.—Albert Einstein

The Viewing Box

A Moveable Abdominal Mass

The x-ray films below are from the colon (Figure 1) and the small bowel (Figure 2) studies performed on a 49-year-old white female whose chief complaint was an enlarging abdomen. Physical examination showed a large firm mass in the left mid-abdomen which the patient stated had enlarged over the past six months. It was moveable laterally but not up or down. No other signs or symptoms were present.

The barium-filled small bowel film shows medial and posterior (corroborated by lateral films) displacement of bowel loops around a well-defined lucent area in the abdomen. (On this film, some barium remains in the colon from the preceding colon study.)

What is your diagnosis? (See next page.)

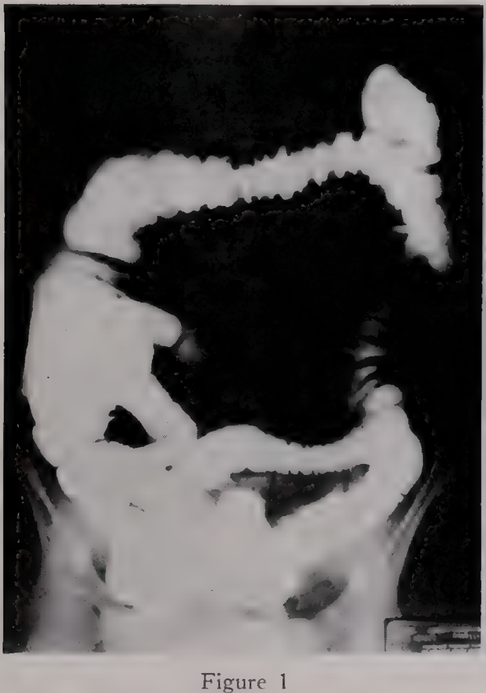

Figure 1

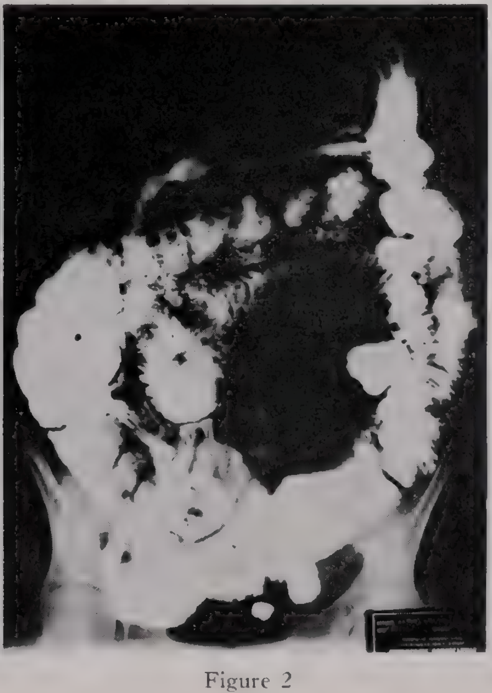

Figure 2

Diagnosis: Mesenteric cyst.

Following the x-ray studies, surgery was performed and a well-encapsulated cystic mass was encountered at the root of the mesentery. The mass was shelled out in toto; pathologically it was a pseudocyst containing a rather thick lymphoid material.

Discussion

Cysts of the mesentery are rare lesions. They give rise to varied and noncharacteristic symptoms. On physical examination, a moveable abdominal mass is palpated. Roentgen signs are fairly characteristic on barium examination of the small bowel. Plain film study usually shows an ill-defined soft tissue radiodensity. On barium contrast studies of the small bowel, the mass is sharply delineated as it is surrounded by loops of bowel (Figure 2). Its position and roentgen appearance place it in the mesentery, and this helps to rule out other possible abdominal masses. Unless very large, no obstructive signs are present. The bowel is displaced but not invaded or compressed. Occasionally the cyst wall will be calcified. Treatment is surgical removal with or without sacrificing a segment of the small bowel, depending on the cyst's location in the mesentery and its relationship to the small bowel loops themselves.

Fracture-Trauma Conference

Nerve Injuries in Fractures of the Lower Extremity

Dr. Einer W. Johnson:*

The incidence of sciatic nerve palsy in dislocation of the hip is probably about 16%, the exact number depending on whose report you read. The incidence of sciatic nerve lesions in fractures of the pelvis has been reported in the literature as probably less than 1%. Yet for those who have become interested in fractures of the pelvis with involvement of the sciatic nerve, the situation resembles that with stress fractures. When you begin to look for this entity, the incidence increases to 9, 10, or 11%. Also, nobody really knows the incidence of peroneal palsy or paresis after fractures of the tibia or fibula, or both; we do know that it is fairly common, it is generally transitory, and it resolves itself with minimal or no residual effect. These comments are by way of introduction.

Dr. Ingvars J. Vittands:†

The first case is that of a 14-year-old boy who was pinned underneath an overturned tractor for an hour. At the time of the accident he had noted immediately that he was unable to move his left leg. He was brought to the emergency room where roentgenograms (Figure 1) were made. He was noted to be unable to dorsiflex his right foot, and there was numbness of the lateral aspect of his right calf and foot. A neurologic examination showed weakness of the psoas and hamstring muscles and marked weakness of the gastrocnemius, anterior and posterior tibial, peroneal, and foot flexor muscles; there was also decreased sensation on the lateral aspect of the right leg and dorsal and plantar aspects of the foot. A diagnosis of trauma to the sciatic nerve, especially to the peroneal division, was made.

Conference held May 15, 1968 at the Mayo Clinic.

*Associate Professor of Clinical Orthopedic Surgery, Mayo Graduate School of Medicine (University of Minnesota), Rochester, and Consultant, Section of Orthopedic Surgery, Mayo Clinic, Rochester.

†Resident in Orthopedic Surgery, Mayo Graduate School of Medicine.

Dr. Johnson:

In this case there has been disruption of the pelvis—the so-called pelvic ring is broken—and probably a dislocation in one sacro-iliac joint. The symphysis seems to be spread, and the superior and inferior rami are fractured. The patient has had a crushing injury of the pelvis and has a sciatic nerve lesion.

Dr. Vittands:

Subsequently, the neurologic deficit stabilized, and it turned out that most of the weakness of the proximal muscles in the leg was due to pain in the pelvis; mainly, there was weakness in the peroneal division. Serial electromyograms confirmed the lesion; on the last neurologic examination only the anterior tibial, toe extensor, and peroneal muscles were weak. There was a slight decrease in sensation on the anteromedial aspect of the foot. By three and a half years after the injury, his condition seemed to have become stable and there was no further neurologic improvement. He was still unable to dorsiflex his foot. He had a foot drop and wore a brace. He has been considered for arthrodesis of his foot or transplant of the posterior tibial tendons.

The next case also involves a victim of a tractor accident; the patient was a 28-year-old man who had sustained a fracture of the shaft of the left femur. Shortly after the accident he had noted that he was unable to dorsiflex his foot and that he had lost sensation on the lower part of his left leg. He had been treated elsewhere (traction and, subsequently, a long-leg cast) (Figures 2 A and B); however, when the cast was removed, it was noted that an ulcer had developed over his heel. He was referred to the Mayo Clinic (six months after the injury) and, on neurologic examination,

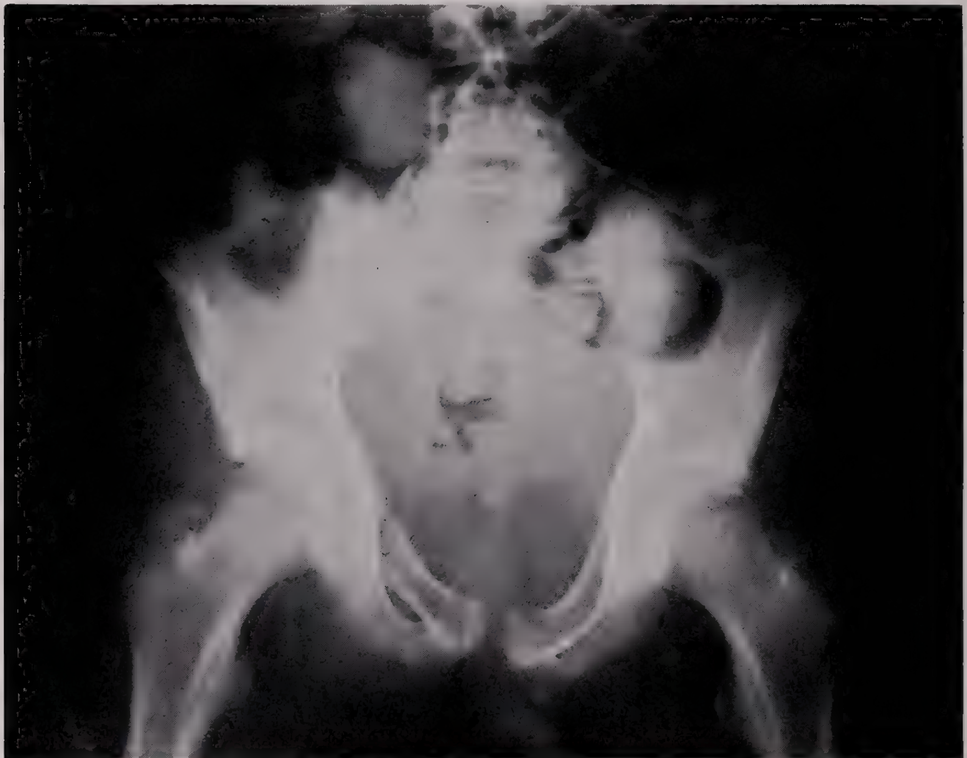

Fig. 1—(Case 1). Fractures of both pubic rami and dislocation of right sacro-iliac joint.

was found to have complete anesthesia of the sole and dorsilateral aspect of the foot and lateral aspect of the lower third of the leg. Ankle jerk was absent and there was essentially no movement at the ankle or toes. An electromyogram was consistent with a lesion of the sciatic nerve on the left side.

Dr. Johnson:

In this case there was a fracture at the junction of the middle and lower thirds of the femur and a sciatic nerve lesion; union was achieved after treatment with traction (elsewhere) with about two inches of shortening (Figures 2 C and D); but a sciatic nerve lesion was still evident when we saw him half a year after his accident. After extensive neurologic consultation, it was decided to explore the nerve; it was found to be divided and trapped in the scar tissue at the posterior aspect of the fracture. From a quick search of the literature, division of the sciatic nerve in the case of a fracture of the femur is rare; we have not been able to find another case.

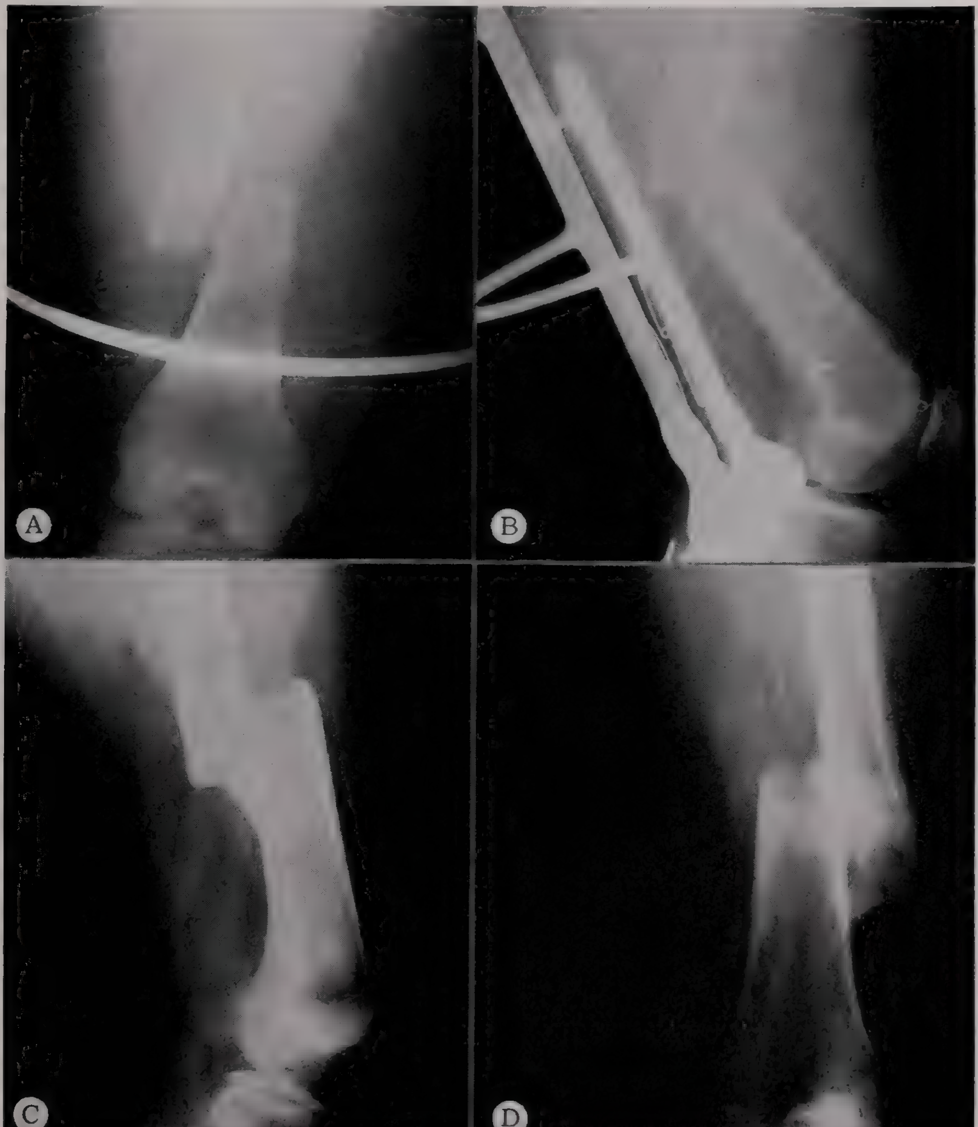

Fig. 2—(Case 2). Fracture of shaft of left femur. (A) and (B), In traction, shortly after original injury. (C) and (D), At admission at Mayo Clinic.

The nerve was repaired and we are waiting to see whether it will redevelop.

Dr. Vittands:

In the third case, a 20-year-old man sustained a crush injury of the tibia, which had been treated elsewhere with a cast. He had noted that he was unable to move his toes and that there was numbness of his foot at the time of injury. When the cast was removed 14 weeks later, he had painless ulcers on the posterior aspect of the right calf and over the right fifth metatarsal, as well as a foot drop. Sixteen months after the accident his right peroneal nerve had been explored (elsewhere) and the scar tissue around the nerve had been resected; however, there was no improvement. He was referred here for an indolent ulcer over the head of the fifth metatarsal of the right foot. On examination he was found to have a right foot drop and weakness of the anterior tibial, toe extensor, toe flexor, and peroneal muscles. Sensation was decreased on the sole and dorsal aspect of the foot and lateral aspect of the leg. A diagnosis of partial injury of the right peroneal and tibial nerves was made. The electromyogram was consistent with a lesion of the right peroneal nerve.

The Sciatic Nerve

These three cases illustrate lesions of the sciatic nerve caused by fracture and dislocation of the pelvis or bones of the lower extremity. Except for lesions of the common peroneal nerve, such injuries are relatively rare in a civilian practice. Only a few large series have been reported. In one report,[1] by the Medical Research Council in England, World War II injuries were analyzed. Woodhall[2] analyzed 7,050 nerve injuries and found that a quarter of them involved the sciatic nerve. Most of these, however, were not due to fractures and, in the study in England, only 6% were due to fractures primarily. Lewis and Miller[3] reviewed 253 fractures associated with nerve lesions and found eight involving the common peroneal nerve, one the sciatic nerve, and one the sacral plexus. Gurdjian and Smathers[4] reported on 53 nerve injuries; eight involved the peroneal nerve and one, the sciatic nerve. They concluded that the peroneal was the third most commonly injured nerve, after the radial and the ulnar nerves.

The sciatic nerve is particularly vulnerable at several points along its course; for this reason a brief review of its relationship is in order.[5] It derives from the sacral plexus, the last two lumbar and first three or four sacral nerves. The plexus itself lies against the posterolateral wall of the pelvis between the piriform muscle and the hypogastric vessels; from here it converges toward the greater sciatic notch to form the trunk of the nerve. In this location it is subject to injury in sacral and pelvic fractures, particularly the lumbosacral trunk which lies close to the posterior pelvic ring. After leaving the pelvis, the nerve lies on the posterior surface of the ischium between the ischial tuberosity and the greater trochanter muscle crossing the external rotators of the hip, where it can be injured in posterior dislocations of the hip. The posterior fragment of the acetabulum may stretch or lacerate the peroneal part of the nerve. More distally the nerve lies well protected on the adductor magnus under the biceps femoris and is injured here only very rarely.

Posterior Tibial Nerve

The two major divisions of the sciatic nerve are the peroneal and the posterior tibial. The posterior tibial nerve continues deep to the biceps femoris, crosses the popliteal fossa, passes between the heads of the gastrocnemius deep to the soleus, and finally divides into the medial and lateral plantar nerves. Thus it is well protected and rarely injured in ordinary fractures. The peroneal nerve runs along the lateral side of the popliteal fossa close to the medial border of the biceps femoris, winds around the neck of the fibula, and passes through the peroneal muscles, dividing into the superficial and deep peroneal nerves. It is thus quite exposed and accordingly the most frequently injured part of the sciatic nerve.

In 1961 Patterson and Morton[6] reviewed the neurologic complications of fractures and dislocations of the pelvis and reported on 15 cases of nerve injury found in 809 pelvic fractures. They concluded that their incidence, 1.2%, was low and would probably increase with the increasing awareness of this complication. In their series, 33% of cases also had associated sacral fractures, which they thought were frequently overlooked. They quoted Bonnin[7] who found that 24% of all pelvic fracture cases also included sacral fractures. The incidence of nerve injury is lower in pelvic fractures than in traumatic hip dislocations. Morton[8] found an incidence of 16% in the latter. Cave[9] reviewed the Massachusetts General Hospital series and found sciatic lesions in 12% of all cases of injured hips, all posterior dislocations of the hip. Among this type of hip injury these nerve injuries were found in 27% of cases. None of the series mentioned any sciatic nerve lesion due to fracture of the femoral shaft, such as in our second case.

Peroneal Nerve

Lesions of the common peroneal nerve are well known and occur after crush injuries and adduction injuries of the knee. Nobel[10] recently recorded two cases of peroneal lesions after spiral fractures of the distal tibia and fibula. Both cases were characterized by an unusual amount of pain and progressive neurologic deficits which were relieved by evacuation of the hematoma from the sheath of the common peroneal nerve. Oppenheim,[11] who reported on peroneal palsies after inversion sprains of the ankle, demonstrated on cadavers that pulling on the cutaneous branches of the superficial peroneal nerve could markedly displace the common peroneal nerve at the knee, making such injuries of the peroneal nerve possible.

Although the total incidence of injury to the sciatic nerve in civilian practice is low, the incidence in certain specific fractures and dislocations is high and should be suspected in such injuries. The possibility of an interneural hematoma should be suspected in tibial fractures and ankle injuries with an unusual amount of pain, especially if this pain is "neuritic" in nature and is associated with a neurologic deficit.

Dr. Johnson:

Thank you, Dr. Vittands. I think this issue is pretty much like the matter of stress fractures that we were speaking about earlier. If we do not think about it, we probably will not recognize it. It is not very hard to detect a foot drop if you ask the patient to dorsiflex his foot and toes. However, if you do find a foot drop, what do you do? Well, I imagine that, in Case 1—

a fracture-dislocation of the pelvis—there is not very much you can do except hope that the thing will resolve by itself. But the second case is a different matter. Dr. Laurnen, what do you think should have been done in Case 2?

Dr. Edwin L. Laurnen:[*]

It is a rare case. I think I would consider exploring the sciatic nerve at the level of the fracture in the femur. There is some controversy on this point.

Dr. Johnson:

What you say is that, because there is an obvious neurologic deficit, a foot drop, and a fracture, the nerve should be explored in Case 2. Is that right? Perhaps part of your decision might be based on whether or not the foot drop was immediate or came on slowly. If you could find out from the patient that his foot drop occurred immediately after the fracture, what would you do: explore the nerve, fix the fracture, or both?

Dr Laurnen:

I think you should do both at the same time.

Dr. Johnson:

I would think that this might be a lot of surgery at one time. I would say that, although this is not an ideal location, perhaps you should do an intramedullary fixation of this fracture and, if you have to open it up extensively, you could explore the nerve at the same time. But if not, then one should wait a few days, then go back posteriorly and explore the nerve if necessary. In any event, I think we can agree that in Case 2 the nerve should have been explored earlier instead of half a year later when the trophic[†] ulcer was already present on the heel, the patient already had the foot drop, and the fracture had united with two inches of shortening. As far as Case 3 is concerned, this patient was caught between rolling pieces of pipe, and the upper part of his tibia was crushed. He had an immediate foot drop and trophic ulcers on the calf, on the heel, and over the head of the fifth metatarsal when the cast was removed. So he probably had an immediate nerve lesion as well. I think the nerve should have been explored. It is hard to say how exploration could have been accomplished in this third case, because I suspect that the nerve was considerably traumatized. However, there is very little, if any, damage done to the nerve by gentle exploration as long as you do not strip its sheath, deprive it of its blood supply, or dislocate a lot of its surrounding and protective soft tissue. Surely this would solve the problem of deciding between division and trauma to the nerve. You have to wait three weeks to get any sensible beginning evidence for nerve loss by electromyography and so may lose three weeks of time.

Dr. William H. Bickel:[†]

I once had a case in which a boy had an undisplaced fracture of the junction of the middle and lower thirds of the tibia and subsequently lost the use of the muscle to his great toe, the extensor hallucis. It was out completely, but he had no other nerve injuries. Six months later, when the electromyogram showed that it was still out, the neurologist gave up and said it was not going to return. I was getting ready to fuse the interphalangeal joint of the great toe, because the boy was a swimmer and went around barefoot; but now, a year and a half later, the muscle is coming back. So the electromyogram is not completely reliable as far as return of the nerve is concerned.

[‡] Professor of Orthopedic Surgery, Mayo Graduate School of Medicine (University of Minnesota), Rochester, and Consultant, Section of Orthopedic Surgery, Mayo Clinic, Rochester.

Dr. Joseph M. Janes:*

Would you often wait 18 months to see the final results of a nerve lesion?

Dr. Johnson:

Full return may not be evident at 18 months. In the first case it has been more than that—three or four years. The patient's condition became stable in about three years. We recorded serial electromyograms every six months for several years.

I am sure one can see return of nerve function 18 months and later after nerve injury. And sometimes, as in our first case, it is wise to wait even longer.

In summary let me make these points:

1. Nerve injury is always possible in almost any fracture and should be looked for.
2. Immediate loss of nerve function often means division of the nerve, whereas gradual loss means partial loss due to swelling or encroachment. Immediate loss of function may be a reason for exploration of the nerve under selected circumstances, as in Case 2.
3. If the nerve has not been divided you can look for return of function for several months after injury, and sometimes several years.

THIS SPACE CONTRIBUTED BY THE PUBLISHER AS A PUBLIC SERVICE

Nose clear as a whistle

(THANKS TO DIMETAPP®)

Dimetapp Extentabs® does an outstanding job of helping to clear up the stuffiness, drip and congestion of colds and upper respiratory allergies and infections. Each Extentab keeps working up to 12 hours. And for most patients drowsiness or overstimulation is unlikely. Try Dimetapp. It clearly works.

UP TO 12 HOURS CLEAR BREATHING ON ONE TABLET

Dimetapp Extentabs®

Dimetane® (brompheniramine maleate), 12 mg.; phenylephrine HCl, 15 mg.; phenylpropanolamine HCl, 15 mg.

FOR UPPER RESPIRATORY ALLERGIES AND INFECTIONS

Indications: Dimetapp is indicated for symptomatic relief of the allergic manifestations of respiratory illnesses, such as the common cold and bronchial asthma, seasonal allergies, sinusitis, rhinitis, conjunctivitis, and otitis.
Contraindications: Hypersensitivity to antihistamines. Not recommended for use during pregnancy.
Precautions: Until patient's response has been determined, he should be cautioned against engaging in operations requiring alertness. Administer with care to patients with cardiac or peripheral vascular diseases or hypertension.
Side Effects: Hypersensitivity reactions including skin rashes, urticaria, hypotension and thrombocytopenia, have been reported on rare occasions. Drowsiness, lassitude, nausea, giddiness, dryness of the mouth, mydriasis, increased irritability or excitement may be encountered.
Dosage: 1 Extentab morning and evening.
Supplied: Bottles of 100 and 500.

A.H. ROBINS COMPANY
RICHMOND, VA. 23220

A-H-ROBINS

Mild ulcerative colitis may be triggered here...

In mild ulcerative colitis, a number of factors can precipitate an attack: for instance, dietary indiscretion, such as eating raw foods, or emotional overreaction, such as that aroused by financial difficulties. No matter what causes the patient's sensitive colon to "act up," he soon suffers from acute discomfort...and often, from anxiety and apprehension as well. Such patients frequently respond well to adjunctive dual-action Librax® therapy.

Librax combines, in a single convenient capsule, the well-known antianxiety effect of Librium® (chlordiazepoxide HCl) and the dependable anticholinergic /antispasmodic effect of Quarzan® (clidinium Br). Therefore, as Librax helps to relieve the patient's excessive anxiety and reduce his overreaction to stress, it also, at the same time, helps to control hypersecretion and hypermotility, thus relieving spasm and abdominal discomfort.

With Librax, the dosage schedule is simple: 1 or 2 capsules, t.i.d. or q.i.d., will in most cases bring the patient significant relief of both the emotional and physical elements that contribute to his psychovisceral disorder.

Before prescribing, please consult complete product information, a summary of which follows.

INDICATIONS: Indicated as adjunctive therapy to control emotional and somatic factors in gastrointestinal disorders.

CONTRAINDICATIONS: Patients with glaucoma; prostatic hypertrophy and benign bladder neck obstruction; known hypersensitivity to chlordiazepoxide HCl and/or clidinium bromide.

WARNINGS: Caution patients about possible combined effects with alcohol and other CNS depressants. As with all CNS-acting drugs, caution patients against hazardous occupations requiring complete mental alertness (*e.g.*, operating machinery, driving). Though physical and psychological dependence have rarely been reported on recommended doses, use caution in administering Librium (chlordiazepoxide hydrochloride) to known addiction-prone individuals or those who might increase dosage; withdrawal symptoms (including convulsions), following discontinuation of the drug and similar to those seen with barbiturates, have been reported. Use of any drug in pregnancy, lactation, or in women of childbearing age requires that its potential benefits be weighed against its possible hazards. As with all anticholinergic drugs, an inhibiting effect on lactation may occur.

PRECAUTIONS: In elderly and debilitated, limit dosage to smallest effective amount to preclude development of ataxia, oversedation or confusion (not more than two capsules per day initially; increase gradually as needed and toler-

or here.

ated). Though generally not recommended, if combination therapy with other psychotropics seems indicated, carefully consider individual pharmacologic effects, particularly in use of potentiating drugs such as MAO inhibitors and phenothiazines. Observe usual precautions in presence of impaired renal or hepatic function. Paradoxical reactions (*e.g.*, excitement, stimulation and acute rage) have been reported in psychiatric patients. Employ usual precautions in treatment of anxiety states with evidence of impending depression; suicidal tendencies may be present and protective measures necessary. Variable effects on blood coagulation have been reported very rarely in patients receiving the drug and oral anticoagulants; causal relationship has not been established clinically.

ADVERSE REACTIONS: No side effects or manifestations not seen with either compound alone have been reported with Librax. When chlordiazepoxide hydrochloride is used alone, drowsiness, ataxia and confusion may occur, especially in the elderly and debilitated. These are reversible in most instances by proper dosage adjustment, but are also occasionally observed at the lower dosage ranges. In a few instances syncope has been reported. Also encountered are isolated instances of skin eruptions, edema, minor menstrual irregularities, nausea and constipation, extrapyramidal symptoms, increased and decreased libido—all infrequent and generally controlled with dosage reduction; changes in EEG patterns (low-voltage fast activity) may appear during and after treatment; blood dyscrasias (including agranulocytosis), jaundice and hepatic dysfunction have been reported occasionally with chlordiazepoxide hydrochloride, making periodic blood counts and liver-function tests advisable during protracted therapy. Adverse effects reported with Librax are typical of anticholinergic agents, *i.e.*, dryness of mouth, blurring of vision, urinary hesitancy and constipation. Constipation has occurred most often when Librax therapy is combined with other spasmolytics and/or low residue diet.

two good reasons for prescribing LIBRAX®

Each capsule contains 5 mg chlordiazepoxide HCl and 2.5 mg clidinium Br.

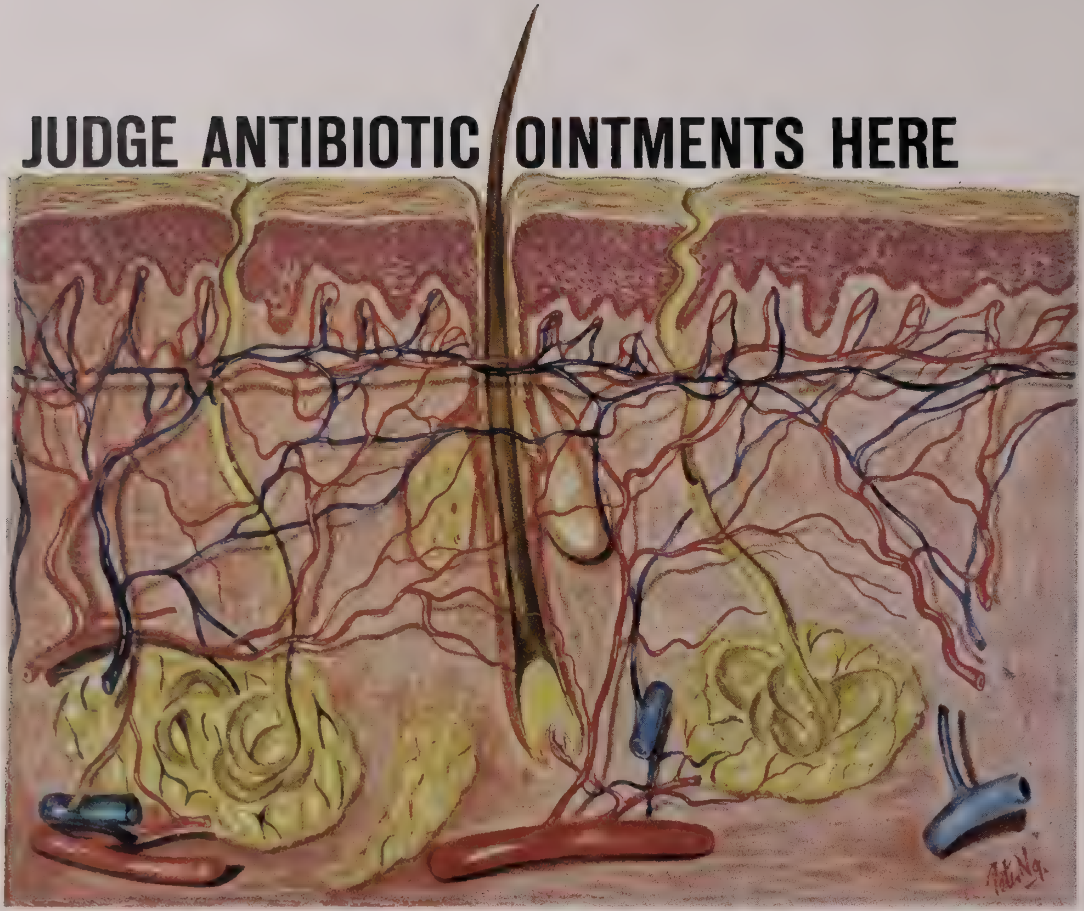
JUDGE ANTIBIOTIC OINTMENTS HERE



Results on skin are final proof of any topical antibiotic's effectiveness

No in vitro test can duplicate a clinical situation on living skin. 'Neosporin' (polymyxin B—bacitracin—neomycin) Ointment has consistently proven its effectiveness in thousands of cases of bacterial skin infection. The spectra of the three antibiotics overlap in such a way as to provide bactericidal action against most pathogenic bacteria likely to be found topically. Diffusion of the antibiotics from the special petrolatum base is rapid since they are insoluble in the petrolatum, but readily soluble in tissue fluids. The Ointment is bland and nonirritating.

Caution: As with other antibiotic preparations, prolonged use may result in overgrowth of nonsusceptible organisms and/or fungi. Appropriate measures should be taken if this occurs. Articles in the current medical literature indicate an increase in the prevalence of persons allergic to neomycin. The possibility of such a reaction should be borne in mind.

Contraindications: This product is contraindicated in those individuals who have shown hypersensitivity to any of its components.

Supplied: Tubes of 1 oz., ½ oz. with applicator tip, and ⅛ oz. with ophthalmic tip.

Tumor Conference

Hamartoma of the Liver in a Pregnant Woman*

To have a hamartoma† of the liver is uncommon. For a pregnant woman to have one is rare. For a pregnant woman to have a hamartoma of the liver, then to deliver a normal child, and finally to have the tumor resected after delivery has yet to be recorded. This is an account of such a case.

Case Report

A 20-year-old white woman, pregnant for the first time, was seen at our clinic on September 11, 1964. Her last menstrual period had been July 1. On examination, she was about two and one-half months pregnant. The physical was otherwise normal, and laboratory work—hemoglobin, serological test for syphilis, Papanicolaou smear—and a chest film were also normal.

In her fourth month of pregnancy, the patient was in an automobile accident, but she was not seriously injured.

At 34 weeks of gestation, she noted a mass in the upper abdomen. We palpated it,

---

*Presentation to the Minnesota Obstetrical and Gynecological Society, Duluth, Minnesota, May 6, 1967.

†See Test Your Word Score Page 672.

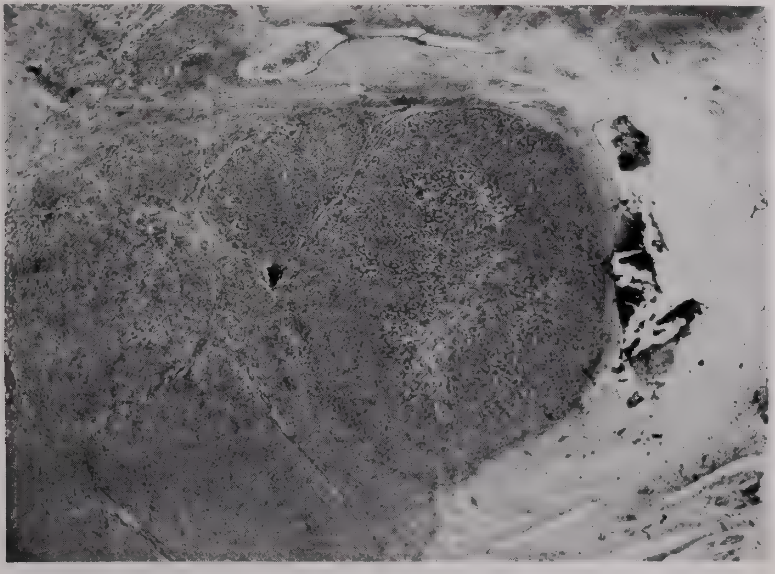

Fig. 1-A.—View showing nodularity, radiating striae of fibrous tissue, and loss of normal architecture.

and it felt like a nodular hard round 10-cm mass over the liver. It was our opinion that it might be a fibroid extending upward from the uterus, and we decided to let her go to term.

In her last trimester, she had mild preeclampsia with a 2+ albuminuria and a blood pressure of 144/100. We hospitalized her, induced labor with oral Pitocin, and ruptured the membranes. She delivered a normal seven-pound, one ounce girl.

After delivery, we could not palpate the tumor when the patient was supine. But when she stood and leaned forward, we could delineate a hard mass which was not connected to the uterus.

A flat plate of the abdomen, intravenous pyelograms, an upper gastrointestinal series, a barium enema, and blood and urine tests were of no help in localizing the tumor (Figures 1-A, B and C). One radiologist ventured the opinion that it might be a mesenteric cyst. Because of our uncertainty about the diagnosis, we performed a laparotomy. Arising from the anterior aspect of the left lobe of the liver was a 10-cm lobulated mass. We excised the tumor and a wedge of surrounding liver.

After operation she did well and was discharged one week later. She is now in good health, active, and has no complaints.

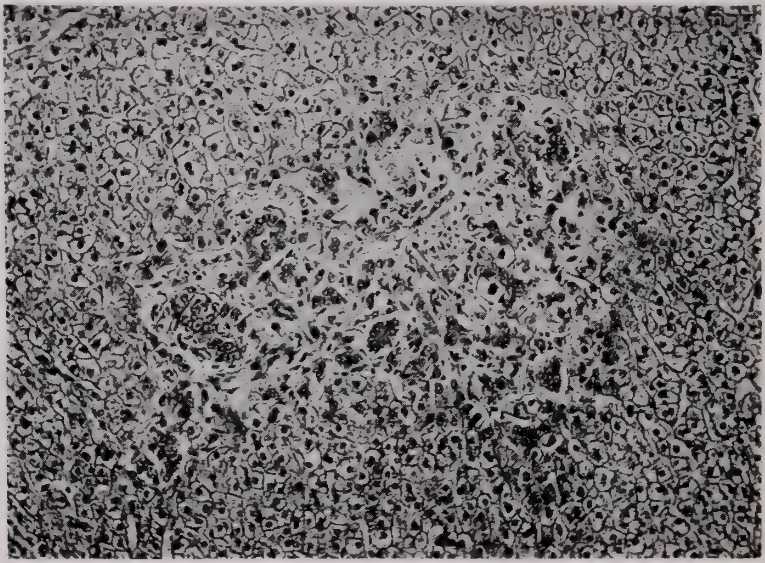

Fig. 1-B—View showing hyperplasia of the bile ducts.

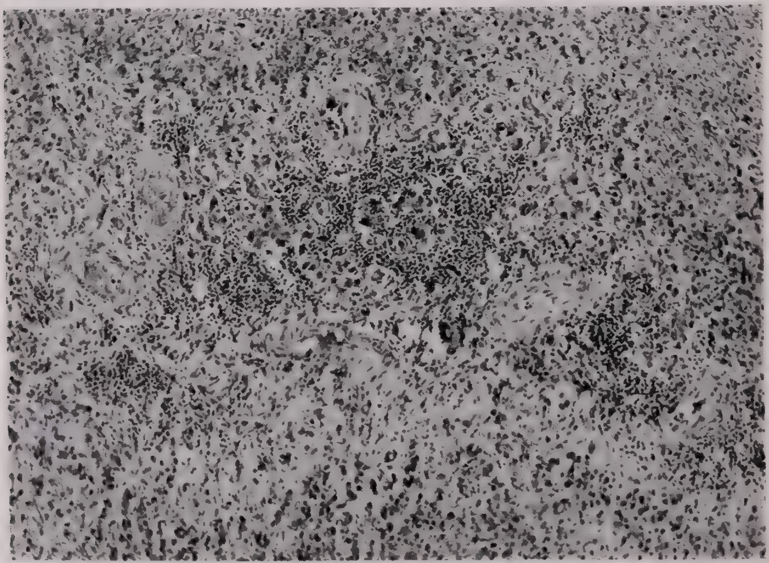

Fig. 1-C—View showing infiltration of leukocytes, indicative of pericholangitis.

Pathological Findings

The pathologist's report read as follows: "Specimen from the left lobe of the liver is an irregular, lobular mass, 9x8x5 centimeters over all. On one margin there is a segment of hepatic tissue of normal appearance over a zone of about 7x1.5 centimeters which appears to be the plane of the polypoid mass. On section the mass is rather finely nodular and has essentially the appearance of a cirrhotic liver." Microscopically, he described fibrous septa which divided liver tissue into irregular islands. The small bile ducts were proliferating, and many of them were not related to the portal triads. He also noted prominent venous channels and pericholangitis. He concluded his report by saying he thought the mass was most likely a hamartoma.

Comment

Although Kiser et al. have reported a hamartoma of the kidney in a pregnant woman,[1] we are not aware of any accounts of hepatic hamartoma in pregnancy. Liver disease of any kind is unusual in pregnancy. Some women develop a cholestatic jaundice late in their gestation; others may contact hepatitis if exposed; and a rare patient may have cirrhosis. Fulminating eclampsia can produce necrosis in the liver.

A hamartoma is a tumor composed of an abnormal mixture of normal constituents of an organ. Benz and Baggenstoss[2] believe that hamartomas of the liver, benign hepatomas, solitary hyperplastic nodules, focal cirrhosis, adenomas, and cholangiohepatomas strongly resemble each other, and may, indeed, represent the same lesion. They reviewed 24 recorded cases of adenomas and hamartomas. Ages of patients ranged from seven months to 88 years. Then they gathered 34 more cases from their autopsy files. Ages varied from 27 to 74 years. All lesions were incidental, and none had caused symptoms. Most lesions arose from the right lobe of the liver. The largest was 5.5 cm; the smallest 0.3 cm; the average 1.2 cm.

Of the 34 livers (40 lesions) they studied histologically, they considered only two true adenomas. These two had no bile ducts, portal triads, or inflammatory cells. Most lesions had bile ducts. Kay and Talbert have emphasized that bile ducts often proliferate in hamartomas.[3]

Anderson[4] describes liver hamartomas as cystic and gray-white to red-purple. He says they usually spring from the lower margin of the right lobe of the liver before two years of age. They grow rapidly because they accumulate fluid. Microscopically, acellular collagenous connective tissue cells often predominate, and remnants of bile ducts and fluid-filled spaces occur.

Summary

A 20-year-old woman observed an abdominal mass in the 34th week of pregnancy. After she delivered a normal girl, a laparotomy was done, and a 9-cm hamartoma was resected from the left lobe of the liver. The patient is active and in good health nearly three years after the tumor was removed.

in cerebrovascular disorders

Arlidin increases blood flow

Arlidin decreases cerebral vascular resistance, increases cardiac output, helps maintain mean arterial pressure.

Arlidin helps control vasoconstriction, vasospasm, and ischemia.

Arlidin may thus relieve symptoms of cerebrovascular insufficiency, such as vertigo, lightheadedness, and mental confusion.

Arlidin also increases blood flow to the eye and inner ear to help manage ischemic disorders of those organs.

Arlidin is well tolerated and relatively free of severe adverse reactions.

DOSAGE: Usual effective dosage ½ to 1 tablet t.i.d. or q.i.d.; increased, if necessary, to 2 tablets t.i.d. or q.i.d. Parenterally, 0.5 cc. by subcutaneous or intramuscular injection; increased gradually to 1 cc. one or more times daily, as needed. SIDE EFFECT: Occasional palpitation. PRECAUTIONS: Use with caution in the presence of a recent myocardial lesion, paroxysmal tachycardia, severe angina pectoris, thyrotoxicosis. CONTRAINDICATION: Acute myocardial infarction.

SUPPLIED: Tablets, 6 mg., scored; bottles of 100 and 1000. Parenteral, 5 mg. per cc., 1 cc. ampuls (5 per box); 10 cc. multiple-dose vials (1 per box). CONSULT PRODUCT BROCHURE.

Wall Chart of Abnormal Values

For busy physicians, diagnosing disease ought to be an act of judgment, not a feat of memory. But for this to be so, you must have readily accessible information at your fingertips or in your range of vision. This wall chart, listing conditions that cause high or low values for certain chemistry tests, should help you rapidly sort through diagnostic possibilities when you receive an abnormal result.

Richard L. Reece, M.D.
Minneapolis, Minnesota

SMA—12/60 WALL CHART

Tests in Same Numerical Order as Those on Graph (See M.M.)

I

Elevated Values of Serum Calcium

- Hyperparathyroidism
- Hypervitaminosis D
- Multiple myeloma
- Prolonged immobilization
- Sarcoidosis
- Secondary carcinomatosis involving bone
- Certain neoplasms, even without demonstrable bone metastases
- Leukemia
- Milk-alkali syndrome
- Idiopathic hypercalcemia of infancy
- Hyperthyroidism (rarely)

Decreased Levels of Serum Calcium

- Hypoparathyroidism
- Osteomalacia
- Steatorrhea
- Acute pancreatitis
- Renal insufficiency (phosphorus increased)
- Vitamin D deficiency
- Renal tubular acidosis

II

Elevated Serum Phosphorus

- Children (4-6 mg.%)
- Renal insufficiency
- Diabetic acidosis
- Acromegaly
- Hypoparathyroidism
- Hemolysis

Decreased Serum Phosphorus

- Primary hyperparathyroidism
- Osteomalacia
- Renal tubular disorders (Fanconi syndrome)
- Use of certain antacids which bind phosphorus
- After insulin or large carbohydrate meal.

III

Elevated Levels of Glucose

- Diabetes mellitus
- Some cases of adrenal, pituitary, or thyroid hyperactivity
- Some cases of sepsis, tumors, and anoxia
- Pheochromocytoma

III (Continued)

Increased intracranial pressure
Nephrosis
Thiazide diuretics, corticoids, and nicotinic acid
Recent or current IV infusions of glucose

Decreased Levels of Glucose

Excessive insulin administration
Pancreatic islet cell tumors (insulinomas)
Myxedema
Glycogen storage disease
Leucine-sensitive hypoglycemia in infants
Certain large fibromas, sarcomas and carcinomas
Adrenal cortical insufficiency
Congenital adrenal hyperplasia
Adenohypophysial hypofunction
Diseases of the liver
After starvation, prolonged exercise, lactation, diarrhea, renal glycosuria
"Functional or reactive" hypoglycemia
Therapy with sulfonylureas, amino acids, and ganglionic blocking agents.

IV

Elevated Values of Bun

Renal insufficiency
G. I. bleeding
Lower urinary tract obstruction
"Pre-renal" azotemia from shock, dehydration, diarrhea, diabetic coma, heart failure

Decreased Values of Bun

Severe liver impairment
Normal pregnancy
Decreased protein intake
Excessive intravenous fluids

V

Elevated Values of Uric Acid

Gout
Renal failure
Toxemia of pregnancy
Excessive destruction of cells—lymphoma, leukemia, hemolytic anemia, resolving pneumonia, polycythemia, myeloma, pernicious anemia, infectious mononucleosis
Use of thiazides, acetazolamide, and low doses of salicylates
Certain cases of hypertension
Starvation
Violent muscular exercise
X-linked primary hyperuricemia
Diabetic acidosis
Ethanol intoxication
Certain types of glycogen storage disease
Psoriasis

Decreased Values of Uric Acid

Rare except after probenacid, high doses of salicylates, and allopurinol

VI

Elevated Values of Serum Cholesterol

Normal pregnancy
Nephrotic syndrome
Hypothyroidism
Hypophysectomy
Pancreatitis
Diabetes mellitus
Primary of familial hypercholesterolemia

Decreased Values of Total Cholesterol

Hyperthyroidism
Hepatic disease
Tangier disease
Abeta-lipoproteinemia
Malnutrition and malabsorption

VII

Decreased Albumin

Malnutrition
Cirrhosis
Hepatic disease—hepatitis, cirrhosis
Nephrotic syndrome
Supine position

Increased Albumin

Dehydration

VIII

Increased Globulin*

Infection
Liver disease
Malnutrition
Neoplasms, especially multiple myeloma
Dysproteinemias (macroglobulins and cryoglobulins)
Hypersensitivity states
"Collagen diseases"
Granulomatous diseases (sarcoidosis, etc.)

Decreased Globulin

Congenital or acquired hypogammaglobulinemia
Some granulomatous diseases

*NOTE—Globulin equals total protein minus albumin

IX

Elevated Values of Total Bilirubin

Neonatal jaundice
Erythroblastosis
Crigler-Najjar syndrome
Gilbert's disease
Dubin-Johnson syndrome
Hemolytic anemia
Intra- or extra-hepatic biliary obstruction
Cirrhosis
Hepatitis (viral, toxic, etc.)

X

Elevated Values of Alkaline Phosphatase

Children up to puberty
Healing of a fracture
Bone metastases
Rickets
Paget's disease (high levels in active disease)
Hyperparathyroidism (specially when the diet is deficient in calcium)
Biliary obstruction due to stones or neoplasm
Metastatic tumor to the liver
Cirrhosis
Hepatitis
Congestive heart failure
Pulmonary infarction (The elevation is maximal 1 to 3 weeks after pulmonary embolism
Normal pregnancy (elevations are found especially during the last trimester; these values return to normal within 2 to 6 weeks postpartum). Higher values of serum alk. phosphatase are noted in preeclampsia than in normal pregnancy.

Decreased Alkaline Phosphatase

Hypophosphatasia (an inborn error of metabolism in which alkaline phosphatase is deficient in all body tissues)
Pernicious anemia (patients with pernicious anemia may have a relative decrease in serum alkaline phosphatase with a return to normal levels with B12 treatment).

XI

Elevated Levels of Serum LDH

Hemolysis
Myocardial infarction (the SGOT)
Pulmonary infarction (usually elevated)
Leukemia, lymphoma, carcinoma

Collagen disease

XII

Elevated Values of SGOT

Hemolysis
Myocardial infarction (the SGOT usually rises 6-12 hours after mycardial infarction, reaches a peak at 24 to 28 hours and returns to normal in 4-7 days.
Congestive failure (due to central lobular necrosis of the liver)
Dicumerol therapy
Pericarditis
Myocarditis
Alcoholic myopathy (CPK also elevated)
Hepatitis
Muscle disease including muscular dystrophy, dermatomyositis, and gangrene
Trauma, including surgical trauma
Convulsions (will elevate both LDH and SGOT)
Renal infarction
Acute pancreatitis
Hemolytic anemias
Toxemia of pregnancy (extremely high levels are obtained after convulsions)

Karl Marx—Utopia

Karl Marx wrote: "In a Communist society where nobody has one exclusive sphere of activity, but each can become accomplished in any branch he wishes, society regulates the general production and thus makes it possible for me to do one thing today and another tomorrow, to hunt in the morning, fish in the afternoon, rear cattle in the evening, criticize after dinner, just as I have in mind, without ever becoming hunter, fisherman, shepherd or critic."

Marx was an escapist. He wanted to flee from time, scarcity, and earthly limitations. His economic analysis was directed at this world and therefore totally critical; his hopes for the future were Utopian and unrealistic.*

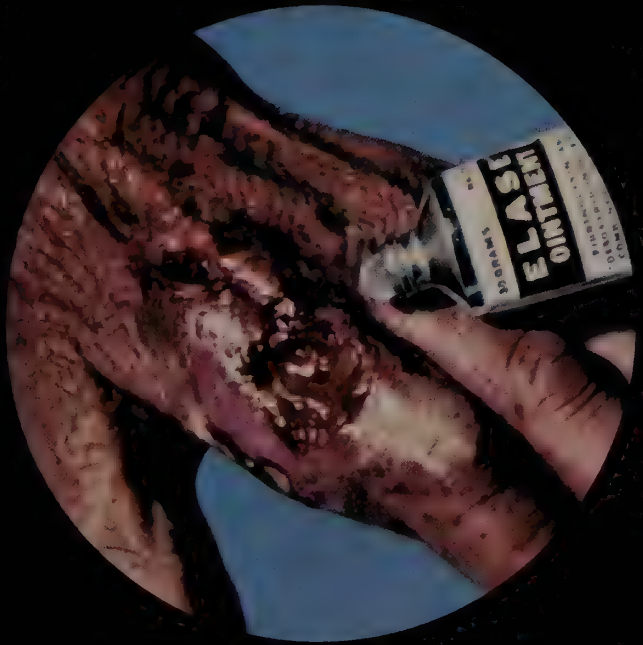
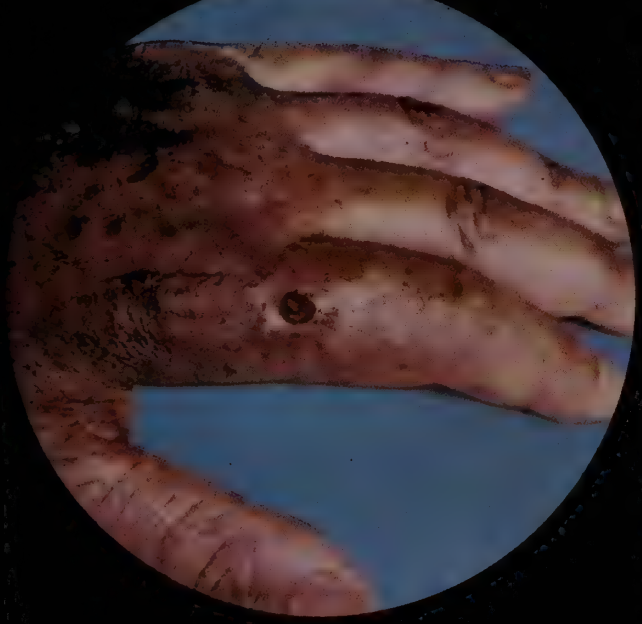
Kindness goes a long way lots of times when it ought to stay at home—Frank Hubbard

this ulcer did not heal...until its surface was cleared of dead tissue and debris



FIRST APPLICATION
ELASE Ointment is applied to a deep ulceration of a finger.

EIGHTEEN DAYS LATER
Healing has progressed rapidly without interruption or interference from any accumulated purulence or necrotic tissue. Greatly reduced size of lesion and minimal scar tissue indicate quality and vigor of healing which is almost complete.



to aid in debridement
to facilitate healing
in chronic cutaneous ulcers...

Elase® Ointment

(fibrinolysin and desoxyribonuclease, combined, [bovine] ointment)

PARKE-DAVIS

By helping to remove dead tissue and debris from the ulcer's surface, ELASE Ointment creates a better environment for the elimination of infection, for healthy granulation...*for healing.* Its lytic enzymes effectively break down DNA in dead leukocytes and other debris...the fibrin in blood clots, serum, and purulent exudates...and the denatured proteins in necrotic tissue. Protein elements of *living* tissue are relatively unaffected. ELASE Ointment is indicated in stasis ulcers and in other infected or inflamed ulcers caused by circulatory disturbances. In cases requiring skin grafting, it is used preoperatively for debridement. For ambulatory patients debridement with ELASE Ointment is a convenient therapy and a regimen likely to be followed. *Precautions:* Observe usual precautions against allergic reactions, particularly in persons with a history of sensitivity to materials of bovine origin or to mercury compounds. *Adverse Reactions:* Side effects attributable to the enzymes have not been a problem at the dose and for the indications recommended. *Discussion:* Successful use of enzymatic debridement depends on several factors: (1) dense, dry eschar, if present, should be removed surgically before enzymatic debridement is attempted; (2) the enzyme must be in constant contact with the substrate; (3) accumulated necrotic debris must be periodically removed; (4) the enzyme must be replenished at least once daily; and (5) secondary closure or skin grafting must be employed as soon as possible after optimal debridement has been attained. It is further essential that wound-dressing techniques be performed carefully under aseptic conditions and that appropriate systemically acting antibiotics be administered concomitantly if, in the opinion of the physician, they are indicated. *Available:* ELASE Ointment is supplied in 30-Gm. tubes containing 30 units (Loomis) of fibrinolysin and 20,000 units of desoxyribonuclease with 0.12 mg. thimerosal (mercury derivative); and in 10-Gm. tubes containing 10 units of fibrinolysin and 6,666 units of desoxyribonuclease with 0.04 mg. thimerosal. ELASE Ointment has a special base of liquid petrolatum and polyethylene; contains sodium chloride and sucrose used during manufacture; is stable at room temperature through the expiration date stated on the package.

Anxiety is expected in the cardiovascular patient. A little may even be desirable.

But when anxiety is exaggerated . . . when it nterferes with sleep . . . when it aggravates cardiovascular symptoms, your help may be needed.

Naturally, you'll want to reassure the patient.

And perhaps prescribe Equanil (meprobamate) as adjunctive therapy. It helps relieve anxiety and tension specifically, yet gently.

Almost 15 years' use has shown that Equanil s usually well tolerated as well as effective. Side effects are generally limited to transient drowsiness; serious, therapy-interrupting side effects are rare.

Contraindications: History of sensitivity to meprobamate.

Important Precautions: Carefully supervise dose and amounts prescribed, especially for patients prone to overdose themselves. Excessive prolonged use has been reported to result in dependence or habituation in susceptible persons, as alcoholics, ex-addicts, and other severe psychoneurotics. After prolonged excessive dosage, reduce dosage gradually to avoid possibly severe withdrawal reactions. Abrupt discontinuance of excessive doses has sometimes resulted in epileptiform seizures.

Warn patients of possible reduced alcohol tolerance, with resultant slowing of reaction time and impairment of judgment and coordination.

Reduce dose if drowsiness, ataxia or visual disturbance occurs; if persistent, patients should not operate vehicles or dangerous machinery.

Side Effects include drowsiness, usually transient; if persistent and associated with ataxia, usually responds to dose reduction; occasionally concomitant CNS stimulants (amphetamine, mephentermine sulfate) are desirable. Allergic or idiosyncratic reactions are rare, but such reactions, sometimes severe, can develop in patients receiving only 1 to 4 doses who have had no previous contact with meprobamate. Previous history of allergy may or may not be related to incidence of reactions. Mild reactions are characterized by itchy urticarial or erythematous maculopapular rash, generalized or confined to groin. Acute nonthrombocytopenic purpura with cutaneous petechiae, ecchymoses, peripheral edema and fever have been reported. One fatal case of bullous dermatitis following intermittent use of meprobamate with prednisolone has been reported. If allergic reaction occurs, meprobamate should be stopped and not reinstituted. Severe reactions, observed very rarely, include angioneurotic edema, bronchial spasms, fever, fainting spells, hypotensive crises (1 fatal case), anaphylaxis, stomatitis and proctitis (1 case) and hyperthermia. Treat symptomatically as with epinephrine, antihistamine and possibly hydrocortisone. Aplastic anemia (1 fatal case), thrombocytopenic purpura, agranulocytosis and hemolytic anemia have occurred rarely, almost always in presence of known toxic agents. A few cases of leukopenia, usually transient, have been reported on continuous administration.

Meprobamate may sometimes precipitate grand mal attacks in patients susceptible to both grand and petit mal. Extremely large doses can produce rhythmic fast activity in the cortical pattern. Impairment of accommodation and visual acuity has been reported rarely. After excessive dosage for weeks or months, withdraw gradually (1 or 2 weeks) to avoid recurrence of pretreatment symptoms (insomnia, severe anxiety, anorexia). Abrupt discontinuance of excessive doses has sometimes resulted in vomiting, ataxia, tremors, muscle twitching and epileptiform seizures. Prescribe very cautiously and in small amounts for patients with suicidal tendencies. Suicidal attempts have resulted in coma, shock, vasomotor and respiratory collapse and anuria. Excessive doses have resulted in prompt sleep; reduction of blood pressure, pulse and respiratory rates to basal levels; and occasionally hyperventilation. Treat with immediate gastric lavage and appropriate symptomatic therapy. (CNS stimulants and pressor amines as indicated.) Doses above 2400 mg./day are not recommended.

Composition: Tablets, 200 mg. and 400 mg. meprobamate. Coated Tablets, WYSEALS® EQUANIL (meprobamate) 400 mg. (All tablets also available in REDIPAK® [strip pack], Wyeth.) Continuous-Release Capsules, EQUANIL L-A (meprobamate) 400 mg.

A little sunshine for summer cold and allergy sufferers.

Novahistine LP can brighten things in a hurry for your summer cold and allergy patients.

These continuous-release, decongestant tablets contain a vasoconstrictor-antihistamine formulation that goes to work promptly and usually provides effective relief even in those cases of nasal congestion caused by repeated allergic episodes.

And, convenient twice-a-day dosage with Novahistine LP lets most patients enjoy relief all day and all night.

Use with caution in patients with severe hypertension, diabetes mellitus, hyperthyroidism or urinary retention. Caution ambulatory patients that drowsiness may result.

Pityriasis Rosea

In 1860 Gibert described pityriasis rosea, an acute papulosquamous dermatosis. The disease affects males and females equally, and it is more common between the second and fifth decades. The cause is unknown. The disorder shows seasonal variations (spring and fall), causing speculation as to a viral nature. However, to date there is no proof of this.

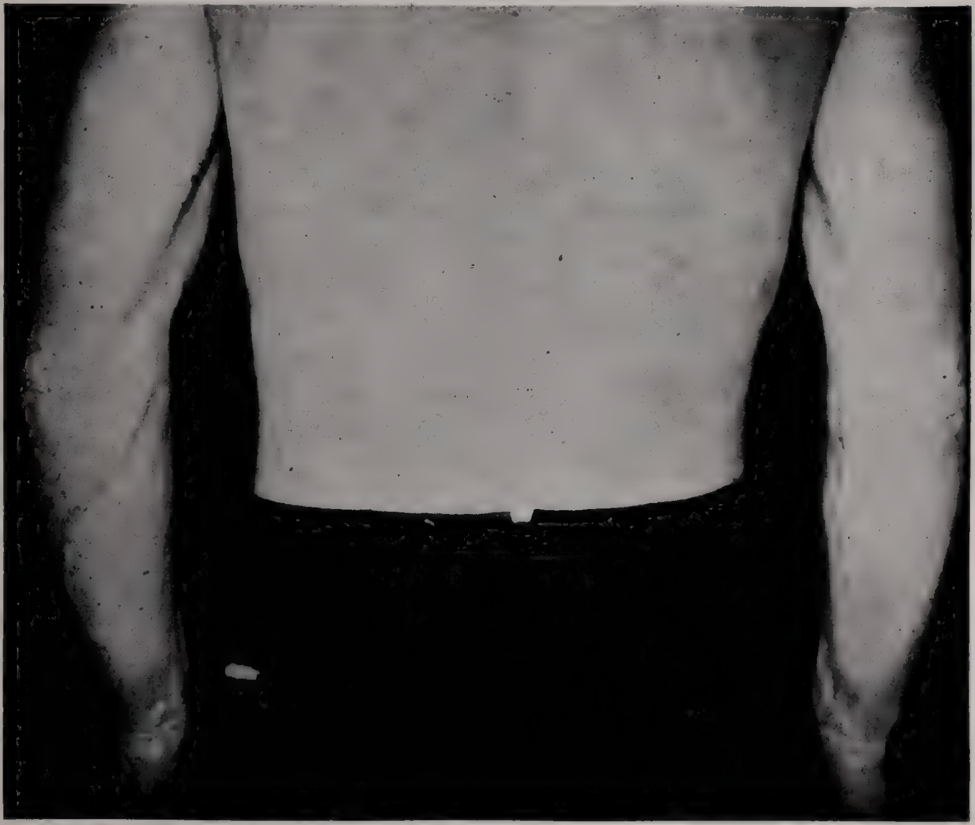
Clinical

In a majority of cases the eruption begins with an isolated lesion (herald* or mother patch), usually located on the neck, trunk, or elsewhere. The primary lesion is pink and scaly and resembles tinea corporis. The herald plaque may not always be evident; sometimes it has regressed when the physician sees the patient.

Approximately seven to 10 days after the appearance of the primary lesion, the general eruption occurs. These lesions are usually macular, maculopapular or papular with little or no infiltration. Color varies from yellowish-red to scarlet. Individual lesions range from ½ to 3 cm. in diameter, although

---

*See Test Your Word Score Page 672.



Figure

1 cm. is most common (smaller than the herald patch). There is a fine adherent collarette of scale at the periphery. The lesions enlarge by peripheral extension, leaving a clear center.

Distribution of the eruption is helpful in diagnosis. It usually affects the upper trunk; if more extensive, there are lesions on the proximal extremities. Involvement of the head, hands, lower legs, and feet is rare. On the trunk the long axis of the lesion follows the lines of cleavage and presents a characteristic appearance (Figure). Variations may occur, such as unilateral involvement, oral lesions, etc.

The most important general symptom is pruritus which varies from insignificant to severe and is usually worse at night and after a hot bath. Occasionally, fever, congestion of the fauces, and submaxillary and cervical adenitis occur. The disease usually runs a self-limited course of four to eight weeks. Secondary eczematization is an uncommon complication.

Differential Diagnosis

Macular syphilid, seborrheic dermatitis, psoriasis, and tinea corporis enter into the differential diagnosis. In macular syphilid the lesions are smaller and less scaly. Mucous membrane lesions, general adenopathy, and positive serologic tests are other signs of secondary syphilis. Seborrheic dermatitis commonly occurs on the scalp, central face, sternum, and intertriginous areas. The lesions usually have a greasy scale. In psoriasis the eruption has more infiltration, abundant silvery adherent scales, and a predilection for extensor surfaces. Tinea corporis is neither as extensive nor symmetric as pityriasis rosea. The lesions are larger and show more active inflammation at the border. Culture or examination with potassium hydroxide may be necessary for differentiation in some cases.

Treatment

Treatment consists of topical hydrocortisone lotions, creams, or ointments. If itching is severe, oral antihistamines are of value. Avoid anything which heats the skin (hot baths, exercise, etc.). If there is any question regarding diagnosis, serologic tests for syphilis should be performed.

Grand Rounds

Lactic Acidosis*

Erik E. Carlson, M.D.
Minneapolis, Minnesota

LACTIC ACID, an important product of normal glycogen metabolism, was first discovered in increased amounts in peripheral blood, following strenuous exercise, by Ryffel in 1909.[1] Barr, Himwich and Green studied the metabolic acidosis associated with exercise in 1923 and found elevated blood lactic acid concentrations.[2]

Clausen, in 1925, discussed the acidosis of anhydremia: a clinical syndrome then characterized by the "acute loss of fluid by diarrhea and vomiting in a previously well nourished person." He found elevated levels of blood lactic acid in the metabolic acidosis associated with both cardiac decompensation and anhydremia. Clausen linked this elevation of lactic acid to both inadequate circulation and/or reduced oxidative processes in the body and recommended that lactic acidosis was best treated by relief of the underlying circulatory condition.[3]

Sporadic references were made in the literature in subsequent years to lactic acidosis in association with a variety of disease states. However, it was not until Huckabee's initial report in 1961 of nine patients with lactic acidosis that this was felt to be of clinical significance.[4,5]

Lactic Acid Production

Glycogen (or glucose via glucose-6-phosphate) is normally metabolized to pyruvic acid in the first stage of carbohydrate dissimilation.[6] This process may occur under both aerobic and anaerobic conditions.

In the presence of *adequate oxygen* little lactic acid is formed. Rather, the pyruvic acid is broken down to CO_2, H_2O, and the reduced coenzyme 1 ($DPNH_2$) is reoxidized to diphosphonucleotide to again act as a hydrogen acceptor in stage one dissimilation.

---

*Presented as a Medical Grand Rounds at Hennepin County General Hospital, Minneapolis, September 5, 1967.

Under *anaerobic* conditions pyruvate acts as a temporary hydrogen acceptor and oxidizes (dehydrogenates) the $DPNH_2 \rightarrow DPN$. In the process pyruvic acid is converted to lactic acid under the mediation of the enzyme lactic dehydrogenase according to the following equation:

(1) Pyruvate + $DPNH_2 \rightleftarrows$ Lactate + DPN

If we rewrite this equation (1) in its mass action form, we obtain the following:

$$(2)\ \{\text{Lactate}\} + \{\text{Pyruvate}\} \times K \frac{\{DPNH_2\}}{\{DPN\}}$$

Clearly then the direction of this reversible reaction depends upon the relative concentrations of the factors involved, i.e., pyruvate, lactate, diphosphonucleotide, $DPNH_2$ and lactic dehydrogenase. Huckabee[7] suggests that on a theoretical basis lactate production may be considered to reflect three situations:

(A) Relative inadequacy of oxygen supply with regard to metabolic needs,

which is expressed by $K \frac{\{DPNH_2\}}{\{DPN\}}$

(B) Changes in pyruvate concentration

(C) Changes in both factors simultaneously.

Experimentally, Huckabee found that the infusion of bicarbonate, glucose, pyruvate and hyperventilation in both humans and animals would produce a change in blood lactate concentrations in the absence of any detectable hypoxia on the basis of arterial and mixed venous blood oxygen saturation. Further, the blood lactate changes were paralleled by the pyruvate concentrations without an increase in excess lactate. He therefore concludes that lactate production is not controlled exclusively by the adequacy of cellular oxygenation but is also under the significant influence of pH, blood glucose levels and probably other stimuli yet unknown.[7]

In a series of reports relating to pyruvate and lactate during anaerobic metabolism[8,12] Huckabee has found that exercise with subsequent oxygen debt formation, and inhalation of low oxygen gases will produce calculated "excess lactate" concentrations which correspond well with the magnitude of oxygen debt developed.[8,9]

In-vitro experiments[13] suggest that lactate moves freely and passively across a permeable membrane according to the considerations of the Donnan equilibrium, while the pyruvate gradient is a result of cellular metabolic activity plus passive diffusion.

This is important in the interpretation of blood levels of pyruvate as being representative of tissue pyruvate concentration in metabolic studies. Furthermore, delay in the denaturation of blood causes much lower pyruvate and somewhat higher lactate concentrations, with much higher ratios of lactate to pyruvate than appear to exist in the body.[13] Because of differences in pH, pCO_2 and pO_2 and rates of flow between arterial and venous blood, it must be stressed that when knowledge of the total body aerobic-anaerobic state is being sought, only arterial blood samples are satisfactory.[2,7] Using a technique involving an indwelling needle in the brachial artery with collection of the blood samples in ice-cold 10% trichloracetic acid in 0.5 N HCl for rapid denaturation, Huckabee obtained the following results for basal conditions in the arterial blood of 69 normal human subjects:[7]

Lactate, 0.618 mM/L ($\delta = 0.077$)
Pyruvate, 0.142 mM/L ($\delta = 0.026$)
Lactate/Pyruvate ratio, 4.24 ($\delta = 0.44$)

Lactic Dehydrogenase

In regard to the rate of reaction of equation 1, it can be assumed, because of the distribution of the enzyme lactic dehydrogenase in all the tissues of the body, that this enzyme is present in excess and is not a normally limiting factor in the rate or direction of this reaction.[14,15] Bonting has found that the enzyme lactic dehydrogenase is almost exclusively located in the extramichrosomal extramitochondrial nonparticulate cell cytoplasm. This suggests the necessity of lactic acid being oxidized to pyruvic acid in the extramitochondrial cytoplasm prior to entering the glycolytic Krebs cycle in the mitochondria.[14]

Lactic dehydrogenase is a heterogenous protein molecule which exists as a tetramer* composed of four subunits of two parent molecules.[16] It has been shown that these two parent molecules which may be termed H (heart) and M (muscle), for the organs in which they are the predominant forms, have different electrophoretic, antigenic, amino acid and metabolic properties. The active enzyme may then be a tetramer of one of five possible combinations:

$$H_4, \quad H_3M, \quad H_2M_2, \quad HM_3, \quad M_4$$

Metabolically, these different forms of lactic dehydrogenase differ primarily in the degree to which they are inhibited by pyruvate. The type H_4, which is predominantly present in the heart, is maximally active at low concentrations of pyruvate, while being strongly inhibited if excess pyruvate is present. The M form, however, remains active at relatively high pyruvate concentrations. Functionally they are related to the requirements of their basic tissues. Cardiac muscle, which requires large amounts of a steady energy source, is benefited by an enzyme which functions best in the oxidative, aerobic cycle with complete oxidation of pyruvate to H_2O and CO_2 in the mitochondria, i.e., the free energy yield of the total oxidation of glucose is 686,000 cal per mole, while only about 8% of this or 56,000 cal per mole is available if the dissimilation of glucose proceeds only as far as lactic acid.[17]

In skeletal muscle, which may require the sudden, sporadic release of large amounts of energy in a relative insufficiency of oxygen, the enzyme M_4 which will function in the presence of large amounts of pyruvate provides a source of energy in a state of relative anaerobiosis. The lactate thus formed then enters the blood and is metabolized elsewhere. Experimentally, the ratios of M and H units of lactic dehydrogenase have been found to change in response to a variety of stimuli, including exposure to high or low oxygen concentrations, denervation and cell maturation.[16]

Biologically, the various zones of the kidney represent an example of graduated oxygen tensions in which the presence of lactic dehydrogenase subunits may be studied. Because of the counter-current pattern of circulation the papillae and medullary portions are relatively anoxic with reference to the cortex.[18] Analysis of lactic dehydrogenase concentrations in the various zones of rat kidneys reveals the following distribution of H subunits:[16]

---

*See Test Your Word Score Page 672.

Zone	% of H Subunits
Papilla	9
Medulla	44
Cortex	98

Diphosphonucleotide-$DPNH_2$

The final major determinant in the rate and direction of equilibrium at equation 1 is the ratio of reduced to oxidized diphosphonucleotide in the non-particulate, extra mitochondrial cell sap. The significance of cell oxygenation and the adequacy of the respiratory pathway in the production of oxidized, active diphosphonucleotide have been discussed in detail elsewhere[19] in literature considering intracellcular hydrogen transport mechanisms. The importance of the redox potential of the cell as reflected by the ratios $DPNH_2$/diphosphonucleotide in the production of varying ratios of pyruvate and lactate is discussed by Huckabee[7,12] and previously mentioned in this paper.

Clearly then, any agent interfering with cellular respiration or hydrogen transfer within the cell will produce an altered redox potential, an accumulation of $DPNH_2$ and a consequent rise in total lactic acid. Furthermore, any reaction in the oxidation cycle which is catalyzed by a diphosphonucleotide dependent system of enzymes may produce, in the presence of excess substrate, an excess of $DPNH_2$ which in turn will drive our steady state equilibrium to the right, with consequent production of lactic acid.

Ungar, Psychoyos and Hall have shown[19] that phenethylbiquanide (DBI) when added to tissue and mitochondrial preparations in the concentration range $10^{-4}M$ will inhibit directly the diphosphonucleotide/dependent reactions of the Krebs cycle, i.e., the oxidation of citrate, keto-glutarate, fumarate, oxalacetate and pyruvate.

Phenethylbiquanide was also shown to inhibit oxidative phosphorylation in mitochondrial preparations. The addition of agents which uncouple oxidation from phosphorylation, such as 2, 4 dinitrophenol, dicumerol and salicylate, tended to reverse this inhibition. Experimentally, the addition of diphosphonucleotide and vitamins also reverses the effects of phenethylbiquanide on the tricarboxylic acid cycle. Ungar et al. interpret this as being caused by competition between diphosphonucleotide and phenethylbiquanide at some unknown enzymatic site. The inhibition of cellular respiration has been described[19] for the following drugs also:

P—aminophenol
Barbiturates
Diethel stilbesterol
Sulfonamides
Salicylates
Antabuse
Antihistamines
Adrenergic blocking agents
Chlorpromazine

Clinical Considerations

Definition

Lactic acidosis may be defined chemically as a metabolic acidosis characterized by a *reduced arterial pH* and the presence of *elevated levels* of *lactate* in the *extracellular fluids.*[4,20]

By definition then, we exclude the more common form of acidosis due to diabetes, uremia or ingestion of acidifying compounds. Likewise, we exclude the pronounced respiratory or metabolic alkalosis associated with elevated lactate concentrations in the absence of a reduced pH.[4,7]

Clinical Syndrome

Huckabee describes his nine patients as follows:

> "The first sign of lactic acidosis was usually *hypernea* with more or less marked *tachypnea*, and occasionally slight *cyanosis*. The patients usually also complained of *weakness, fatigue* and moderate to marked *dyspnea* in the early stages. The clinical syndrome progressed to *stupor* and finally to death."[5, p. 842]

Clinically, patients with lactic acidosis may be separated into two major groups. The metabolic acidosis associated with disease states significantly decreasing tissue oxygenation and consequently *increasing anaerobic metabolism*, OR conditions *inhibiting lactate utilization* may be considered *secondary lactic acidosis*. A second group consists of those patients in whom no satisfactory explanation can be given either in clinical or laboratory terms for their marked lacticacidemia. This is the same as Huckabee's group 2B in which all nine patients were acidotic and died, and it may be termed *idiopathic* lactic acidosis.[4,5,20]

Differential Diagnosis

Both laboratory studies and the appropriate history are extremely valuable in making the diagnosis in the presence of a severe metabolic acidosis of unexplained etiology.

Routine laboratory studies will show: (1) marked decrease in serum carbon-dioxide content, (2) low pH and (3) a large increase in the concentration of unmeasured anions, i.e., the "anion gap."

However, the presence of a marked anion gap does not in itself indicate lactic acidosis, since a variety of other disorders including diabetic ketoacidosis, salicylate and methyl alcohol poisoning, and azotemic renal failure will produce a metabolic acidosis characterized by the accumulation of anions other than chloride in the extracellular fluid.[21]

Also, the presence of an anion gap serves to exclude those metabolic disorders associated with a concomitant rise in chloride equal to the reduction in serum bicarbonate, including diarrhea, ammonium chloride intoxication and some forms of renal tubular disease.[21]

Causes of Lactic Acidosis

Spontaneous or idiopathic lactic acidosis by definition is the presence of "excess lactate" in the absence of known hypoxia, circulatory insufficiency or exogenous toxins. Metabolically this is meaningless, since the production of excess lactate is the result of anaerobic glycolysis. Clinically, to implicate hypoxia as a cause, we must postulate that normal blood pressures do not reflect the adequacy of tissue perfusion. Huckabee[5] has shown experimentally that lactic acidosis appears in dogs whose blood volumes have been reduced by slow hemorrhage, prior to a measurable change in circulation. Huckabee has also induced pericardial tamponade in dogs by the injection of plasma into the pericardial sac, and found a marked rise in excess lactate in the absence of any measurable change in cardiac output or blood pressure[5].

The possibility of some basic defect in one of the enzyme systems elsewhere in the Krebs cycle, such as the cytochrome oxidase system[20] or lactic dehydrogenase,[16] has been postulated.

The literature contains a number of case reports of *spontaneous lactic* acidosis.[21,22,23] In the references noted, one patient with tuberculosis who was operated on for pleural decortication and an extra-pleural-parietal fistula, at autopsy was found to have a diffuse perilobular hepatic necrosis.[22] Since the liver has been found[11,20] to play an important role in the metabolism of lactic acid, this case is suspect as an example of "spontaneous lactic acidosis." Likewise, for a variety of other reasons, the other cases are also suspect.

Secondary lactic acidosis has been found to be a sequela of a wide variety of other disease states. As early as 1925 Clausen, in his discussion of anhydramic acidosis (acute dehydration secondary to diarrhea and emesis), found a marked fall in bicarbonate and a concomitant rise in lactic acid, presumably secondary to circulatory insufficiency.[3] Peretz et al.[24] studied the metabolic acidosis of hypotensive shock in 25 patients and found that blood lactate was elevated ($>$ 1.3 mEq./L) in 24 of 25 patients and that there was good correlation between the rise in blood lactate, the fall in serum bicarbonate, and blood pH in early shock. Correction of the acidosis did not influence blood lactate levels significantly unless the circulation was improved concurrently.

Thus, in one instance a pH of 6.9 was corrected over two hours to 7.4 by administration of 500 mEq. of sodium bicarbonate intravenously. During this time the lactate rose from 132 mg./100 ml. to 148 mg./100 ml. This patient did not recover. It appeared that a decrease in blood lactate could be accomplished only with improved tissue perfusion, and in two instances this took place even in the presence of sustained hypotension after the administration of a sympatholytic agent, phenoxybenzamine (Dibenzyline.)[24]

Reynolds, Sherlock et al.,[25] studying the effect of hexamethonium bromide on the splanchnic system, found no significant alteration in splanchnic oxygen consumption, hepatic glucose output, and arterial and lactic acid concentrations in the presence of a "mean" blood pressure fall from 110 mm. Hg. to 80 mm. Hg.[25]

Paraldehyde intoxication has been found to induce a metabolic acidosis[26] which is not well understood. It may be related to the toxic effect of paraldehyde or its decomposition products, acetic acid and all acetaldehyde upon intermediary metabolism enzyme systems.

Eichenholz et al. have studied salicylate-induced metabolic acidosis in experimental dogs[27] and found that the rise in blood lactate and pyruvate levels accounted for most of the bicarbonate deficit present. Furthermore, the rise in lactate and pyruvate was preceded by a reduction in the pCO_2 secondary to the early respiratory alkalosis. Use of four percent CO_2 in the respired air to prevent respiratory alkalosis inhibited the occurrence of metabolic acidosis. Experimentally, the injection of minute quantities of sodium salicylate into the suboccipital cistern of a lightly anesthetized, spontaneously breathing dog produced a respiratory alkalosis with hyperventilation, decreased pCO_2 and a rise in lactate and pyruvate levels. There was no detectable salicylate in the animal's blood.

Acute leukemia associated with severe metabolic acidosis produced elevated lactic acid levels in 13 patients. In three of four patients, lactic acidosis diminished concurrently with a favorable response to antileukemic therapy. In-vitro lactic acid production was found to be low in the presence of normal oxygen tension but increased eight to twelve-fold with hypoxia.

Field et al. postulated on the basis of calculations utilizing the maximum in-vitro rate, that large aggregates of leukemia cells crowded into organs and, metabolizing anaerobically, could be the source of enough lactic acid to produce clinical lactic acidosis.[29] Lactic acidosis has also occurred in conjunction with a rare case of Reed-Sternberg cell leukemia. This relented following cytotoxic therapy.[30]

Familial infantile lactic acidosis in two siblings has been reported.[31] Each had a chronic metabolic acidosis which decreased in severity with increased age and both are mentally retarded. The basic cellular defect remains unknown.

Lactic acidosis with a necrotizing encephalopathy has been described in two other siblings in England. Both had identical symptoms of hypernea, progressive ataxia, mental deterioration and convulsions. At autopsy each showed degenerative changes of the central nervous system. One brother, who was investigated biochemically, was found to have a severe lactic acidosis. In two periods, when he was *not* hypernic, plasma lactate levels were found to be 30.5 and 38.7 mg. % (normal 6-18 mg. %). There was no "excess lactate" present.

Lactic acidosis of some severity has also been associated with glycogen storage disease.[33,34,35] The pathophysiology here remains obscure.

Daughaday et al.[36] have reported three cases of nonketotic acidosis in diabetic patients *not* receiving the oral hypoglycemic agent, phenformin.[36] Elevated blood lactate levels were present, but there was no detectable hypoxia. The etiology of this acidosis remains obscure.

Lactic acidosis and death, after the treatment of obesity by fasting, in a mild diabetic receiving no hypoglycemic agent has been reported.[37]

The literature contains many documented cases of lactic acidosis occurring in diabetics on phenethylbiquanide.[38,44] Although the exact relationship remains to be elucidated, the frequent association of phenethylbiquanide therapy and lactic acidosis cannot be ignored. Caution is recommended in the use of phenethylbiquanide in the treatment of diabetics when renal function has been impaired by acute or chronic disease.[38]

Therapy

The treatment of lactic acidosis is discussed at length by Huckabee,[5] Field,[28] Waters et al.,[21] and Tranquada.[20]

Two principles of treatment seem to be generally accepted:

(1) Vigorous correction of any possible cause of cellular hypoxia.

(2) Correction of the acidosis to near normal ranges with bicarbonate, i.e., maintenance of pH above 7.30, since in theory, some degree of acidosis may aid in the metabolism of lactate acid by driving our steady state equation to the left.

The use of lactate to correct the acidosis is not recommended.[28,45] In the physiologic range of pH, lactic acid is 99% ionized and unable to produce any direct buffering effect. The theoretical buffering effect of lactate is a product of lactate metabolism and concomitant hydrogen ion utilization. In the presence of excess lactate, as occurs in lacticacidosis, the infusion of *more* lactate presents an unnecessary osmotic load while remaining unavailable as a buffer.

Field[45] and Tranquada[46] have together treated a total of nine patients with methylene blue: a redox dye which can serve as an electron accepter for a number of physiologic oxidation reduction reactions. In Tranquada's series of five patients, methylene blue effected a significant reduction in blood lactate concentration of all five, when given doses in the range of 1.5 to 5.0 mg. per kg. However, only one of his patients survived.

Field treated four patients with from 4.3 to 12.5 mg./kg. of dye without apparent effect on blood lactate concentration and L/P ratios in three. There was an equivocal effect in the fourth patient.

It is felt that the most probable site of action of the dye, in relation to lactic acid production, is the direct or indirect oxidation of DPNH which would result directly in an increased conversion of lactate to pyruvate by driving our equilibrium equation to the left.[46]

Two organic hydrogen ion accepters, Tris (2-amino-2 hydroxy methyl-l, 3-propanediol[47]) and THAM (Tris-hydroxymethl aninomethane)[48] have been used in the treatment of lactic acidosis. Both would seem to provide a theoretical advantage in not being metabolized to CO_2 and consequently requiring respiratory exchange in excretion.

Tris buffer was used in the treatment of lactic acidosis following prolonged, cardiopulmonary bypass for repair of intracardiac defects in 20 patients.[47] The use of larger quantities of buffer (150 mg. per kg. body weight) produced rapid and sustained rises in arterial pH, plasma CO_2 and CO_2 combining power in 13 patients. In lesser doses, the response was minimal or transient.

The experience with hemodialysis in one case reported by Ewry[49] was encouraging. However, Tranquada et al.[20] had equivocal results using peritoneal dialysis with a lactate containing dialysate in three cases. The results were not interpretable in one case where they replaced lactate with acetate.

Finally, dextran has been suggested as an adjunct to therapy in an effort to increase tissue perfusion with blood.[28]

Practical Summary

Diagnosis: Clinical

1. Be suspicious—To make this diagnosis, *Lactic Acidosis* must be in your *differential diagnosis.*
2. Non-specific clinical picture of a metabolic acidosis includes:
   a. Tachypnea
   b. Hypernea
   c. Lethargy
   d. Malaise
   e. Dyspnea
   f. Stupor
   g. Cyanosis
3. Think of Lactic Acidosis particularly:
   a. In the presence of any basic underlying disease causing tissue hypoxia.
      (1) Severe congestive heart failure
      (2) Severe chronic lung disease
      (3) Shock
   b. In patients on oxidative enzyme toxins who have borderline renal

function, these drugs should be stopped immediately:
- (1) P-aminophenol
- (2) Barbiturates
- (3) Diethyl stilbesterol
- (4) Sulfanamides
- (5) Salicylates
- (6) Antabuse
- (7) Antihistamines
- (8) Adrenergic blocking agents
- (9) Chlorpromazine
- (10) DBI, Phenphormin

Diagnosis: Laboratory

1. Use arterial blood only
2. The following suggest a metabolic acidosis with lacticacidemia
    a. Acid pH
    b. Low serum HCO_3
    c. Presence of an "*anion gap*"
    Calculate anion gap from serum electrolyte values as follows:
    Anion gap (AG) $= (Na^+ + K^+) - ((Cl^-) + HCO_3^- + 12)$
    If AG = 10 mEq/L or more consider lactic acidosis.
    Anion gap may also be present in other metabolic acidosis, i.e.,
    (a) Diabetic ketoacidosis
    (b) Salicylate } intoxication
    (c) Methyl alcohol } intoxication
    (d) Azotemic renal failure
3. If above criteria suggest lactic acidosis, determine blood lactate and pyruvate levels.

Therapy

1. Treat any cause of hypoxia *vigorously!!*
    a. Give O_2 10/L/min with humidity
    b. Give digitalis if in heart failure
    c. Maintain adequate pulmonary ventilation—intubate and use respirator as needed
    d. Use vasopressors *sparingly* in shock—intense, peripheral vasoconstriction will enhance tissue hypoxia and increase lactic acid production
    Use (1) Fluid replacement: blood, plasma, albumin
    (2) Steroids
    (3) Isuprel
    as indicated, rather than Aramine or Levophed if possible.
2. Correct acidosis to pH 7.30 in first two hours
    a. Use HCO_3^-, not lactate-containing solutions. This may require *massive* doses of HCO_3^-, to 500 mEq. or more.
    Give *INTRAVENOUSLY*.
3. Follow electrolytes, arterial pH, PO_2, PCO_2, and anion gap at 2-4 hour intervals during the acute phase.
4. The judicious use of:
    a. Dextran
    b. Hexamethanium bromide
    To increase tissue perfusion may be of value in selected cases, but are unproven adjuncts at this time.

Appendix

The lactic dehydrogenase system may be depicted by:

1. $C_3H_4O_3 + DPNHH^+ \rightleftarrows C_3H_5O_3 + DPN$ or by the mass action form.
2. $[Pyruvate] \times [DPNHH^+] = K\ [Lactate] \times [DPN]$ which may be rearranged to show the two physiologic factors affecting lactate concentration at any time t_o:
3. $$[Lactate]_o = [Pyruvate]_o \times K \frac{[DPNH^+H]_o}{[DPN]_o}$$

   The difference in lactate between t_o and any other time t_n provided there is no hypoxia, will be:
4. $$[Lactate]_n - [Lactate]_o = [Pyruvate]_n - [Pyruvate]_o \times K \frac{[DPNH_2]_o}{[DPN]}$$

   Substituting from equation (3) the value obtained by solving for $K \dfrac{[DPNH_2]_o}{[DPN]_o}$
5. $$[Lactate]_n - [Lactate]_o = [Pyruvate]_n - [Pyruvate]_o \times \frac{[Lactate]_o}{[Pyruvate]_o}$$

   The difference between the value $L_n - L_o$ predicted from equation 5 on the assumption that no true hypoxia occurred within the cells and the value of $L_n = L_o$ actually observed to occur is the "excess lactate:"
6. $$XL = \triangle L - \triangle L$$

   and in terms of measurable quantities (all concentrations):
7. $$XL = (L_n - L_o) - (P_n - P_o)\ (L_o/P_o)$$

A sample calculation gives the following result:

Basal blood lactate = 0.550 mM per L.
Basal blood pyruvate = 0.135 mM per L.
Experimental lactate value = 2.680 mM per L.
Experimental pyruvate value = 0.409 mM per L.

$$XL = (2.680 - 5.550) - (0.409 - 0.135)\frac{(0.550)}{(0.135)} = 2.130 - 1.115$$

$$XY = 1.015 \text{ mM per L.}$$

The Patient in the Hospital

These sick people are isolated "specimens." They are segregated from their environment, removed from the circumstances under which they became ill, separated from their families, stripped even of their clothes; all of which is done to create a proper atmosphere for diagnostic study and careful management on the physician's part, free from outside distractions. It may be trite to point out that these "outside distractions" are the very things which the modern doctor, or the student interested in preventive medicine, needs to study also. For if one is to handle patients adequately, it is necessary to bring clinical judgment to bear not only on the patient, but also on the circumstances under which his illness arose.*

Prophylactic Use of Lincomycin in Oral Surgery

PREVIOUSLY, MEMBERS of our group have described some of our experiences with different antibiotics in the attempted prevention of bacterial invasion of the blood after oral surgical procedures.[1-6] Lincomycin hydrochloric monohydrate was selected for a continuation of these studies. The spectrum of antibacterial activity of lincomycin includes *Staphylococcus aureus*, β-hemolytic streptococcus, and *Streptomyces viridans*. It is not active against most trains of entercococci, such as *Streptoccus faecalis,* or against *Neisseria* organisms or gram-negative bacilli.[7,8] Reasons for studying lincomycin included the possible occurrence of postoperative bacterial endocarditis due to penicillin-resistant streptococci,[9-10] the inability of certain patients to tolerate alternative drugs, and the antistaphylococcal property of the antibiotic. The purpose of this project was to investigate the effectiveness of lincomycin, compared to that of drugs previously studied, under the conditions outlined.

Methods and Materials

The patients selected were those undergoing an oral surgical procedure. These procedures consisted of multiple extractions, followed by alveoloplasty because of caries, periodontal disease, or both, and odontectomy of impacted third molars. Lincomycin hydrochloride monohydrate* was administered in capsule form in four successive doses of 500 mg, beginning 18 hours prior to operation. The patients were requested not to take food within a two-hour period before and after taking the medication. Blood for culture was drawn in the operating room immediately after the operation and again approximately 18 hours later. Fifty patients were included in this study; none of these had urinary obstruction or evidence of renal disease, preexisting systemic infection, or cardiovascular defects that would make them susceptible to the development of endocarditis or endarteritis.

Results

Three of the 50 patients had positive cultures from the blood taken immediately after the oral surgical procedure. In two, *Streptococcus mitis* was cultured and, in the third, the organisms were *Neisseria catarrhalis* and *S. mitis*. However, cultures of the blood taken from all 50 patients 18 hours after the operation were negative (Table).

Comment

It is noteworthy that the blood cultures obtained from patients in this study did not reveal staphylococci. In contradistinction to this finding, blood cultures obtained from 6% of our patients receiving phenoxymethyl penicillin[3] and 3.7% of those receiving cloxacillin[4] grew staphylococcal organisms. In the studies of erythromycin[5] and nafcillin,[6] none of the blood cultures revealed staphylococci.

---

*Supplied as Linocin, courtesy of the Upjohn Company, Kalamazoo, Mich.

Six per cent of the blood cultures obtained after operation from patients in this study grew *S. mitis,* which compares favorably to the 15% of blood cultures obtained from patients receiving cloxacillin[4] and the 21% of those obtained from patients receiving nafcillin[6] that grew streptococcal organisms. However, it should be stressed that those patients receiving optimal amounts of phenoxymethyl penicillin[1,3] or erythromycin[5] had consistently negative blood cultures for *S. mitis.* Because postoperative invasion of the blood by *S. mitis* is especially feared as a mechanism in the genesis of bacterial endocarditis, our studies to date indicate that phenoxymethyl penicillin and erythromycin are superior to the other drugs studied for prophylaxis prior to oral surgery.

Currently, we are studying ampicillin, which theoretically should produce antistreptococcal effects similar to those achieved on administration of phenoxymethyl penicillin and might in addition decrease the incidence of postoperative invasion of the blood by gram-negative bacilli. In our studies employing phenoxymethyl penicillin for prophylaxis prior to oral surgery, we have noted such gram-negative bacillary invasion of the blood.[1,3]

Ultimately, we hope to restudy both lincomycin and nafcillin when these drugs are given for a longer period before operation, in an attempt to determine the total dosage required to achieve an optimal antistreptococcal effect. Similarly, we hope either to restudy cloxacillin or to study dicloxacillin: a newer isoxazolyl penicillin[11] that provides even higher levels in the blood than does cloxacillin.

Summary

Fifty patients were studied, each of whom received four doses of 500 mg of lincomycin beginning 18 hours before oral surgery. In three (6%) of the patients, cultures of the blood taken immediately after surgery grew *Streptococcus mitis.* One of these three cultures also grew *Neisseria catarrhalis.* None of the cultures revealed staphylococcal organisms. Although lincomycin compares favorably with erythromycin and nafcillin in preventing invasion of the blood by staphylococcal organisms, it is not as effective as phenoxymethyl penicillin or erythromycin in controlling such invasion by *S. mitis.*

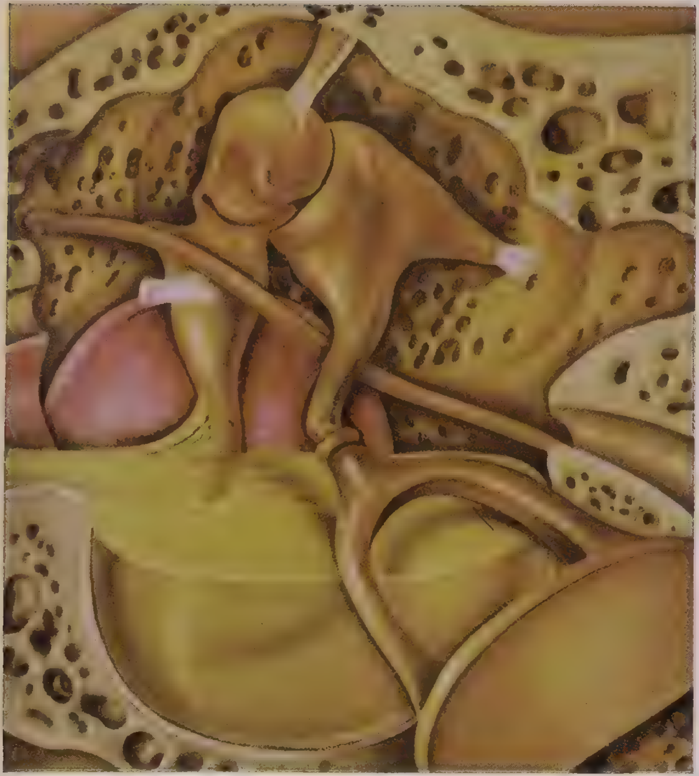
DECLOMYCIN
DEMETHYLCHLORTETRACYCLINE



You've made it one of your specifics in acute otitis media

DECLOMYCIN acts against many strains of H. influenzae, pneumococci and streptococci, the most common invaders. In otitis media, where it is difficult to isolate the causative organism, this coverage may be important. However, some strains may be resistant and other pathogens can be involved.

You've found the high serum levels of DECLOMYCIN important, too. Its prolonged action permits convenient 300 mg b.i.d. or 150 mg q.i.d. administration.

When specimens are obtainable, your culture studies will indicate the usefulness of DECLOMYCIN.

Effectiveness: DECLOMYCIN Demethylchlortetracycline should be equally or more effective therapeutically than other tetracyclines in infections caused by organisms sensitive to the tetracyclines.
Contraindication: History of hypersensitivity to demethylchlortetracycline.
Warning: In renal impairment, usual doses may lead to excessive accumulation and liver toxicity. Under such conditions, lower than usual doses are indicated, and, if therapy is prolonged, serum level determinations may be advisable. A photodynamic reaction to natural or artificial sunlight has been observed. Small amounts of drug and short exposure may produce an exaggerated sunburn reaction which may range from erythema to severe skin manifestations. In a smaller proportion, photoallergic reactions have been reported. Patients should avoid direct exposure to sunlight and discontinue drug at the first evidence of skin discomfort. Necessary subsequent courses of treatment with tetracyclines should be carefully observed.
Precautions: Overgrowth of nonsusceptible organisms may occur. Constant observation is essential. If new infections appear, appropriate measures should be taken. In infants, increased intracranial pressure with bulging fontanels has been observed. All signs and symptoms have disappeared rapidly upon cessation of treatment.
Side Effects: Gastrointestinal system—anorexia, nausea, vomiting, diarrhea, stomatitis, glossitis, enterocolitis, pruritus ani. Skin—maculopapular and erythematous rashes; a rare case of exfoliative dermatitis has been reported. Photosensitivity, onycholysis and discoloration of the nails (rare). Kidney—rise in BUN, apparently dose-related. Transient increase in urinary output, sometimes accompanied by thirst (rare). Hypersensitivity reactions—urticaria, angioneurotic edema, anaphylaxis. Teeth—dental staining (yellow-brown) in children of mothers given this drug during the latter half of pregnancy, and in children given the drug during the neonatal period, infancy and early childhood. Enamel hypoplasia has been seen in a few children. If adverse reaction or idiosyncrasy occurs, discontinue medication and institute appropriate therapy. Demethylchlortetracycline may form a stable calcium complex in any bone-forming tissue with no serious harmful effects reported thus far in humans.
Average Adult Daily Dosage: 150 mg q.i.d. or 300 mg b.i.d. Should be given 1 hour before or 2 hours after meals, since absorption is impaired by the concomitant administration of high calcium content drugs, foods and some dairy products. Treatment of streptococcal infections should continue for 10 days, even though symptoms have subsided.

DECLOMYCIN®
DEMETHYLCHLORTETRACYCLINE

Capsules: 150 mg; **Tablets:** film coated, 300 mg, 150 mg and 75 mg of demethylchlortetracycline HCl.

Review

Steroid Diabetes

THE DIABETOGENIC action of several hormones has long been recognized. As far back as 1901 parenteral administration of the active principle of the adrenal medulla was found to produce diabetes.[1] Later it was shown that anterior pituitary extract can also produce diabetes.[2,3] Adrenalectomy was found to ameliorate experimental diabetes in cats,[4] and subsequently the role of the adrenal cortex in carbohydrate metabolism in man was extensively studied.[5-7]

The purpose of this article is to review briefly the effects of "carbohydrate-active" adrenal steroids (glucocorticoids) as related to carbohydrate metabolism. The term "steroid diabetes" is used to designate the development of decreased tolerance for carbohydrate in the presence of excessive glucocorticoid of either endogenous or exogenous origin.[7,8]

Mechanism of Steroid Diabetes

Accumulated evidence indicates that adrenocorticosteroids are powerful hormonal agents which are capable of influencing many tissues of the body. In particular, glucocorticoids are intimately involved in the metabolism of carbohydrate. The impaired carbohydrate tolerance in steroid diabetes involves both overproduction and underutilization of glucose.

Glucose Production

Adrenal steroids stimulate gluconeogenesis from noncarbohydrate sources, mainly through a catabolic action on protein.[9,10] Liver is the principal site of gluconeogenesis. Gluconeogenesis results in increased glycogen synthesis and storage in both liver and muscle. While glucocorticoids increase hepatic glucose production, insulin antagonizes this by decreasing gluconeogenesis. Evidence for gluconeogenesis following glucocorticoid administration includes: (1) increased extra-hepatic protein catabolism, increased plasma amino acids and widespread protein depletion,[11] (2) increased hepatic uptake of plasma amino acids,[12] and (3) increased rate of transamination and deamination in the liver.[13]

It has been suggested that an increase in the activities of certain specific hepatic phosphatases following cortisone administration may augment glucose production.[14,15] However, this is felt to reflect an increase in gluconeogenesis rather than a primary process for glucose formation.[16]

Glucose Utilization

Loss of carbohydrate tolerance is probably not fully explained by gluconeogenesis from protein.[17] An additional mechanism might be conversion of fat to glucose. Glucocorticoids stimulate the release of free fatty acids from adipose tissue.[18] Unlike epinephrine-induced lipolysis,[19] this process is not associated with oxidation of glucose. However, since significant conversion of fat to glucose does not occur, one must assume that utilization of carbohydrate by peripheral tissues has been impaired.[5] Since insulin is the primary hormone involved in the regulation of glucose utilization, this impairment is probably due to direct antagonism of glucocorticoids to insulin at a cellular level.

Regulation of Phosphorylation

Glucocorticoids are not involved in the regulation of glucose phosphorylation by liver.[20] Insulin stimulates and cortisol decreases glucose uptake by adipose tissue in vitro.[21] Furthermore, cortisol diminishes lipogenic activity in both hepatic and adipose tissues.[22] The effect of glucocorticoids on muscle is profound. In normal muscle, adrenal hormones seem to be involved in the regulation of both glucose phosphorylation and cell permeability. In the presence of insulin, phosphorylation, rather than penetration, becomes rate-limiting.[23] It has been shown that adrenal cortical extract can modify the hexokinase reaction by intensifying the inhibitory effect of anterior pituitary extract upon the action of insulin.[24] In muscle the hormones of the adrenal cortex decrease the conversion of carbohydrate and acetate to fat, favor the formation of lactate, and diminish the oxidation of pyruvate. Lactic acid is then oxidized rather than being repolymerized to glycogen,[25-27] which may explain in part the elevated plasma lactate and pyruvate in hyperadrenocorticism.

The effects of both glucocorticoids and insulin on the metabolism of liver, muscle and adipose tissue are summarized in the table.

TABLE*

Effects of Insulin and Glucocorticoids Upon Tissue Metabolism

PARAMETER	HORMONE	LIVER	MUSCLE	ADIPOSE
Glucose Utilization	Insulin	↑	↑	↑

Characteristics of Steroid Diabetes

There is general agreement that endogenously and exogenously induced adrenal steroid diabetes are similar. Steroid diabetes has several features that distinguish it from pancreatic diabetes. It is usually mild and disappears with correction of the steroid excess upon which it depends.[7,28] Even in steroid diabetes of long standing the diabetic state may not be permanent.[28] There is a tendency toward insulin insensitivity, negative nitrogen balance, and elevated levels of blood pyruvate and lactate.[5,29] Blood sugar is rarely greatly elevated, and occasionally there may be renal glycosuria which has been attributed to decreased tubular reabsorption of glucose.[30,31] Ketosis is rare and glycosuria is likely to be absent during fasting.[5,29]

Administration of cortisone or physiologically related steroids, or of adrenocorticotropic hormone, to normal subjects may produce temporary hyperglycemia, glycosuria and decreased glucose tolerance.[32-34] It has been shown that impairment of glucose tolerance may be induced in many nondiabetics when large doses of glucocorticoids are used and that the degree of impairment depends upon the potency and dose of the drug used, the duration of administration and the recipient.[35-37] The variation in individual response to the cortisone-induced impairment of glucose tolerance can be used as a test to unmask the potential diabetic who has a normal carbohydrate tolerance on other tests.[38]

The development of diabetes in patients receiving adrenal steroids is a rare occurrence. A transitory diabetic state was noted in only a few of several hundred patients who received cortisone or corticotrophin.[39] In the great majority of normal people, after an initial decrease in carbohydrate utilization, tolerance returns to normal despite continuation of glucocorticoid administration. This has been interpreted as an attempt on the part of the beta cells to compensate for the decreased glucose utilization and increased glucose production (see above).[5]

Adrenal Cortex and Diabetes Mellitus

Whether adrenal cortical dysfunction plays a role in diabetes mellitus and its vascular complications in man has received much attention.[5,6,40,42] It has been suggested that increased adrenal cortical function exists in patients with diabetes mellitus.[43] Although decreased excretion of 17-ketosteroids was found in diabetics, there was no apparent correlation between the amount of 17-ketosteroids excretion and the severity of diabetes.[40] Several workers have reported great elevations in the urinary corticosteroids in patients with diabetic acidosis.[44,45] It is suggested that in the depancreatized rat the glucocorticoids produce ketosis by mobilizing fat to liver and by accelerating ketogenesis by the liver.[46] Thus important hormonal factors for ketosis are insulin deficiency and glucocorticoid excess. In the intact animal the glucocorticoid-induced hyperglycemia may stimulate insulin production, which in turn inhibits ketogenesis.[6]

In adrenal cortical hyperfunction of the type which produces Cushing's syndrome a diabetic glucose tolerance curve was present in 94 percent of cases, but frank diabetes was observed in only 14 percent.[47] Co-existence of Addison's disease and diabetes mellitus is much less frequent; only 113 cases were collected by 1965.[48] Since Addison's disease preceded diabetes in 71 cases, it is evident that adrenocortical insufficiency does not necessarily protect against subsequent development of diabetes mellitus. While the role of the adrenal gland in human diabetes has not been precisely defined, most investigators agree that there is little evidence to support adrenal cortical dysfunction among patients with diabetes mellitus.[29,42]

Summary

A brief review of the major effects of the adrenal steroids upon glucose metabolism is presented. Glucocorticoids of either endogenous or exogenous origin may result in an impairment of glucose tolerance (steroid diabetes). The characteristics of steroid diabetes are discussed. The possible relation

of the adrenal cortex to diabetes mellitus is also discussed.

Abstracts, Briefs and Commentaries

COMPLICATIONS FOLLOWING RESUSCITATION

External cardiac massage was introduced in 1960. This method combined with artificial ventilation has been widely used and is occasionally accompanied by complications. Related to chest massage the most common complications are fractures of the ribs, fracture of the sternum, rupture of the liver, rupture of the spleen, bone-marrow emboli, hemothorax, pulmonary hemorrhage, hematoma or rupture of the heart, hemorrhage of the pancreas, and retroperitoneal hemorrhage.

Intracardiac injections may cause pneumothorax or hemopericardium. Improper artificial ventilation in the newborn may result in interstitial emphysema, pneumomediastinum, pneumothorax and/or pneumoperitoneum. From January 1964 to April 1967, 16 patients died from resuscitation efforts and have been autopsied at the Pathology Department at the Ulleral Hospital. Rib and sternum fractures were the most common findings following cardiac massage. All 16 cases are briefed here.

Case 1

An eight-hour-old infant received external cardiac massage and mouth-to-mouth/nose breathing by a doctor. Autopsy revealed prematurity and atelectatic lungs, a tear in the liver and blood in the peritoneal cavity.

Case 2

A 17-hour-old premature became cyanotic. External cardiac massage and mouth-to-mouth/nose breathing were done by a doctor for 10 minutes. Autopsy revealed mitral stenosis, atresia of the aorta, a tear in the liver and 20 ml. of blood in the peritoneal cavity.

Case 3

A 31-hour-old infant, born asphytic, was given external cardiac massage and mouth-to-mouth/nose breathing by a doctor. Autopsy revealed atelectatic lungs, hyaline membrane disease, rupture of the liver 6 cm. in length and blood in the peritoneal cavity.

Case 4

An 18-month-old infant developed gastroenteritis and became unresponsive. External cardiac massage and mouth-to-mouth breathing were performed by an ambulance attendant during transport. Autopsy revealed acute enteritis, cerebral edema, fatty infiltration of the liver, a rupture of the lesser curvature of the stomach (2 cm.), pneumoperitoneum and collapse of the lungs with tension pneumothorax.

Case 5

A 43-year-old man collapsed at home. In the hospital emergency room he received external cardiac massage and artificial respiration. Autopsy revealed multiple pulmonary emboli, thrombi in the periprostatic veins and a tear in the spleen 4 cm. long.

Case 6

A 46-year-old man collapsed on the street. In the emergency room he received cardiac massage and intratracheal intubation by a doctor. Autopsy revealed coronary disease, fractures of the third through the sixth ribs on the left side, fracture of the sternum, a tear 7 cm. long in the liver and 100 ml. of blood in the peritoneal cavity.

Case 7

A 57-year-old man collapsed at home. During transportation to the hospital external cardiac massage and mouth-to-mouth breathing were performed. In the hospital he was given cardiac massage and intratracheal intubation by a doctor. Autopsy revealed coronary occlusion, rupture of the liver (2 cm.) and 400 ml. of blood in the peritoneal cavity.

Case 8

A 62-year-old man with abdominal pain and shock was brought to the hospital. An abdominal aneurysm required surgery. On the first postoperative day he developed cardiac arrest, and external cardiac massage was performed by a doctor. Autopsy revealed intact transplant of the aorta, fracture of the fourth and fifth ribs on the right side, 700 ml. of blood in the peritoneal cavity, and a 7-cm. rupture of the liver.

Case 9

A 64-year-old man with chest pain collapsed at home. During transportation to the hospital an ambulance attendant performed external cardiac massage. Autopsy revealed coronary disease with old infarction, multiple fractures of the ribs, and a tear of the liver 4 cm. long.

Case 10

A 65-year-old man with chest pain entered the hospital. A diagnosis of myocardial infarction with collapse was treated by a doctor by external cardiac massage. Autopsy revealed coronary occlusion and rupture of the heart.

Case 11

A 68-year-old man was given external cardiac massage by an ambulance attendant. Autopsy showed myocardial infarction, multiple rib fractures, hemorrhagic patches in the lungs and hemorrhage around the portal vein.

Case 12

A 63-year-old woman was treated for fractures of the left ankle. Two weeks later she collapsed. House doctors performed external cardiac massage and intratracheal intubation with positive pressure for three hours. Autopsy showed a large pulmonary embolus, thrombosis of the femoral vein, fracture of the sternum, fracture of the right second and third ribs, and of the second through the sixth ribs on the left side, rupture of the spleen 4 cm. in length and 3000 ml. of blood in the peritoneal cavity.

Case 13

A 70-year-old woman entered the hospital with myocardial infarction and collapsed. External cardiac massage and mouth-to-mouth breathing were performed by a doctor. Autopsy showed coronary occlusion, myocardial infarction with rupture of the heart, a rupture of the liver (6 cm.), and tears 4 cm. in length in the mucosa of the lesser curvature of the stomach.

Case 14

A 71-year-old woman collapsed immediately on entering the hospital. External massage was rendered by a doctor. Autopsy showed myocardial infarction, fatty infiltration of the liver, with a tear 2 cm. in length, multiple deep ruptures, and 400 ml. of blood in the peritoneal cavity.

Case 15

A 78-year-old woman collapsed in the hospital emergency room. External cardiac massage and mouth-to-mouth breathing were employed by nurses. Autopsy showed coronary occlusion, myocardial infarction, multiple fractures of the ribs and 300 ml. of blood retroperitoneally.

Case 16

An 82-year-old woman collapsed soon after entering the hospital. External cardiac massage and intratracheal intubation with positive pressure were rendered by a doctor. During the artificial ventilation cervical emphysema was noted. Autopsy revealed severe coronary sclerosis, old myocardial infarctions, multiple fractures of the ribs, a rupture of the spleen (5 cm.) with

300 ml. of blood within the peritoneum, and severe pneumomediastinum.

Comments: Experiences reveal both the benefits and the hazards of resuscitation. The record states that of the 16 reported emergency cases eleven were treated by doctors, one by nurses and three by ambulance attendants.

Rib fractures may occur when pressure is applied to the side of the midline, and lacerations of the liver when pressure is applied over the tip of the sternum. Two cases that had rupture of the liver had fatty infiltration; three were in children because of the higher position of that organ. Mouth-to-mouth breathing frequently produces distention of the stomach, most often in children. "Most of the complications are probably due to unsatisfactory technique."

Discussion

The unhappy results disclosed in this article are shocking but rewarding. It takes honesty and courage to report such experiences. It proves without doubt the need of proper teaching of methods of resuscitation to all who may be required to give first aid. The services in the above reports were given by doctors, nurses and ambulance attendants and reveal the need of instructing persons who might happen to be required to act in an emergency. This article brings out the fact that even highly trained personnel can make mistakes that cause fractures of the chest wall and injury to thoracic and abdominal viscera.

RATE OF FORMATION OF COMMON BILE DUCT STONES FROM NONABSORBABLE SILKWORM GUT

"A case is reported in which 10 days after choledocholithotomy and transduodenal sphincterectomy, silkworm ligatures, used to suture the cystic duct and a vein near the common bile duct wall, had passed into the common duct, and calcium bilirubinate had accumulated on their surface to form gallstones."

Fresh calculus formation after removal of the gallbladder, using nonabsorbable suture material, has been reported several times. From these previously reported cases, however, it is not clear how quickly nonabsorbable sutures placed outside the bile ducts pass into the ducts to form a nucleus for new stones.

This patient, a female 61 years of age, had been operated on for gallstones one year previously; a preoperative x-ray study had revealed dilated common duct and stones. At operation the common duct was opened, the stones were removed, and transduodenal sphincterectomy was performed. A bleeder near the common duct was ligated with silk; a stump of cystic duct left at previous surgery was removed and sutured with silk; and a t-tube was placed in the common duct.

The patient evidently did poorly, and six days later x-ray revealed inadequate filling of the right hepatic duct, poor exit through the common duct, and also stones. After 10 days, re-laparotomy was performed with choledocholithotomy, and a number of stones were removed.

Postoperative study of the stones revealed silk ligatures in two. Several factors (necrosis and infection) may contribute to loosen nonabsorbable sutures outside the duct, thus enabling them to find their way into the common duct. Suction inside the common duct towards the intestine, produced by duodenal tonus and peristalsis, is enough to produce this effect. (Sandblom et al. 1935; Watts and Dumpy 1966). Even sutures of nonabsorbable material within the abdominal wall have found their way into the common duct.

Note: In this article the time element between the first and the second operation with the reformation of stones was only 10 days.

Are Doctors Human?

The truth is that doctors *are* human; that they seem otherwise at times is purely the fault of us patients. Doctors know our deepest secrets not by some demoniac process of mental telepathy but because we insist on trotting the secrets out. We do this ostensibly to aid in treatment, actually to ease our guilty consciences or to show what rips we are or maybe just to keep the old tongue wagging.

Doctors are pampered, certainly, and yet how many of them go out of their way to attract an excess of esteem? Generally it comes to them against their will and for reasons so transparent that a two-year-old could see through them. So-and-So butters Dr. Smith to the skies at Mrs. Jones' bridge party, hoping to get a bit of free medical advice later on in the evening. Mr. Brown is also there buttering away at a great rate.

Closely connected with the pampering is the tendency to envelop doctors in an aura of infallibility. . . . Few doctors relish this role of infallibility. They know perfectly well that the real workers of miracles are the patients themselves, nine out of ten of whom meet the test of illness with astonishing heroism, persistence, patience, and self-discipline. Doctors set the stage by surgery or medicine or advice. The patient has to put the show over.

Every one of my sixteen docs has been ready and eager to admit that he is as apt to pull bloopers as any professional man or craft worker. The surgeon who yanked out my appendix frankly informed me next day that the appendix was not my trouble and that he was darned if he could find anybody who could tell him what *was* my trouble. Six months later I went through a diagnostician's clinic, garbed in a sheet like Gandhi and drinking gallons of barium. After two days of this, the head diagnostician announced his findings. "All I can discover," he said sheepishly, "is that you're allergic to turnips. To be honest with you, that doesn't mean a thing. Practically everybody I ever put through the clinic is allergic to turnips."

My present doctor has a favorite yarn about a convalescent in our hospital who hadn't seen his doctor in two years. When the doctor finally turned up, he said to the anxious convalescent, "Are you still here? Why, I meant to tell you two years back to get up and go home!"*

In the complex picture of moderate to severe anxiety...

there is a new reason for prescribing Mellaril (Thioridazine HCl)

effectiveness in mixed anxiety-depression

Long recognized for its usefulness in the treatment of moderate to severe anxiety, Mellaril is now also known to be effective against mixed anxiety-depression.

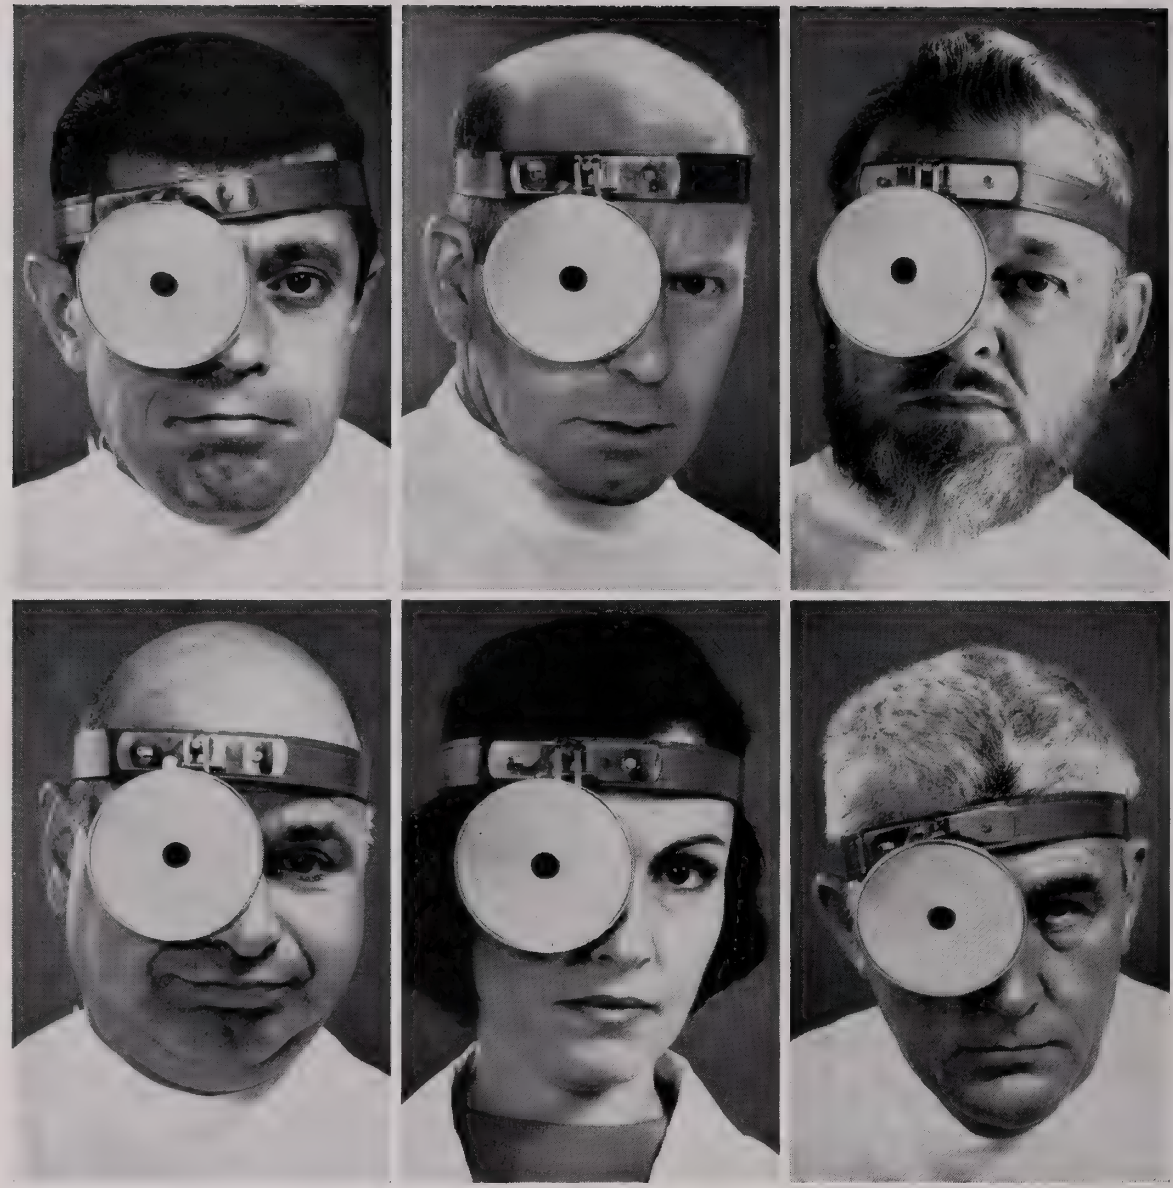
Often the symptoms of anxiety states are difficult to sort out—even with the most careful probing. The patient may manifest symptoms of agitation, restlessness, insomnia, somatic complaints. But what of the depression that may be mixed in the total picture? It is reassuring to know that Mellaril may be prescribed—with strong possibilities of success—when there is anxiety alone or a mixture of anxiety and depression.

Before prescribing or administering, see Sandoz literature for full product information, including adverse reactions reported with phenothiazines. The following is a brief precautionary statement.
Contraindications: Severe central nervous system depression, comatose states from any cause, hypertensive or hypotensive heart disease of extreme degree.
Warnings: Administer cautiously to patients who have previously exhibited a hypersensitivity reaction (e.g., blood dyscrasias, jaundice) to phenothiazines. Phenothiazines are capable of potentiating central nervous system depressants (e.g., anesthetics, opiates, alcohol, etc.) as well as atropine and phosphorus insecticides. During pregnancy, administer only when necessary.
Precautions: There have been infrequent reports of leukopenia and/or agranulocytosis and convulsive seizures. In epileptic patients, anticonvulsant medication should also be maintained. Pigmentary retinopathy may be avoided by remaining within the recommended limits of dosage. Administer cautiously to patients participating in activities requiring complete mental alertness (e.g., driving). Orthostatic hypotension is more common in females than in males. Do not use epinephrine in treating drug-induced hypotension. Daily doses in excess of 300 mg. should be used only in severe neuropsychiatric conditions.
Adverse Reactions: *Central Nervous System*—Drowsiness, especially with large doses, early in treatment; infrequently, pseudoparkinsonism and other extrapyramidal symptoms; nocturnal confusion, hyperactivity, lethargy, psychotic reactions, restlessness, and headache. *Autonomic Nervous System*—Dryness of mouth, blurred vision, constipation, nausea, vomiting, diarrhea, nasal stuffiness, and pallor. *Endocrine System*—Galactorrhea, breast engorgement, amenorrhea, inhibition of ejaculation, and peripheral edema. *Skin*—Dermatitis and skin eruptions of the urticarial type, photosensitivity. *Cardiovascular System*—Changes in the terminal portion of the electrocardiogram have been observed in some patients receiving the phenothiazine tranquilizers, including Mellaril (thioridazine hydrochloride). While there is no evidence at present that these changes are in any way precursors of any significant disturbance of cardiac rhythm, several sudden and unexpected deaths apparently due to cardiac arrest have occurred in patients previously showing electrocardiographic changes. The use of periodic electrocardiograms has been proposed but would appear to be of questionable value as a predictive device. *Other*—A single case described as parotid swelling.

Mellaril®
(Thioridazine HCl)
25 mg. t.i.d.

for moderate to severe anxiety and mixed anxiety-depression

SANDOZ SANDOZ PHARMACEUTICALS, HANOVER, N. J. 68-170



"All Otolaryngologists are Alike"

Just look at them and you can see how much they have in common. Besides, they all go through pretty much the same training, and pass the same kinds of tests, and measure up to the same sort of standards. Therefore, all otolaryngologists are alike. Right?

Wrong! But that's no more preposterous than what some people say about aspirin. Namely: since all aspirin is at least supposed to come up to certain required standards, then all aspirin tablets must be alike.

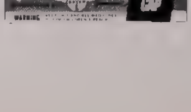
Bayer's standards are far more exacting. In fact, there are at least nine *specific differences* involving moisture content, purity, potency and speed of tablet disintegration, which make the manufacture of Bayer® Aspirin so different.

These Bayer standards result in significant product benefits, including gentleness to the stomach and product stability, that enable Bayer Aspirin tablets to *stay* strong and gentle until they are taken.

So next time you hear someone say that *all* aspirin tablets are alike, you can say, with confidence, that "it just isn't so."

You might also say that all otolaryngologists aren't alike, either.

BAYER
ASPIRIN
FAST PAIN RELIEF



Book Reviews

Libraries are not made, they grow.—Augustine Birrell

SYNOPSIS OF SURGERY. Richard D. Liechty and Robert T. Soper; C. V. Mosby Company, St. Louis; July 1968. $12.50.

This book is a fine addition to the surgeon's bookshelf, and it is a pleasure to review it. In about 1,000 pages in pocketbook format, twenty-one authors from the University of Iowa College of Medicine have accomplished a tremendous task.

It is stated in the foreword that this book was written in regard to the changing demands of medical undergraduate education which stimulates the student to question all theories in a search for fresh answers. As more emphasis in the new curricula is placed upon clinical and bedside teaching, there is even more need to teach the basic clinical subjects as "core courses" to provide time for individual study. With this change in concept of education two different types of textbooks emerge: One designed for the student to whom the subject is fresh, new, and still unconquered; the other a reference book which discusses specific topics in substantial detail.

This book is written for the student. It covers the wide field from abdominal and thoracic surgery to the principles of neurosurgery and orthopedics, as well as touching on general biological principles, anesthesiology, and radiology. Every field seems to be covered well albeit not in depth. There are fine chapters on fluid and electrolyte management, blood transfusions, blood coagulation, wound healing, and shock.

An example of the conciseness and clarity with which this book is written is illustrated by a short paragraph entitled Spontaneous Regression of Cancer. After a short review of these occurrences, it is said: "The reason for these miraculous regressions is one of the most provocative questions in all of medicine today. Spontaneous regression of cancer strongly suggests an immune response in the host. Much current research effort is directed toward identifying and intensifying this immune response." What more needs to be said to an enthusiastic medical student!

This book does not intend to show how to do things, but what to look for and how to understand disease. Like so many of my contemporary colleagues, I have always had a folder with cutout articles, bits and pieces of useful information, tables, etc. This surgical synopsis makes it almost unnecessary to keep and maintain my favored folder which I can never find when I am in a hurry.

The price is reasonable, the text is excellent, the illustrations—including the x-ray reproductions—are of high quality, and the paper, cover, type, and general makeup of the book are quite pleasing.

Herman W. Heupel, M.D., Ph.D.
Minneapolis, Minnesota

MEDICAL PHYSIOLOGY, Edited by: Vernon B. Mountcastle, M.D.; C. V. Mosby Company, 1968; Two Volumes, 12th Edition; Price: $24.00.

The 12th edition of this comprehensive textbook on medical physiology edited by Dr. Mountcastle of the Johns Hopkins University is brought up to date and retains the high quality and excellence of the previous editions. The text covers all areas of physiology in detail, is well illustrated, and contains key references to the medical literature. The material presented is basic normal physiology with little reference to clinical disease abnormality.

The book is intended primarily for medical students and graduate students in the field of physiology rather than as a reference source of pathophysiology for the clinician. Clinicians, however, will find the text easy to read and worthwhile for review and updating of their knowledge of physiology as a basic science. As Dr. Mountcastle states in the preface, this book is not merely a compilation of currently known facts in physiology but rather an attempt to provide the reader with a method and an attitude which, along with scholarly reflection, will serve him long after the concepts presented are replaced by new and more cogent ones.

The book is recommended to medical students, graduate students in physiology, and clinicians, as a basic science text in normal physiology.

azole) effective against *E. c*
and other sensitive organism
gram-positive and gram-negat
—commonly seen in cystitis a
other urinary tract infectio
Wide clinical usage of Gantan
has confirmed the efficacy of t
wide-spectrum antimicrob
agent in the treatment of cystit

The rapidity of bacterial m
tiplication in a favorable urina
environment is well know
Prompt control of acute bladd
infection is therefore essent

Before prescribing, please consult co
plete product information, a summary
which follows:

Indications: Acute and chronic urina
tract, respiratory and soft tissue inf
tions due to susceptible microorganis
prophylactically following diagnostic
strumental procedures on genitourina
tract.

Contraindicated in sulfonamide-sensit
patients, pregnant females at term, p
mature infants, or newborn infants d
ing first 3 months of life.

Warnings: Use only after critical
praisal in patients with liver or re
damage, urinary obstruction or blo
dyscrasias. Deaths reported from h
persensitivity reactions, Stevens-Johns
syndrome, agranulocytosis, aplastic an
mia and other blood dyscrasias. In clos
intermittent or prolonged therapy, blo
counts and liver and kidney function te
should be performed. Clinical data ins
ficient on prolonged or recurrent thera
in chronic renal diseases of children u
der 6 years.

Precautions: Occasional failures may
cur due to resistant microorganisms. N
effective in virus and rickettsial inf
tions. Sulfonamides not recommend

ot only to reduce the patient's iscomfort but to prevent chron:city and possible ascending in:ection.

Gantanol (sulfamethoxazole) ›rovides antibacterial activity vithin two hours of the initial 2-Gm dose, and subsequent 1-Gm oses, taken morning and eveing, maintain therapeutic blood nd urine levels lasting up to 12 ours. Significant symptomatic esponse is frequently achieved vithin 24 to 48 hours in acute, ncomplicated cystitis and other esponsive urinary tract infecions. In addition, Gantanol is sually well tolerated. Should rolonged therapy be required, he convenient *b.i.d.* dosage helps o minimize the problem of kipped doses.

Over eight years' clinical use as thoroughly demonstrated the ualities that make Gantanol a ood choice for initial therapy of ost urinary tract infections, inluding acute cystitis.

---

or therapy of acute infections caused by roup A beta-hemolytic streptococci. At resent, penicillin is drug of choice in cute group A beta-hemolytic streptococal infections; although Gantanol has roduced favorable bacteriologic converon rates in this infection, data insuffient on long-term follow-up studies as to s effect on sequelae of rheumatic fever r acute glomerulonephritis. If other eatment cannot be used and Gantanol employed in such infections, *important at therapy be continued in usual recmmended dosage for at least 10 days.* bserve usual sulfonamide therapy preutions, including adequate fluid intake. se with caution if history of allergies nd/or asthma. Follow closely patients ith renal impairment since this may use excessive drug accumulation. Need r indicated local measures or surgery ot obviated in localized infections.

dverse Reactions: Depending upon the verity of the reaction, may withdraw ug in event of headache, nausea, vomitg, urticaria, diarrhea, hepatitis, pancreitis, blood dyscrasias, neuropathy, drug ver, Stevens-Johnson syndrome, skin sh, injection of the conjunctiva and lera, petechiae, purpura, hematuria and ystalluria.

Gantanol®
(sulfamethoxazole)
assures rapid, sustained, antibacterial activity with b.i.d. dosage

Gantanol® B.I.D.
(sulfamethoxazole)

Help the Needy!

This patient may appear to "have everything" but, like so many people getting along in years, she may well be in need—*medically*. Though there is no evidence of organic disease, she does have symptoms (fatigue, vague aches and pains, malaise) that may be indicative of—

a need to maintain anabolic balance... to counteract declining gonadal hormone secretion and forestall premature degenerative changes related to estrogen deficiency;

a need for mood elevation... to impart a gentle emotional uplift;

a need for nutritional supplementation... to compensate for the poor eating habits and subsequent dietary insufficiency of so many older people.

For these needs, consider MEDIATRIC for your next "needy" patient... medically.

MEDIATRIC provides specific agents to fulfill a need in the three areas:

1. **Gonadal steroids** [PREMARIN® (conjugated estrogens-equine), an orally active, natural estrogen, and methyltestosterone] for physiologic and metabolic benefits.

2. **Methamphetamine** to provide gentle elevation of mood.

3. **Nutritional supplements** specially selected to meet the requirements of the elderly individual.

Mediatric®

tablets • capsules • liquid

Steroid-nutritional compound

	Each MEDIATRIC® Tablet or Capsule contains:	Each 15 cc. (3 teaspoonfuls) of MEDIATRIC® Liquid contains:
Conjugated estrogens-equine (PREMARIN®)	0.25 mg.	0.25 mg.
Methyltestosterone	2.5 mg.	2.5 mg.
Methamphetamine HCl	1.0 mg.	1.0 mg.
Cyanocobalamin	2.5 mcg.	1.5 mcg.
Intrinsic factor concentrate	8.0 mg.	–
Thiamine HCl	–	5.0 mg.
Thiamine mononitrate	10.0 mg.	–
Riboflavin	5.0 mg.	–
Niacinamide	50.0 mg.	–
Pyridoxine HCl	3.0 mg.	–
Calcium pantothenate	20.0 mg.	–
Ferrous sulfate exsic.	30.0 mg.	–
Ascorbic acid	100.0 mg.	–
		Contains 15% alcohol† †Some Loss Unavoidable.

Contraindication: Carcinoma of the prostate, due to methyltestosterone component.

Warning: Some patients with pernicious anemia may not respond to treatment with the Tablets or Capsules, nor is cessation of response predictable. Periodic examinations and laboratory studies of pernicious anemia patients are essential and recommended.

Side Effects: In addition to withdrawal bleeding, breast tenderness or hirsutism may occur.

Suggested Dosages: *Male and female*—1 Tablet or Capsule, or 3 teaspoonfuls Liquid, daily or as required.

In the female: To avoid continuous stimulation of breast and uterus, cyclic therapy is recommended (3 week regimen with 1 week rest period—Withdrawal bleeding may occur during this 1 week rest period).
In the male: A careful check should be made on the status of the prostate gland when therapy is given for protracted intervals.

Supplied: No. 752—MEDIATRIC Tablets, in bottles of 100 and 1,000.
No. 252—MEDIATRIC Capsules, in bottles of 30, 100, and 1,000.
No. 910—MEDIATRIC Liquid, in bottles of 16 fluidounces.

Medicine and History

Dostoevsky's Pulmonary Disease

Physician readers justifiably might ask why anyone in medicine would be interested in Fyodor Michailovich Dostoevsky. Certainly Dostoevsky was a very interesting and complex man but, specifically, this communication concerns his pulmonary disease which seems to have escaped medical attention. Dostoevsky manifested many problems of consuming interest to psychiatrists and neurologists, but perhaps there was one problem to evoke the interest of specialists in pulmonary disease as well.

Biographies of Dostoevsky usually recount the tempestuous life of this great writer, his neurotic temperament, his Siberian prison experiences, his obsessive gambling, and his epilepsy. He was the son of a physician. The murder of his father by the serfs was cited by Freud as the genesis of an oedipal guilt which affected Dostoevsky's entire life and purportedly is reflected in his works. His personal problems were quite intriguing, but it was a surprise to me to discover that the cause of his death had no relation to his epilepsy but was rather the consequence of an 11-year course of progressive pulmonary disease.

Dostoevsky died in St. Petersburg (Leningrad) on January 28, 1881, in his 60th year. Because several available biographies indicated he had coughing, wheezing, and dyspnea, it became a challenge to delve into the medical aspects of the terminal years of his life.

The last three years of Dostoevsky's life[1] were only rarely marred by grand-mal epileptic seizures. However, his worsening dyspnea, cough, and hoarseness have been described. According to a letter from N. V. Shakhalova (personal communication, April 1968) of the Dostoevsky Museum in Moscow, Dostoevsky's pulmonary disease appeared around 1870. Because of it he made several visits to a health resort in Ems, Germany. In 1878, at the request of his second wife, Anna, Dostoevsky was examined by Dr. M. N. Snitkin, a relative of hers. Dr. Snitkin diagnosed emphysema of a rapidly progressive type and cautioned about the danger of rupture of pulmonary blood vessels.

Mochulsky, in describing the public appearances during Easter, 1879, stated: "These public appearances caused him great strain; he was suffering from emphysema, easily lost his breath, controlled his breath with muted and hoarse voice with difficulty." This quotation suggests that dyspnea and speaking were more of a problem than was coughing. The following is from a letter* (translated) written by Dostoevsky at Ems to his wife on July 25, 1879:

> Yesterday I went to [Dr.] Ort; after three years he immediately recognized me. He examined me thoroughly. He said that it is emphysema but still in its beginning and although it is impossible to cure it, it can be treated with great and significant success. That you did not come in three years strengthens the action of Krenken (mineral water) and in Krenken you will revive. But in the beginning we will use Krenken and later we will try Kesselbrunnen

---

*Supplied by the Dostoevsky Museum, Moscow.

> (also a mineral water). He found that I had some type of change in the lungs and the heart, all the consequences of emphysema.

The above letter suggests that the physicians thought that their patient had pulmonary hypertension. This is in accord with the opinion of Dr. Snitkin, particularly concerning the possibility of a pulmonary hemorrhage. The way the letter is worded also suggests the possibility of pulmonary fibrosis.

Mochulsky stated that:

> On the night of January 25 to 26 [1881] while working in his study he began to cough blood. The extravasation was so insignificant he paid no attention; on January 26 there were two new hemorrhages. The doctor was summoned. The patient lost consciousness.

Another account of this event is translated from a book by L. Grossman[2] published in Moscow in 1965.

> Dostoevsky arose from behind the table and went to his study. Here he had a gushing forth of blood from his throat but this did not last long. He attempted to calm his family and showed the children inscriptions in the journal "Chips" with humorous pictures and verses.

Apparently the hemorrhages recurred the evening of the 26th; so Dr. Koshlakov* was summoned, who, following his examination, diagnosed the condition as rupture of a small vessel and not likely to be serious. On January 27th Dostoevsky spent a comfortable day. He received a few friends and read to his children, but he awoke in the early hours on January 28th with an overwhelming premonition of his impending death. As translated from Grossman's book: "In the 11th hour, throat hemorrhages recurred. The patient felt unusual weakness. . . . After a new hemorrhage at the 7th hour in the evening, he lost consciousness and died at 8:38 p.m."

There is no report of an autopsy, and we have no access to records that will throw any additional light on these final days. Since reports of the physicians who attended Dostoevsky in his final days are unavailable in this country, we are left to speculation.

My colleagues in the specialty of pulmonary disease assure me it would be most unusual for hemoptysis to occur with emphysema. We know that Dostoevsky was a heavy smoker of cigarettes and cigars virtually all of his life. The diagnosis of emphysema therefore would be in accord with this information. Is it possible also that chronic bronchitis or even bronchiectasis may have developed? Pulmonary hemorrhage can occur in bronchiectasis; therefore, this must be considered as a diagnostic possibility. We also know that he was given positive-pressure breathing treatments of some sort during his stay at Ems on at least one occasion.

Consideration of pulmonary carcinoma seems rather unfounded in view of his health and relative vigor up until the last few days of his life. In other words, from all evidence at hand, he did not deteriorate physically or mentally and was active in both writing and in conferring with his publishers. However, there does seem to be another possibility, particularly in view of its prevalence in Russia 100 years ago—pulmonary tuberculosis.

Dostoevsky's mother died of tuberculosis, as did his first wife. No doubt he was also intimately exposed to tuberculosis during his four years in a Siberian prison camp. It seems odd that nowhere has this diagnosis been mentioned in the references examined. It also seems unlikely that a diagnosis of pulmonary tuberculosis would have eluded the physicians who treated him, familiar as they were with the disease at that time. No mention was found in the sources examined regarding expectoration or medications.

---

*According to a personal communication from L. Pantserova, February 1968.

It seems most probable to me that tuberculosis played the major role in Dostoevsky's death. It also seems reasonable that Dostoevsky had chronic pulmonary disease, perhaps even emphysema, but developed pulmonary tuberculosis with cavity formation. Tuberculous erosion of a vessel could therefore have produced the hemoptysis which resulted in his death.

John A. Tobin, M.D.

Doctor Tobin took the cover picture while on vacation in Western Montana. He was driving along the highway around 4 o'clock in the afternoon and came upon this beautiful scene at a bend in the road.

Born in Mitchell, South Dakota, Dr. Tobin attended Creighton University Medical School in Omaha, Nebraska, and his residency training was taken at the University of Michigan. He is a member of Radiologist Consultants and is on the radiology staffs of five metropolitan hospitals.

T.B. and Big Shots

The list of those afflicted with tuberculosis leads me to conclude that here is the most admirable of all diseases. Termed "The Great Destroyer", T.B. seems to have contributed more to the world's knowledge and enjoyment of life than all the nondestructive, beneficial agencies put together—assuming that the psychologists are right in their theory that T.B. inspires men to improve themselves. Although some famous T.B.-ers died young, the majority lived as long as the average citizen of their times in spite of the fact that nobody knew how to cure T.B. then.

Moliere was fifty-one when he died in harness shortly after collapsing on the stage during the opening performance of *Le Malade Imaginaire.* Sir Walter Scott recovered from T.B. as a young man and went on to turn out almost as much fiction as Edgar Wallace. Goethe had T.B. for a while and undoubtedly it shortened his life to a mere eighty-two years. Voltaire was never free of it and so he tossed in the sponge at eighty-three. Ralph Waldo Emerson, a typical T.B.-er in every physical respect, benefited humanity by living and working for nearly eighty years. Balzac, like Moliere, died probably of T.B. at 51, but by that time he had written more novels than any single man was apt to read. Just before he died, he took himself a wife, so maybe the T.B. wasn't entirely to blame.

Paganini, Laennec, Raphael, Watteau, John Calvin, Henry Thoreau, Merimee, Laurence Sterne, Robert Louis Stevenson, Schiller, Spinoza—all these allegedly suffered from T.B.*

Hot under the collar...
high under the cuff.

Sometimes
he forgets he has hypertension, gets hot under the collar. . . high under the cuff.

For such patients, consider **Regroton®**

chlorthalidone 50 mg.
reserpine U.S.P. 0.25 mg.

To lower blood pressure and allay anxiety in hypertension.

For brief summary of prescribing information, see next page.

RE-6392

Regroton® Geigy

chlorthalidone 50 mg.
reserpine U.S.P. 0.25 mg.

the once-a-day tablet for anxious hypertensives

Regroton is a combination of two basic antihypertensives designed to lower blood pressure and allay anxiety in hypertension. With Regroton he can keep his shirt on and you can keep his blood pressure down.

Before prescribing, please review carefully the indications, contraindications, warning, precautions, adverse reactions and dosage information below.

Regroton®
Each tablet contains:
chlorthalidone 50 mg.
reserpine U.S.P. 0.25 mg.

Indications: Hypertension.
Contraindications: History of mental depression, hypersensitivity, and most cases of severe renal or hepatic diseases.
Warning: With the administration of enteric-coated potassium supplements, which should be used only when adequate dietary supplementation is not practical, the possibility of small-bowel lesions (obstruction, hemorrhage, and perforation) should be kept in mind. Surgery for these lesions has frequently been required and deaths have occurred. Discontinue coated potassium-containing formulations immediately if abdominal pain, distention, nausea, vomiting, or gastrointestinal bleeding occur. Discontinue one week before electroshock therapy, and if depression or peptic ulcer occurs.
Use in pregnancy: Because chlorthalidone may cross the placental barrier and appear in cord blood and thiazides may appear in breast milk, this drug should be used with care in pregnant patients and nursing mothers. When used in women of childbearing age, the potential benefits of the drug should be weighed against the possible hazards to the fetus. Use of chlorthalidone may result in fetal or neonatal jaundice, thrombocytopenia, and possibly other adverse reactions which have occurred in the adult. Increased respiratory secretions, nasal congestion, cyanosis and anorexia may occur in infants born to reserpine-treated mothers.
Precautions: Antihypertensive therapy with this drug should always be initiated cautiously in postsympathectomy patients and in patients receiving ganglionic blocking agents, other potent antihypertensive drugs, or curare. Reduce dosage of concomitant antihypertensive agents by at least one-half. To avoid hypotension during surgery, discontinue therapy with this agent two weeks prior to elective surgical procedures. In emergency surgery, use, if needed, anticholinergic or adrenergic drugs or other supportive measures as indicated. Because of the possibility of progression of renal damage, periodic kidney function tests are indicated. Discontinue if the BUN rises or liver dysfunction is aggravated. Hepatic coma may be precipitated. Electrolyte imbalance, sodium and/or potassium depletion may occur. If potassium depletion should occur during therapy, the drug should be discontinued and potassium supplements given, provided the patient does not have marked oliguria.
Take particular care in cirrhosis or severe ischemic heart disease and in patients receiving corticosteroids, ACTH, or digitalis. Severe salt restriction is not recommended. Use cautiously in patients with ulcerative colitis or gallstones (biliary colic may be precipitated). Bronchial asthma may occur in susceptible patients.
Adverse Reactions: The drug is generally well tolerated. The most frequent side effects are nausea, gastric irritation, vomiting, diarrhea, constipation, muscle cramps, headache, dizziness and acute gout. Other potential side effects include angina pectoris, anxiety, depression, bradycardia and ectopic cardiac rhythms (especially when used with digitalis), drowsiness, dull sensorium, hyperglycemia and glycosuria, hyperuricemia, lassitude, restlessness, transient myopia, impotence or dysuria, orthostatic hypotension which may be potentiated when chlorthalidone is combined with alcohol, barbiturates or narcotics, leukopenia, aplastic anemia, skin rashes, thrombocytopenia, agranulocytosis, nasal stuffiness, increased gastric secretions, nightmare, purpura, urticaria, ecchymosis, weakness, uveitis, optic atrophy and glaucoma, and pruritus. Eruptions and/or flushing of the skin, a reversible paralysis agitans-like syndrome, blurred vision, conjunctival injection, increased susceptibility to colds, dyspnea, weight gain, decreased libido, dryness of the mouth, deafness, anorexia, and pancreatitis when epigastric pain or unexplained G.I. symptoms develop after prolonged administration. Jaundice, xanthopsia, paresthesia, photosensitization and necrotizing angiitis are possible.
Average Dosage: One tablet daily with breakfast.
Availability: Pink, single-scored tablets in bottles of 100 and 1000.

RE-6392

MINNESOTA STATE MEDICAL ASSOCIATION
116TH ANNUAL MEETING MAY 26 • 27 • 28, 1969
CONVENTION HALL, MINNEAPOLIS AUDITORIUM
"THE UPPER-MIDWEST'S GREAT MEDICAL MEETING"

All under one roof . . .

THINGS WERE bound to happen when our energetic Committee on Scientific Assembly decided to devote its efforts to plan an annual meeting scientific program with a new twist.

A series of 32 workshops have been scheduled to highlight the 116th Annual Meeting of the Minnesota State Medical Association May 26, 27 and 28 in the new Minneapolis Auditorium Convention Hall. The spacious new Convention Hall will house all major scientific and most business sessions of the meeting. This arrangement will make it possible for physicians to attend the meeting without spending valuable time getting to and from events scheduled at remote locations.

The workshop innovation will replace the customary programs on Monday and Tuesday afternoons and Wednesday morning. Each workshop will be repeated twice—in sessions lasting from 2:00 to 3:00 P.M. and 3:45 to 4:45 P.M. on Monday and Tuesday and 9:30 to 10:30 A.M. and 11:00 to 12:00 noon on Wednesday. This arrangement will make it possible for physicians to attend workshops of their preference with a minimum amount of conflict. Everyday problems encountered by the practicing physician will be given preferential treatment by speakers selected primarily from the ranks of eminent Minnesota specialists and consultants.

The new format is based on the results of nearly a year of exploration of a number of possibilities, including a study of some of the most successful medical meetings in the nation, conducted by the Committee and its Chairman, Doctor O. L. N. Nelson.

"Hand Injuries—13 Things to Avoid," "Drugs for Nervousness," "Menopause—an Organic vs. a Psychiatric Problem," "The New Diuretics," "Thyroid Disease—A Therapeutic Controversy," are among the topics selected for presentation at the 32 workshops.

"In depth" discussion of two major subjects have been scheduled for Monday and Tuesday morning. "Fluids & Electrolytes—How Much, What Kind and When" will be discussed Monday, May 26, at 9:30 A.M. by Doctor William E. Segar, Rochester. His paper will be concerned with the presentation of a simple usable system of parenteral fluid therapy. Emphasis will be placed upon avoiding complications that might prove fatal to the child.

"Cancer Chemotherapy" will be the subject of the Tuesday "in depth" presentation scheduled to begin at 9:30 A.M., arranged by Doctors David Ahmann and J. M. Kiely, both of Rochester. The topics are "The Chemotherapy of Solid Tumors in Children," "The Chemotherapy of Gastrointestinal Cancer," "Progress in the Management of the Patient with Lymphoma," "Current Thoughts About the Chemotherapy of Leukemia," "Testicular Cancer—Current Chemotherapy," and "The Medical Management of Disseminated Breast Cancer."

Two major luncheon meetings have been scheduled for Monday and Tuesday noon at the Minneapolis Auditorium Convention Hall. On Monday, May 26, Doctor A. C. Aufderheide, Duluth, will discuss his trip "To the North Pole by Snowmobile." Physicians are encouraged to bring their wives to this event. "Alcoholism" will be the topic of discussion at the Tuesday luncheon. The presentation will be made by the Reverend Philip L. Hansen, White Bear Lake. Reverend Hansen is chairman of the Minnesota Commission on Alcohol Problems.

The House of Delegates will convene Sunday, May 25, at 2:00 P.M. The second session of the House will be called to order Tuesday, May 27, at 7:00 P.M. Both sessions will be held at Holiday Inn Central.

Reference Committee meetings of the House of Delegates will be held Sunday at 8:00 P.M. and again Monday morning at 9:30 A.M. (if necessary) at the Holiday Inn Central.

A majority of the scientific and non-scientific committees of the Association have scheduled breakfast meetings, and committee members are urged to make necessary reservations to attend meetings in which they have an interest.

The Annual Banquet will be held Monday evening at 7:00 P.M., another change from the traditional Tuesday date. Outstanding entertainment and the customary awards will highlight the banquet program.

The Delegates, New Members, Officers and Sportsmen's dinner will be held Sunday evening at 6:00 P.M. following the opening meeting of the House of Delegates.

Because most of the Annual Meeting activities will be held in the Minneapolis Auditorium Convention Hall, physicians will have more time to visit the many excellent scientific and technical booths. All physicians attending the meeting are invited to visit the technical exhibits and extend their appreciation to the representatives of the firms who have participated in this meeting, thus insuring future meetings for our Association.

Future Annual Meeting information, including the official program and necessary registration materials, will be mailed to all members.

The Woman's Auxiliary will meet in conjunction with the Annual Meeting of the Minnesota State Medical Association. Hosts for this year's events are the members of the Hennepin County Medical Society and Auxiliary.

Physicians are encouraged to pre-register by completing the registration card enclosed with current issues of the Newspage and the official Annual Meeting program mailed to all members. By completing and returning this card by May 5 to the State Office, they can be certain that their badges will be waiting for them at the advance registration desk in the Minneapolis Auditorium Convention Hall.

The best way to get ahead is to have one.—Pure Globe

Time Table for Workshops

HOUR	Monday, May 26	HOUR	Tuesday, May 27	HOUR	Wednesday, May 28
Workshops given simultaneously. Each topic presented twice. First time: 2:00 to 3:00 p.m. Second time: 3:45 to 4:45 p.m.	"What to Do Until the Psychiatrist Comes" Thomas Burton Minneapolis	Workshops given simultaneously. Each topic presented twice. First time: 2:00 to 3:00 p.m. Second time: 3:45 to 4:45 p.m.	"Children Who Don't Grow" A. B. Hayles Rochester	Workshops given simultaneously. Each topic presented twice. First time: 9:30 to 10:30 a.m. Second time: 11:00 to 12:00 p.m	"Prevention of Rh Disease" H. F. Polesky E. B. Berglund A. R. Thelemann Minneapolis

During Intermission Visit Exhibits

Rehabilitation Medicine

A Decade of Progress

REHABILITATION MEDICINE as an in-patient hospital specialty developed in the military hospitals of the Second World War and continued to grow during the poliomyelitis outbreaks of the next ten years. A new body of knowledge concerning the management and treatment of chronic neuromuscular problems accumulated around techniques of muscle strengthening and re-education, range of motion exercises, and therapeutic physical agents.

By the time poliomyelitis was eliminated as a major crippler, rehabilitation medicine had already begun to adapt the concepts and techniques it had developed for the management and treatment of that disease to other disabling conditions. Hemiplegia, paraplegia, quadriplegia, multiple sclerosis, lower motor neuron disease, and cerebral palsy all fit into the category of chronic neuromuscular disability, and the concern of rehabilitation centers shifted to patients with these problems, plus arthritics and amputees.

Present Trend

In the decade since rehabilitation medicine made the transition from polio to these other diseases, a new look has become apparent in the field. The complex disease processes being treated require comprehensive management; the rehabilitation team has become the most prominent aspect of rehabilitation medicine. Not only the patient but his family and community are involved in evaluation, diagnosis, and treatment. The patient's social, environmental and vocational problems as well as his physical limitations are dealt with by such paramedical personnel as psychologists, social workers, speech pathologists, audiologists, etc.

With the increased severity of involvement and the greater utilization of paramedical personnel, the rehabilitation process has become more time-consuming and costly. Rising rates for standard hospital services, added to the cost of comprehensive complex care, have put rehabilitation beyond the reach of the individual, unless he has extraordinary third-party coverage or large independent financial resources. Thus, rehabilitation centers have found it necessary to subsidize their services in order to avoid placing undue financial burdens on the patient. No comprehensive rehabilitation center in the United States operates without a substantial financial loss. Paradoxically, the more efficient and effective the center's treatment of the chronic-disease patient, the larger the deficit. This is a result of increased paramedical personnel costs and decreased number of total patient days.

Changes in Length of Hospital Stay

Just how effective has the rehabilitation process become, and what standards do we have for tracing the changes in its performance? A recent survey at the Kenny Rehabilitation Institute revealed the following facts:

In 1959 the average length of stay at Kenny Rehabilitation Institute was 52.3 days. The diagnostic categories treated were:

Hemiplegia	47%
Paraplegia and quadriplegia	6%
Cerebral palsy	15%
Rheumatoid arthritis	12%
Amputations	0%
Mixed neurological categories (including multiple sclerosis, muscular dystrophy, amyotrophic lateral sclerosis, Guillain-Barre syndrome, and some post-poliomyelitic residuals)	21%

In 1967 the average length of stay at Kenny Rehabilitation Institute was 29.6 days. The diagnostic categories treated were:

Hemiplegia	32%
Paraplegia and quadriplegia	19%
Cerebral palsy	23%
Rheumatoid arthritis	10%
Amputations	10%
Mixed neurological categories	6%

The diagnostic categories are the same, except that amputations are now included. Nor has there been any major change in the distribution of cases among the categories; there has been some increase in spinal cord injuries and some decrease in stroke, but the mix is fairly similar.

The important difference is the decrease in length of stay. It should be emphasized that both sets of figures refer to patients who entered the hospital with comparable degrees of disability and who had achieved similar levels of improvement at the time of discharge. Despite the increase in the number of paraplegics and quadriplegics, whose rehabilitation requires longer periods of time than that of patients in other categories, the patient's time in hospital was reduced by 1967 to little more than half the duration in 1959.

This decline has been reflected in all the diagnostic categories. In 1959 the average length of stay for a hemiplegic patient was 53.7 days. By 1964 this had decreased to 36.7, and by 1967 to 29.5 days. Paraplegic and quadriplegic patients, whose rehabilitation 10 years ago required six to nine months, now require about four months to attain the same degree of improvement. These two categories account for the majority of patients in an intensive rehabilitation center, but similar decreases are recorded in the other categories.

Quality of Care

Sheps[1] has pointed out that there are four methods of approaching the problem of quality control in the area of medical care. They are: (1) selected prerequisites or standards; (2) indexes, or components of the process; (3) evaluations of clinical performance by expert judges; and (4) indexes of the effects of care on patients. As Ellwood has remarked,[2] only the last is actually a measure of "the true goal—the outcome of medical care," and it is not often used in nonfatal processes.

When outcome criteria are used in rehabilitation medicine, they are often based on subjective appraisals of improvement. This approach has proved somewhat less than satisfactory, because of the chance of misinterpretation by the evaluator when he assesses improvement or change in the patient, and because of the general unreliability of non-objective criteria. Many rehabilitation centers have utilized objective rating scales to determine functional mobility and self-care capabilities. These scales enable the specialist in rehabilitation medicine and the rehabilitation team to assess their therapeutic techniques better, and also to compare various treatments.

At the Kenny Rehabilitation Institute, rating scales have been developed[3] which accurately measure the self-care status of patients. Each of 17 activities is rated on a five-point scale, and each point on the scale is explicitly and operationally defined in terms of how much assistance the patient needs in order to perform the activity. High inter-observer reliability has been shown to exist in the scoring.[4]

Using this self-care assessment as the criterion measure, researchers at Kenny have sought to develop prediction criteria that can be applied upon admission, as soon as the pertinent data have been gathered.[4] The capability of setting goals which are realistic and attainable for the individual patient conserves the time and effort of the rehabilitation team, saves excessive cost, and limits the patient's rehabilitation process to a definable period of time.

The Future

We feel a certain sense of accomplishment in the expeditiousness with which patients in the disease categories mentioned earlier are now being rehabilitated, but at the same time we are looking ahead to a new decade which will bring an expansion in the scope of rehabilitation services.

With objective criteria we can now apply the skills of rehabilitation medicine to more obscure and diffuse diagnostic categories which include diminished functional capabilities among their effects, such as mental retardation, learning disorders, emotional disturbances, and diseases of the geriatric population.

We must also be more selective in our treatment programs, improving our utilization of scarce professional personnel. By the use of objective outcome criteria, therapeutic emphasis can be placed at appropriate times during the course of the patient's illness and rehabilitation. We must select the optimum points of intervention in this process and assign the specialized therapies which will enable the patient to make the most rapid progress possible.

The tools of the electronic communication systems adapt themselves well to the field of rehabilitation medicine, providing rapid and accurate dissemination of information to communities and units which are not large enough to support an intensive rehabilitation center. Television consultation, computer data pools, and electronic treatment simulation systems will become practical tools for both the rehabilitation specialist and the family physician. In the coming decade, disability—physical, social, and vocational—may be treated as aggressively as acute disease.

In Memoriam

Death, so called, is a thing which makes men weep,
And yet a third of life is pass'd in sleep.
—*Byron*

LAWRENCE M. RANDALL, M.D.

Dr. Lawrence M. Randall, 73, nationally-known specialist in obstetrics and gynecology, died January 11. He had retired in 1960 after a 34-year career at the Mayo Clinic.

Born in LaMoille, Iowa, Dr. Randall received his medical degree from the State University of Iowa. He came to Rochester in 1924 and was appointed to the staff of the Mayo Clinic in 1926. In 1946 he was elected president of the Clinic staff and became a member of the board of governors in 1948. Dr. Randall served as president of the American Association of Obstetrics and Gynecology in 1954 and also as president of the Minnesota Society of Obstetrics and the Central Association of Obstetricians and Gynecologists.

Dr. Randall was a member of the Zumbro Valley Medical Society and the American Medical Association and an Associate Member of the Minnesota State Medical Association.

He is survived by his wife, a daughter, and two sons, one of whom is Dr. David Randall of Minnetonka.

NORMAN LENDE, M.D.

Dr. Norman Lende, 72, retired staff member of the Faribault State School and Hospital, passed away January 21. He had been ill for over a year.

Dr. Lende graduated from the University of Minnesota Medical School in 1928, interned at St. Mary's Hospital in Duluth, and was a member of the Alpha Omega Alpha Fraternity. He was also a member and past president of the Rice County Medical Society, a member of the American Medical Association and an Associate Member of the Minnesota State Medical Association.

Dr. Lende is survived by his wife and daughter.

JOHN H. GRINDLAY, M.D.

Dr. John H. Grindlay, 59, member of the Mayo Clinic's staff and head of the surgical research section, died December 14.

A native of Philadelphia, he received his Medical degree from the Harvard Medical School in 1935 and came to Rochester as a Mayo Graduate School resident in 1937. He was a member of the Zumbro Valley Medical Society, the American Medical Association and an Associate Member of the Minnesota State Medical Association.

Dr. Grindley is survived by his wife, two daughters and one son.

WALLACE P. RITCHIE, M.D.

Dr. Wallace P. Ritchie, 63, St. Paul surgeon, died January 22 during the night of a heart ailment. He was a life-long resident of St. Paul and began practicing medicine in the city in 1932. He was a graduate of Yale University and Johns Hopkins University, obtaining his medical degree at Johns Hopkins.

Dr. Ritchie was a past president of the St. Paul Surgical Society and was on the board of governors of the American College of Surgeons. He was a member of the Ramsey County Medical Society, the American Medical Association and the Minnesota State Medical Association.

He is survived by his wife and three sons.

HARRY LEROY SMITH, M.D.

Dr. Harry LeRoy Smith, widely-known specialist in diseases of the heart at the Mayo Clinic and emeritus professor of medicine in the Mayo Graduate School of Medicine, died in the La Mesa Hospital in La Mesa, California, February 13.

Born in Fairport, Missouri, he obtained his degree of doctor of medicine in 1916 from the State University of Iowa. In 1928 he was appointed to the staff of the Mayo Clinic.

Dr. Smith was certified as a specialist in cardiovascular diseases by the American Board of Internal Medicine, was a fellow of the American College of Physicians, a former president of the Zumbro Valley Medical Society, member of the Minnesota Society of Internal Medicine, the Minnesota Heart Association, the American Heart Association, the American Medical Association and a 50 Club and Associate Member of the Minnesota State Medical Association.

He is survived by his wife, one daughter, and a son, Dr. Meredith P. Smith of Seattle, Washington.

CLARENCE WILLIAM MOBERG, M.D.

Dr. Clarence Moberg, 66, prominent state physician and resident of Detroit Lakes for the past 34 years, died March 1, after a two-year illness. He is credited with originating the Minnesota Blue Shield Health Insurance Program and the Becker County Blood Bank.

He was a former vice president of the Minnesota State Board of Medical Examiners, vice president of the Minnesota State Medical Association, member of the American Academy of General Practitioners, member of the Clay-Becker County Medical Society, and a member of the American Medical Association.

He is survived by his wife, a daughter, and two sons, one of whom is Dr. Allen Moberg of Minneapolis.

HEWITT B. HANNAH, M.D.

Dr. Hewitt B. Hannah, 72, Minneapolis psychiatrist and neurologist, died February 7. He attended Miami University in Oxford, Ohio, and graduated from the University of Cincinnati Medical School. At the time of his death he was on the staffs of Northwestern, Abbott and St. Barnabas Hospitals.

Dr. Hannah was a member of the American Medical Association, the Minnesota State Medical Association, the Hennepin County Medical Society, the American Psychiatric Association, the Neuro-Psychiatric Society, the Central Electroencephalographical Society, the Minneapolis Academy of Medicine and the Minnesota Society of Neurology and Psychiatry.

He is survived by his wife, a daughter, and a son.

NABOTH O. PEARCE, M.D.

Dr. N. O. Pearce, 89, one of the first pediatricians to practice in Minneapolis, died March 5, in Tavernier, Florida. A graduate of the University of Minnesota Medical School, Dr. Pearce practiced in Minneapolis from 1914 to 1968.

He was a past president of the Minnesota State Medical Association, the Hennepin County Medical Society and the Hennepin County Tuberculosis Association. Dr. Pearce was also a member of the American Medical Association.

He is survived by his wife and one son.

WILLIAM L. BENEDICT, M.D.

Dr. William L. Benedict, head of the Section of Ophthalmology of the Mayo Clinic from 1917 to 1949, died February 18 at the age of 84. Born in Springport, Indiana, he received his medical degree from the University of Michigan.

He was a member of the American Board of Ophthalmology, founder of the American Board of Opticianry and chairman of its Advisory Committee, fellow of the American College of Surgeons, former president of the American Ophthalmological Society, former vice president of the Pan-American Association of Ophthalmology, former chairman of the American Medical Association's Section of Ophthalmology, former member of the House of Delegates of the American Medical Association, executive secretary-treasurer of the American Academy of Ophthalmology and editor-in-chief of the bimonthly *Transactions* of the Academy. Dr. Benedict was a member of the editorial boards of six other scientific journals and a member or honorary member of numerous scientific societies.

He is survived by his wife, two daughters, and a son, Dr. Walter Benedict of Knoxville, Tennessee.

They Never Quite Leave Us

They never quite leave us, our friends who have passed
Through the shadows of death to the sunlight above;
A thousand sweet memories are holding them fast
To the places they blessed with their presence and love.
The work which they left and the books which they read
Speak mutely, though still with an eloquence rare,
And the songs that they sang, the words that they said,
Yet linger and sigh on the desolate air.
And oft when alone, and oft in the throng,
Or when evil allures us, or sin draweth nigh,
A whisper comes gently, "Nay, do not the wrong,"
And we feel that our weakness is pitied on high.

—**Margaret E. Sangster**

Address

Opportunity Unlimited*

HAROLD S. DIEHL, M.D.
New York, New York

DEAN HOWARD, members of the Medical Faculty, the graduating class of 1968, families and friends: To the graduating class, my greetings and congratulations. You have successfully completed a long and difficult program of preparation for the practice of your chosen profession. You have every reason to feel gratified.

It was on June 20, 1918, that the University of Minnesota awarded me a Doctor of Medicine degree. Nineteen sixty-eight is therefore the 50th anniversary of my graduation from Medical School. The realization of this is thrilling but sobering. For me 1968 is a year of another anniversary; for it was ten years ago that I retired as Dean of the Medical Sciences to accept a position on the National staff of the American Cancer Society.

Fifty years, even ten years, are a long time. It is heartwarming *not* to be forgotten with the passing of these years. Also pleasing was the invitation to participate in this program, the fiftieth year of my own graduation.

I received my medical degree in 1918; but I did not attend my graduation ceremony, escaping that by going to France with the U. S. Army to help make the "world safe for democracy." The reason we were able to leave the University before the end of our senior year was that the Medical Faculty granted us permission to enlist in a base hospital unit that was being organized by the University and staffed jointly by the Medical School and the Mayo Clinic. Little did I dream then that 25 years later as Dean of the Medical School I would be responsible for the organization of a similar hospital unit to serve in World War II; nor that 50 years later I would be talking to a graduating class faced with the possibility of service in another war to make a small country on the other side of the world "safe for democracy."

I am sure that few if any college graduates remember what was said in the addresses delivered at their commencement exercises, or even who the speaker was. Dr. Alan Gregg, long-time Director for Medical Sciences of the Rockefeller Foundation, used to say: "If you want people to remember what you say, tell them a story." I am not going to tell you a story but rather the main theme, as I remember it, of an address given here about fifteen years ago by Dr. Robert Newell, the wise and distinguished Professor of Radiology at Stanford University. The occasion was the dedication of the Mayo Memorial Building. The title of the address was "Mink Coats and Cadillacs." We were surprised when Dr. Newell submitted that title and wondered what he would say. His address was deadly serious. He talked about the priceless rewards that a physician receives from his work. To illustrate, Dr. Newell said that each day on his way to the University Hospital in San Francisco he walked through several blocks of slums occupied mostly by Negroes and Mexicans. And along the way he always noticed several second-hand Cadillacs spotlessly clean and beautifully polished. One's natural reaction, he said, is to criticize anything so out-of-keeping with the environment. But, he continued, we should not do so. Everyone needs something in which he can take pride, something to bolster his ego, to nourish his soul. The men who own and polish these Cadillacs live in a ghetto; they cannot live where we live; they cannot belong to our clubs or afford the restaurants and hotels which we patronize. But these shiny cars are something in which they can take pride: a compensation for their deprivations.

---

*Address to the University of Minnesota Graduating Class in Medicine, June 7, 1968.

Then, he added, some women ostentatiously wear expensive mink coats. They or their husbands obviously have money. But they may have little else to be proud of. We should understand and sympathize with them rather than envy or criticize them.

How different it is with physicians. We are fortunate in being able to get true satisfaction from our work and our profession. The physician does not need a Cadillac nor his wife a mink coat to bolster their egos. Emerson wrote, "The greatest reward of a thing well done is to have done it." This is particularly true of the profession which you are about to enter. Your greatest rewards will be your achievements and the services you render, not the financial remuneration you will receive. Your income should and will be adequate to provide a dignified and comfortable living and the opportunities and security your families deserve. Beyond that, money loses its purchasing power for happiness and may well become one's master instead of being one's servant—a liability instead of an asset.

A poll of several hundred practicing physicians were asked their definition of success and it revealed first and foremost: good doctor-patient relationships, and second: good education and training. Other prerequisites for success were: honesty and integrity, willingness to work hard, availability to patients, high quality of work, judgment and skill in diagnosis and treatment, keeping abreast of medical progress, getting along with colleagues and having their respect, intelligence, unselfish dedication to medicine, drive for self-improvement, community welfare and civic responsibilities, and finally, as least important, financial success.

In these days of insecurity and avariciousness there is a temptation for physicians to follow what seems to be the pattern for labor and for business: to get all one can out of the public, particularly if the Government pays the bill. Commercialism and excessive professional fees bring public disfavor to our profession. The primary service that is expected of a physician is to prevent or to cure disease and, if that is not possible, to relieve suffering and to provide comfort.

It was physicians who developed and then persuaded the public to utilize preventive measures that have virtually eliminated smallpox, diphtheria, tetanus, poliomyelitis, typhoid fever, cholera, malaria, yellow fever and other diseases. Similar possibilities for distinguished service exist today and will continue in the future.

An example, with which I have been greatly concerned in recent years, is the problem of cigarette smoking. The Surgeon General of the United States Public Health Service has said that it is the major preventable cause of illness, disability and premature death in this country. It is responsible for an estimated 70,000 annual deaths from cancer; 145,000 from coronary heart disease; 43,000 from strokes and other cardiovascular diseases, and 44,000 from chronic bronchitis, emphysema and other causes—300,000 in all.

A recent survey by the California State Medical Association indicated that 96 percent of physicians consider cigarette smoking a serious health hazard but that only 38 percent advise their patients not to smoke unless they have symptoms attributable to smoking. Dr. Howard has stated that, "A teacher who influences children not to smoke cigarettes can do more to reduce deaths and disability from lung cancer and emphysema than the most skilled surgeons and physicians who care for the patients who develop these diseases."

As to the years ahead only a crystal gazer would attempt to prophesy; but the need for well trained and dedicated physicians was never greater than today and the advances in medical, biological, chemical, physical and social science research are opening vistas of further progress that over the next half century may well surpass the brilliant achievements of the past.

I congratulate you and I envy you the privilege of participating in the wonderful opportunities that lie ahead as you face the challenges of our changing world. God-speed to you all.

It's the Law

Cost of Kidney Transplant Deductible by Donee

A kidney transplant patient, who paid the kidney donor's plane fare and entire hospital bill, was allowed to deduct these costs as medical expenses, the Internal Revenue Service ruled.

The donor traveled from a distant city and entered the hospital as a patient for the purpose of donating the kidney. The kidney recipient paid all transportation, surgical and hospital expenses incurred.

IRS Rev. Rul. 68-452, I.R.B. 1968-34, 16.
The Citation, Vol 17, No. 12, October 1, 1968.

Shakespeare: Medicine

Miscellaneous

"Here comes lean Jack, here comes bare bones. How long
is't ago, Jack, since thou sawest thy own knee?"
"My own knee? when I was about thy years, Hal, I was not
an eagle's talon in the waist; I could have crept into
any alderman's thumb-ring: a plague of sighing and grief!
it blows a man up like a bladder."
"The king himself is to be feared as the lion. Dost
thou think I'll fear thee as I fear thy father? Nay,
an I do, I pray God, my girdle break!"
"O, if it should, how would thy guts fall about thy knees!"*

---

Courses at the University of Minnesota

Proctology

The University of Minnesota will present a continuation course in Proctology from April 21-25, 1969. Through clinical sessions, attention will be specifically devoted toward teaching each registrant the details of proctoscopy. In addition, management of the more commonly encountered proctologic problems will be discussed, as well as the diagnosis and treatment of the most usual anorectal diseases.

Ophthalmology

The University of Minnesota will present a course in Ophthalmology on April 28-29, 1969. This year's course will be concerned with the medical treatment of ocular disease, with emphasis on the treatment of inflammatory ocular diseases and use of newer drugs in ophthalmology. Ample time will be provided for panel discussion of questions by the lecturers. For further information regarding the above courses contact: Lee D. Stauffer, College of Medical Sciences, Box 193 Mayo Building, University of Minnesota, Minneapolis 55455.

New Knowledge in the Diagnosis and Treatment of Rheumatic Diseases

This course is planned for May 9 and 10, and is directed toward the practicing physicians with emphasis on this newer information and its application to the rheumatic problems encountered in every medical practice. Ample time has been left for discussion after each presentation so participants will have the chance to have their questions answered.

The course has been planned by Doctors John G. Mayne and John W. Worthington, Mayo Graduate School of Medicine, and is co-sponsored by the Committee on Rheumatology and Rheumatic Diseases of the Minnesota State Medical Association, and by the Minnesota Chapter of the Arthritis Foundation. The course is offered by the Office of Postgraduate Educational Activities of the College of Medical Sciences, and conducted by the Department of Conferences and Institutes, General Extension Division, University of Minnesota. Tuition is $25.00. Approved A.A.G.P. hours: 11 hours.

Contact: Lee D. Stauffer, College of Medical Sciences, Box 193 Mayo Building, Minneapolis.

Continued from Page 702.

GENERAL PRACTITIONER wanted to join well-established practitioner. New clinic building—90 miles east of St. Paul—city of 14,000. Early partnership with full hospital facilities. Ideal location. L. W. Picotte, M.D.; Chippewa Falls, Wisconsin.

Minnesota Medicine at a Glance

Infarct of the Prostate—*Antolak* Page 591

Infarct of the prostate is a well recognized entity infrequently diagnosed clinically, but discovered at autopsy or pathologically post-T.U.R. It usually causes symptoms of acute urinary retention that are compatible with benign prostatic hypertrophy. The reported case describes an unusual complication in which the infarct obstructed the ureteral orifice, producing a pyohydronephrosis. The method by which the case was successfully managed is reported.

Thymoma with Myopathy—*Souadjian et al.* Page 595

The authors report an interesting case of a lady with very diffuse symptoms centering around muscle weakness. This patient, in addition, was discovered to have a mediastinal mass which, on removal, was found to be a thymoma. Following the removal of the thymoma, the symptoms regressed. This may be the first report of a patient with thymoma and diffuse myopathy whose symptoms and findings decreased following thymectomy.

Steroid Diabetes—*Gharib* Page 669

Relatively short but concise review of difficult subject.

What's New

Attention: All directors of medical education, intern training committees, nursing instructors and public relations committees!

Smith Kline & French Laboratories has just released its new services catalog for 1969-70. This new catalog contains numerous films, periodicals, and pamphlets directed toward the training and education of physicians, nurses and laymen. The scope of these educational services is broad and does not permit summarization. Those interested are invited to obtain a free copy of this catalog by contacting their SK&F representative or by writing to the Services Department E-10, Smith Kline & French Laboratories, 1500 Spring Garden Street, Philadelphia, Pennsylvania 19101.

* * * *

Physicians are hereby alerted to watch for the appearance of Eskavan, a specially designed, mobile theater of medical information sponsored by Smith Kline & French Laboratories. This self-contained and air-conditioned audio-visual "auditorium" is designed in the form of a traveling bus and will visit hospitals. Inside the bus, the physician may watch and listen to various medical films from six to eleven minutes in length with individual headphones permitting several subjects to be presented simultaneously. Watch for this innovation in your hospital parking lot in the future.

as easy as NTZ®

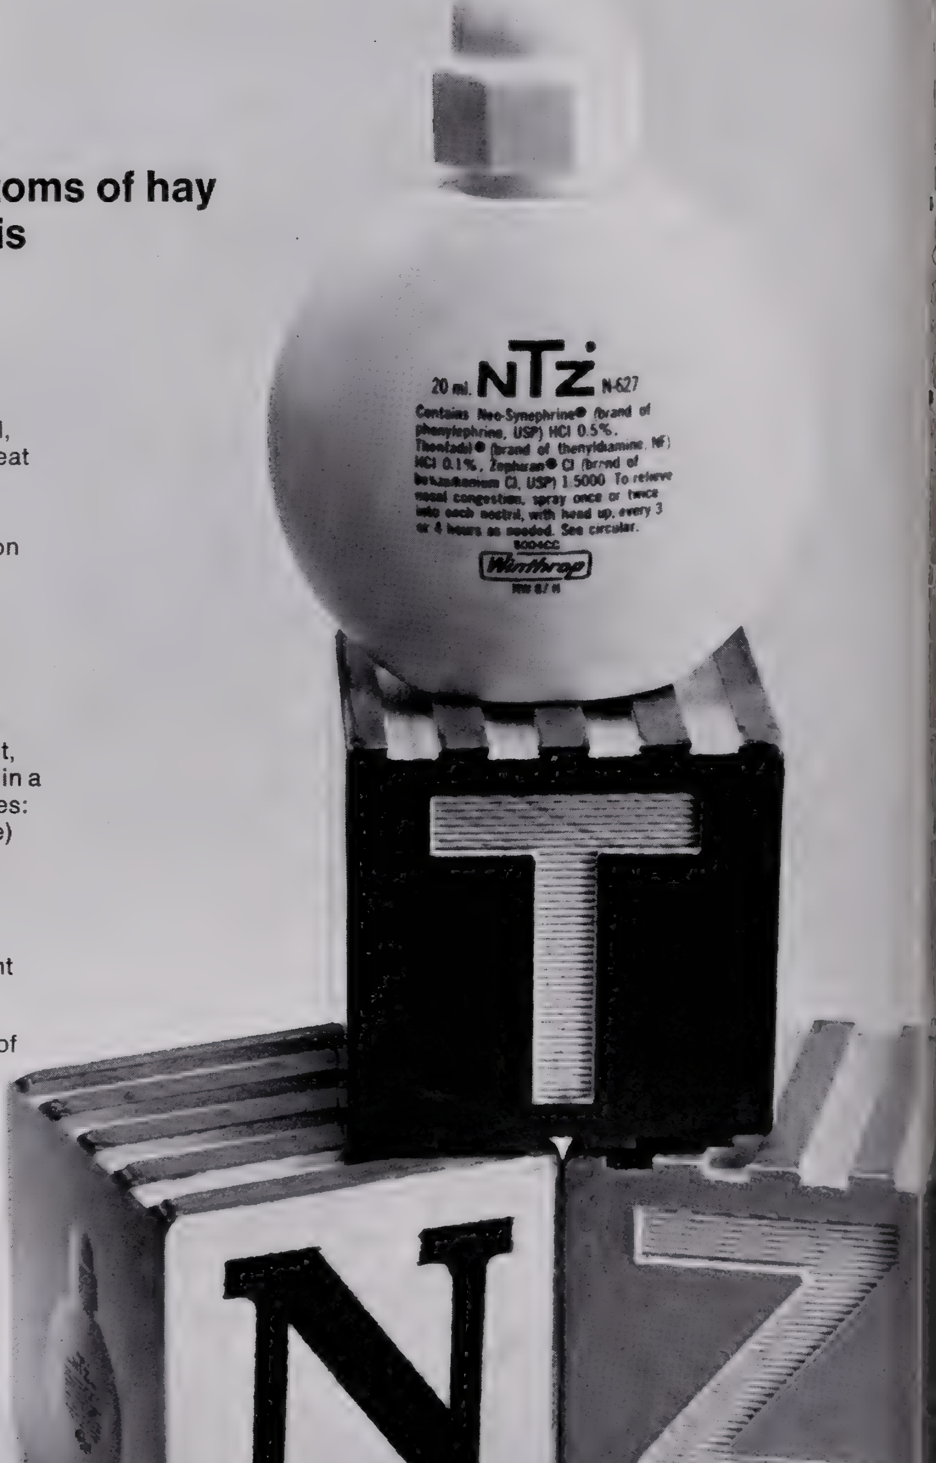
An easy solution to the problem of nasal symptoms of hay fever, colds and sinusitis

- easy to prescribe: just write NTZ Nasal Spray.
- easy to recommend: just say NTZ Nasal Spray.
- easy to use: just one spray in each nostril, quickly followed by a second spray. Repeat q. 3 h. or q. 4 h. for temporary relief.
- easy to dispense: the outer sleeve of the package is removable for easy application of prescription label.
- easy to remember: as easy as NTZ.

But more than a simple vasoconstrictor:

NTZ Nasal Spray affords the well-known benefits of Neo-Synephrine®, 0.5 per cent, the more potent solution (adult strength) in a carefully balanced formula which includes:
Neo-Synephrine (brand of phenylephrine) HCl 0.5 per cent, decongestant
Thenfadil® (brand of thenyldiamine) HCl 0.1 per cent, antihistamine
Zephiran® (brand of benzalkonium, as chloride, refined) Cl 1:5000, wetting agent

Available: NTZ Nasal Spray in squeeze bottles of 20 ml.; NTZ Solution in bottles of 1 oz. with dropper.



20 ml. NTZ® N-627
Contains Neo-Synephrine® (brand of phenylephrine, USP) HCl 0.5%. Thenfadil® (brand of thenyldiamine, NF) HCl 0.1%, Zephiran® Cl (brand of benzalkonium Cl, USP) 1:5000 To relieve nasal congestion, spray once or twice into each nostril, with head up, every 3 or 4 hours as needed. See circular.

DECLOSTATIN® 300 b.i.d.

Demethylchlortetracycline HCl 300 mg
and Nystatin 500,000 units
CAPSULE-SHAPED TABLETS Lederle

To guard susceptible patients against intestinal monilial overgrowth during broad-spectrum therapy—the protection of nystatin is combined with demethylchlortetracycline in DECLOSTATIN.

For your susceptible candidates, prescribe DECLOSTATIN—the broad-spectrum therapy that prevents monilial overgrowth.

Contraindication: History of hypersensitivity to demethylchlortetracycline or nystatin.

Warning: In renal impairment, usual doses may lead to excessive accumulation and liver toxicity. Under such conditions, lower than usual doses are indicated, and, if therapy is prolonged, serum level determinations may be advisable. A photodynamic reaction to natural or artificial sunlight has been observed. Small amounts of drug and short exposure may produce an exaggerated sunburn reaction which may range from erythema to severe skin manifestations. In a smaller proportion, photoallergic reactions have been reported. Patients should avoid direct exposure to sunlight and discontinue drug at the first evidence of skin discomfort. Necessary subsequent courses of treatment with tetracyclines should be carefully observed.

Precautions: Overgrowth of nonsusceptible organisms may occur. Constant observation is essential. If new infections appear, appropria measures should be taken.

In infants, increased intracranial pressure with bulging fontanels h been observed. All signs and symptoms have disappeared rapidly up cessation of treatment.

Side Effects: Gastrointestinal system—anorexia, nausea, vomiting, di rhea, stomatitis, glossitis, enterocolitis, pruritus ani. Skin—maculopa ular and erythematous rashes; a rare case of exfoliative dermatitis h been reported. Photosensitivity; onycholysis and discoloration of t nails (rare). Kidney—rise in BUN, apparently dose related. Transie increase in urinary output, sometimes accompanied by thirst (rar Hypersensitivity reactions—urticaria, angioneurotic edema, anaphylax Teeth—dental staining (yellow-brown) in children of mothers given t drug during the latter half of pregnancy, and in children given the dr during the neonatal period, infancy and early childhood. Enamel hy plasia has been seen in a few children. If adverse reaction or idios crasy occurs, discontinue medication and institute appropriate thera Average Adult Daily Dosage: 150 mg q.i.d. or 300 mg b.i.d. Should given 1 hour before or 2 hours after meals, since absorption is impair by the concomitant administration of high calcium content drugs, foo and some dairy products. Treatment of streptococcal infections sho continue for 10 days, even though symptoms have subsided.

GENERAL INFORMATION

Authors

Send manuscripts, subscriptions and communications for consideration to MINNESOTA MEDICINE, 375 Jackson Street, St. Paul, Minnesota 55101. Telephone 222-6366.

Illustrations, photographs, tables, graphs, and pen and ink drawings are encouraged.

All manuscripts will be edited and stylized to conform to the format used in MINNESOTA MEDICINE.

Minnesota Medicine Award

An award will be given at the annual meeting to the author of the most meritorious manuscript for the preceding year.

Readers and Reviewers

The right is reserved to reject material submitted for reading or advertising columns. The views expressed in this journal do not necessarily represent those of the Minnesota State Medical Association or any of its constituents.

President's Letter

116th Annual Meeting

As the time for the 116th Annual Meeting of the Minnesota State Medical Association approaches, it behooves us to reappraise this meeting. Though not as catastrophic, our experience parallels that of the surrounding states—steadily declining interest, with resultant fall-off in registrants and commercial exhibitors (who, up to now, have underwritten a good share of the expenses). This is probably an inevitable trend in that as we multiply our splinter groups, we divide our members' loyalties. Of further concern is the possibility that the Internal Revenue Service will regard exhibitors' fees as income and tax us accordingly.

It has been my very good fortune to have the support of a strong and innovative program committee this year and last. In 1968 they developed the "in depth" concept—in 1969 they have added the multiple roundtables approach. They have essayed to draft a format acceptable to and palatable for all. Your response will help to shape future policy.

Many of our members have stated that the Annual Meeting should be devoted to socio-economic matters, leaving scientific programs to the splinter groups. The Annual Refresher Courses of the Minnesota Academy of General Practice and of the Mayo Clinic have been most successful, and they are unquestionably competitive with our meeting. In addition, each specialty group has one or more scientific sessions annually. Attempts to meld these diverse parts into an acceptable whole have thus far failed.

With mixed feelings, I surrender this post after a somewhat longer than usual tenure. I am grateful for the generous and continuing support of the Council and officers of your Society. Thanks to Dr. Carl Rice, who has accepted and embellished recommended changes in the President's Page. As always, Mr. Harold Brunn has been the invaluable aide-de-camp. Finally, without the stimulation and assistance of Miss Elaine Nye, these visits could not have been so enjoyable for me.

So, we change the guard—join me in a hearty welcome to Dr. Delmar Gillespie, your President soon to be.

Post - Intubation Granuloma of the Larynx

RICHARD A. SCHLORF, M.D.*
ARNDT J. DUVALL, III, M.D.*
Minneapolis, Minnesota

POST-INTUBATION LARYNGEAL GRANULOMAS have been reported to occur in from one in eight hundred[4] to one in twenty thousand[2] intubations. They are most common in women and have not been previously reported in children.[4,5] A granuloma should be suspected when a patient becomes hoarse, suffers ear pain, or has a persistent cough after translaryngeal intubation. The majority are noted by the eighth week postoperatively.[4] The diagnosis can be confirmed by indirect or direct laryngoscopy.

Case Reports

Case 1

A 32-year-old non-smoking male required surgery for regional ileitis on June 7, 1967. He fared well and was extubated in the Recovery Room following a four-hour operation. The postoperative course was not complicated. Several weeks after surgery he noted the onset of hoarseness. His voice became increasingly breathy.

Indirect laryngoscopy in October, 1967, revealed a red, polypoid, pedunculated mass attached to the posterior portion of the left vocal cord. In December, 1967, under methoxyfluorane (Penthrane) anesthesia using the Zeiss operating microscope, the mass was removed. Postoperatively the patient's voice returned to normal.

Case 2

An eleven-year-old female underwent surgery for pulmonary stenosis. She was intubated for nine hours, six in the operating room and three in the recovery room. Because of increasing pneumonitis and dyspnea, a tracheotomy was performed on the fourth postoperative day. Her respiratory status improved and the tracheotomy tube was removed on the eleventh postoperative day. Recovery was swift and she left the hospital on the fifteenth postoperative day. Twenty days after discharge she developed hoarseness which progressed to a breathy voice and inability to speak above a whisper. In November, 1967, indirect laryngoscopy revealed a mass occluding the glottic chink by fifty per cent. Under general (Penthrane) anesthesia, without intubation, a posteriorly attached subglottic cherry-red mass was removed with a laryngeal biopsy forceps without cautery. Postoperatively the patient's voice returned to normal.

---

*Department of Otolaryngology, University of Minnesota Medical School, Minneapolis.

Granuloma of Larynx

There have been numerous reports in the literature on post-intubation granuloma since the first description by R. J. Clausen in 1932.[1] New and Devine[3] pointed out that it shares many common features with the contact ulcer granuloma. The appearance and histology are similar; the etiology and natural history, dissimilar.

Contact Ulcer Granuloma

The contact ulcer was described by Jackson in 1928 as a chronic ulcer most commonly located on the vocal process of one or, commonly, both vocal cords, with or without granulations. It is caused by vocal cord trauma, and its persistence is thought to be due to anatomical and physiological factors.[10] The granuloma has been described[7] as a complication of the contact ulcer, and is characterized by a smooth, discrete, whitish mass on one or both vocal processes. These growths are much more common in men, particularly "voice users," and tend to recur after removal. The attachment varies from sessile to pedunculated.

Post-intubation Granuloma

In contrast, the post-intubation granuloma is that tumor which arises following intubation and is generally located at, or very close to, the vocal process of the arytenoid cartilage. While this is the most common location, it has been reported on the middle and anterior thirds of the cord and on the subglottic surface.[2] The originally reported lesion was subglottic in location.[1] Posterior commissure granulomas are apparently rare.[9] In Case 2 the granuloma was in this position. In less than 50% of cases both cords are involved.[2,4,5] Holinger found the post-intubation granuloma to be located more often inferior and posterior in the hyaline cartilaginous body in close approximation to the vocal process.

In addition, the post-intubation granuloma is generally larger and broader-based, presenting a more polypoid appearance. Over eighty per cent of the lesions have been reported in women. When surgery is necessary for removal, the recurrence rate of the contact ulcer granuloma is considerable higher than for the post-intubation granuloma.

Etiology

Howland and Lewis[4] state that if the head is in a non-neutral position (extended, turned toward the side and extended) the larynx is in a relatively higher plane with regard to the head, forcing the pressure of the tube posteriorly in the glottic chink.

Size of Glottic Opening

Some appreciation is gained for relative size when we note that the outside diameter of the number 32 uncuffed endotracheal tube is 10.7 mm., while the length of the vocal fold is 23 mm. in adult males and 17-18 mm. in

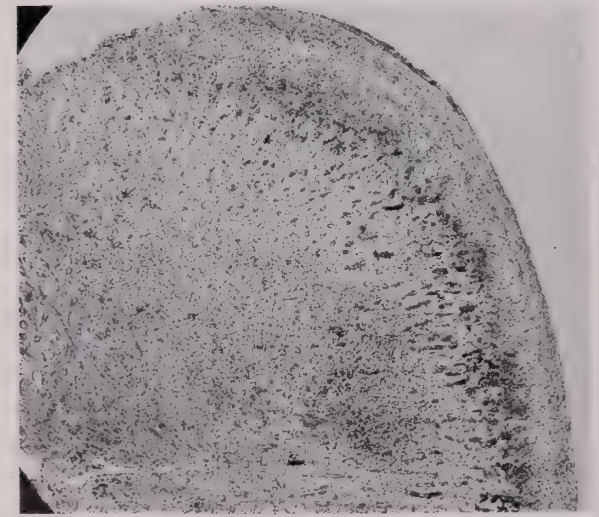

Fig. 1—Granulomatous polyp, Case 1. Fibroblasts, immature collagen fibers and vascular channels with infiltrating polymorphonuclear cells.

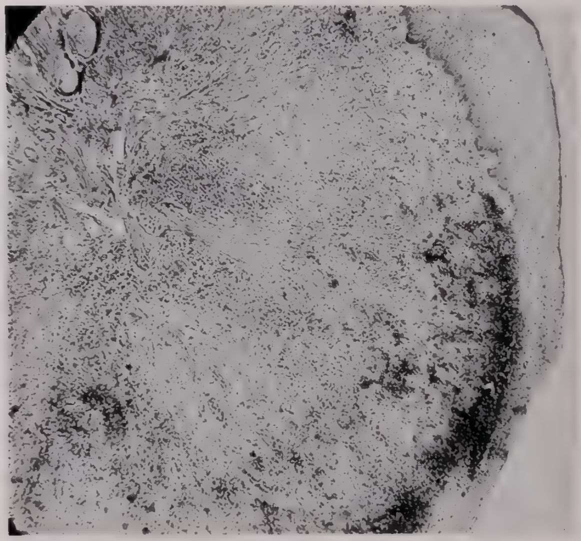

Fig. 2—Case 2. Epithelium partially covers the granulation tissue.

females. The tube can occupy over 50% of the glottic opening in the smaller larynx. The more delicate mucosa of the female larynx probably contributes to its higher incidence; however, the low rate of occurrence in children is not explained by this reasoning. Thyroid operations have been reported to be a major contributor to intubation granulomas, possibly because of the head position required by this operation. Head motion tends to move the tube about in the larynx. A smaller tube may have more freedom to move and thereby cause trauma to the mucosa more easily than a firm-fitting larger tube.

Movement of Larynx

Swallowing movements during light anesthesia increase trauma.[5] The common practice of leaving the endotracheal* tube in place several hours postoperatively while the patient becomes increasingly alert may contribute to mucosal trauma. Prolonged intubation during anesthesia has not increased the incidence of the post-intubation granuloma.[2]

The role of pre-existing infection, allergy, and traumatic intubation is probably secondary to head position in causing granulomas. Applications of antibiotic and steroid medication to the endotracheal tube have not been shown to be of benefit in either decreasing postoperative sore throat or more serious complications.[8] Nor have systemic steroids been found beneficial.

Pathogenesis

These laryngeal tumors are thought to arise from minor, even microscopic, abrasions of the delicate mucosa over the vocal process of the arytenoid cartilage that occur during intubation. The exposed cartilage then becomes infected. This abrasion can be referred to as a "contact ulcer." The ulcer matures to a sessile granuloma as the denuded area becomes covered with granulation tissue in an attempt to cover the exposed cartilage. The lesion becomes an inflammatory polyp, or pyogenic granuloma, through central proliferation. This is generally five to nine millimeters in diameter.[5] If the patient is fortunate, the tumor eventually shrinks as vessels invade it, and organization occurs. Months later these lesions become angiofibromas of the cord and in time may disappear.[6]

Management

The problem of management is complicated by the natural history of the tumor. Early it is characteristically a pyogenic granuloma (chronic non-specific inflammation), greyish in color. In time its size decreases and the color becomes reddish. Later the mass may decrease to an asymptomatic size. Spontaneous auto-amputation has been reported.[1,6]

Rest the Voice

However, the post-intubation granuloma commonly causes troublesome interference with voice production, and difficulty arises when a person depends on his voice for his livelihood. Vocal abuse affects the course of this tumor, and post-intubation voice rest may decrease the incidence. Medical therapy is doomed to fail in a patient unable to cooperate in a program of vocal conservation, hastening the need for surgical intervention. Voice rest after intubation is particularly recommended if signs of laryngeal irritation are present postoperatively.[5]

Surgery

Surgical removal becomes more urgent when the airway is in danger of being obstructed, or when a malignant neoplasm cannot be ruled out. Here excision and pathological study are indicated. In Case 2 the mass was of such a size that any edema in the glottic tissues could easily have caused an airway obstruction.

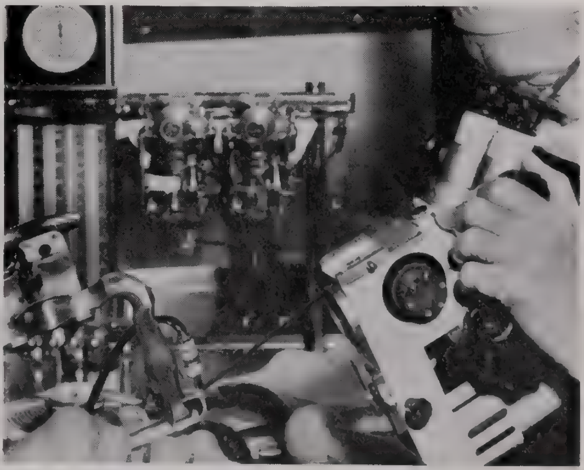

Fig. 3—Posed photograph showing the operating microscope and the laryngoscope in place.

---

*See Test Your Word Score Page 759.

When the treatment becomes surgical, these lesions are easily removed by direct laryngoscopy. Lewy suspension laryngoscopy using the Jako laryngoscope provides good visualization. With the intense light and magnification of the Zeiss operating microscope (Figure 3) it is possible to preserve normal tissue. General anesthesia without intubation is recommended to increase visualization, prevent disruption of the mass, and lessen the possibility of recurrence. Methoxyfluorane (Penthrane) has proved valuable because of the prolonged anesthesia possible without an endotracheal tube. Its slow induction and long recovery time are offset by the adequate anesthesia and the relaxation, as well as the exposure gained without the indwelling tube. Postoperative discomfort is minimal and discharge is possible the next day. Voice rest is useful to insure healing.

Removal would best be accomplished in the pedunculated stage after a trial of voice rest and antibiotics. As many as 50% are thought to disappear spontaneously or with medical treatment, including speech therapy. Early removal of a sessile, vascular granuloma has been shown to predispose to recurrence.

Summary

The uncommon occurrence of post-intubation granuloma would suggest that direct visualization, proper-fitting tubes, muscle relaxants, static head positions, and atraumatic intubations are worthwhile. General anesthesia and the operating microscope are recommended for accurate surgical removal, after a trial of medical treatment.

School of Salernum

Humoral Types

Foure humors raigne within our bodies wholly,
And these compared to foure Elements,
The Sanguine, Choler, Flegme, and Melancholy,
The latter two are heavie, dull of sence,
Th'other two are more Iovial, quicke and Iolly.
And may be likened thus without offence,
Like ayre both warme and moist, is Sanguine cleare.
Like fire doth Choler hot and drie appeare.
Like water cold and moist is Flegmatique,
The Melancholy cold, drie earth is like.

—**Regimen Sanitatis Salerni**

Editor's note: The school classifies men into four types, each type combining in its nature two of the four universal elements: fire, air, water, earth. Thus the sanguine type is warm and moist (fire and air); the choleric type is warm and dry (fire and earth); the flegmatic type is cold and moist (water and air); and the melancholy type is cold and dry (water and earth).

Hepatitis in Infectious Mononucleosis*

GEORGE KITZMILLER, M.D.†
Minneapolis, Minnesota

INFECTIOUS MONONUCLEOSIS commonly causes biochemical evidence of liver involvement[1-7]. There is often histologic evidence of a hepatitis[8,9]. Persistent abnormalities in liver function tests have been noted[10], and cirrhosis following infectious mononucleosis has been reported[11]. This monograph concerns serial serum glutamic-oxalacetic acid transaminase, alkaline phosphatase, and total bilirubin determinations in a group of patients with infectious mononucleosis, to correlate the liver function abnormalities with the clinical course and to note the duration of the abnormalities.

Materials and Methods

Seventy-five cases of infectious mononucleosis from the Naval Hospital, San Diego, California, from October, 1967, to June, 1968, compose the study group. All patients were hospitalized until their symptoms, fever, and splenomegaly subsided, and the serum glutamic-oxalacetic acid transaminase returned to normal. There were 74 males and one female, and their ages ranged from 16 to 30 years. Seventy-six per cent complained of a sore throat; 67%, of malaise; none was asymptomatic. Forty-four per cent had an exudative pharyngitis; 82%, posterior cervical lymphadenopathy; 48%, splenomegaly, and 70%, an oral temperature greater than 100 degrees F. Ninety-four per cent had more than 50% mononuclear forms in their peripheral blood smear and 94% had heterophile titers greater than 1:28 after guinea pig kidney absorption[12]. Serum glutamic-oxalacetic acid transaminase, alkaline phosphatase, and total bilirubin determinations were made at weekly intervals. All determinations were made using the 12-channel Technicon Auto-Analyzer, and the values were considered abnormal if the serum glutamic-oxalacetic acid transaminase exceeded 55 Karmen Units/100 ml, the alkaline phosphatase exceeded 18 King Armstrong Units/100 ml, or the total bilirubin exceeded 1.2 mg/100 ml. Maximal elevations while under observation are reported.

---

*Work done at Naval Hospital San Diego, California.

†Director, Gastroenterology Division, Department of Internal Medicine, Hennepin County General Hospital, Minneapolis.

Results

Incidence and Degree of Hepatic Dysfunction

Seventeen patients had hyperbilirubinemia. All of these had elevated serum glutamic-oxalacetic acid transaminase values, and 13 had associated elevated alkaline phosphatase values (Table 1). Twenty-one patients had elevated serum glutamic-oxalacetic acid transaminase and alkaline phosphatase values with normal total bilirubin values (Table 2), and 23 had elevated serum glutamic-oxalacetic acid transaminase values only (Table 3). Only one patient had an elevated alkaline phosphatase value with normal serum glutamic-oxalacetic acid transaminase and total bilirubin values. Thirteen patients had no evidence of hepatic dysfunction noted by these studies (Table 4).

**+ indicates those cases where a heterophil titer was not done, but which had a positive slide test for infectious mononucleosis.

Correlation with the Clinical Course

When patients who had no evidence of hepatic dysfunction were compared with those who had hyperbilirubinemia, there was no difference in the length of the prodromal* period or the degree of lymphadenopathy or splenomegaly. The patients with hyperbilirubinemia, however, had a more severe clinical illness. They were febrile for an average of five days, and those without hepatic dysfunction for an average of two days. Prednisone was used to relieve severe toxic symptoms of fever, prostration, and inability to take nourishment. Twelve patients had symptoms this severe, and all of these had biochemical evidence of hepatic dysfunction. None of those without evidence of hepatic dysfunction required this treatment.

Duration of Hepatic Dysfunction

The serum glutamic-oxalacetic acid transaminase and total bilirubin returned to normal in most cases within two weeks; and no patients had abnormalities of these values beyond five weeks after their hospital admission. The alkaline phosphatase had not returned to normal in six cases prior to discharge. There were no cases of relapse or chronic hepatitis in this series.

Discussion

Infectious mononucleosis produced hepatitis in 83% of the patients in this series; the degree of hepatic dysfunction appears to correlate with the severity of the clinical illness. The results of this series are compared in Table 5 with those previously reported. These data indicate that, excluding the bromsulphalein excretion test, the serum glutamic-oxalacetic acid transaminase is the most sensitive indicator of hepatic involvement; and that the abnormalities of the alkaline phosphatase and total bilirubin, when they occur, are associated with serum glutamic-oxalacetic acid transaminase elevations. The hyperbilirubinemia receded promptly in those cases with elevations. The serum glutamic-oxalacetic acid transaminase returned to normal in most cases within two weeks after hospital admission; none were abnormal five weeks following hospitalization. There were no fatalities.

*The numbers indicate the number of cases that had abnormalities; the numbers in parentheses indicate the total number of cases in which the test was performed.

Infectious mononucleosis causes some degree of fatty change and a mononuclear round-cell infiltration of the lobular sinusoids of the liver. There is some cellular necrosis, but widespread parenchymal cell damage, loss of lobular architecture, and stromal collapse have not been noted.[8,9] None of the seventy-five patients had liver biopsies.

Persistent abnormalities of the thymol turbidity and cephalin-cholesterol flocculation tests and bromsulphalein excretion have been noted on occasion[10], but conclusive evidence of a chronic active hepatitis following infectious mononucleosis has not been reported. From this series in which patients were confined to a hospital ward and treated symptomatically, it appears that the hepatitis is of a benign nature. Most patients showed a prompt resolution of their symptoms and hepatic dysfunction within two weeks. When they were discharged from the ward, complaints of asthenia were not significant. Since most patients were symptomatic for no more than two weeks prior to hospitalization, the clinically significant disease process is over within one month in most cases.

Summary

Seventy-five consecutive cases of infectious mononucleosis, studied for liver involvement, revealed that 83 per cent had evidence of hepatitis. The degree of involvement appeared to correlate with the severity of the clinical illness. The hepatitis appeared to be benign and resolved within one month after the onset of the illness in most cases. No cases of chronic hepatitis developed. The serum glutamic-oxalacetic acid transaminase was the most sensitive indicator of hepatitis.

The Frontier Granny

The fountainhead of folk medicine on the westering frontier was the granny, who grew in reputation with each wrinkle on her face as well as each cure she effected. Elderly Dr. R. T. Whiteman of Cambridge, Idaho, found the granny still practicing in his town when he was a young physician.

"Many a granny has used a mold scraped from cheese as an application to open sores," Dr. Whiteman told me. "She got results, but she didn't know why. Today we derive penicillin from a certain type of mold. Some grannies applied wet tea leaves to a fresh burn, but modern medicine has substituted tannic acid solution which is the active principle of tea leaves."*

Propranolol in Angina Pectoris

JOHN H. BRINKMAN, M.D.*
CARL S. ALEXANDER, M.D., Ph.D.*
Minneapolis, Minnesota

Propranolol (Inderal®), a beta-adrenergic blocking agent, has been found to be effective in the treatment of angina pectoris.[1,2,3,4] Since January 1968, six patients with intractable angina have been referred to this institution for consideration of bilateral internal mammary artery implantation. Before such a decision was made each patient was given a trial of propranolol and each had a favorable result. It is the purpose of this paper to review our experience with the use of propranolol in angina pectoris, to discuss the physiology of the drug, to review the current therapy for angina pectoris, and to report three deaths with the use of intravenous propranolol (Table).

Case Reports

Case 1

This 51-year-old male was admitted to the Veterans Hospital with a three-year history of recurrent angina on exertion and at rest, currently refractive to nitroglycerin and long-acting nitrates.

Examination

B.P. 124/90, cholesterol 388, FBS 106; electrocardiogram showed nonspecific ST-T changes; cardiac cine revealed left coronary artery calcification with left ventricular enlargement.

Course

Following propranolol 160 mg/D the patient demonstrated a decrease in nitroglycerin requirement, an increase in exercise tolerance and in a sense of well being. Duration of follow-up has been four months.

Case 2

This 42-year-old male was admitted to the Veterans Hospital with a 10-month history of angina on exertion and at rest currently—refractive to nitroglycerin.

Examination

B.P. 135/80, cholesterol 254, FBS 92; electrocardiogram showed T wave changes of ischemia; cardiac cine revealed left and right coronary artery calcification.

Course

Following propranolol 80 mg/D this patient, who had previously been diagnosed as type IV Fredrickson's hyperlipoproteinemia, demonstrated a decrease in nitroglycerin requirement, an increase in exercise tolerance and in a sense of well being. Duration of follow-up has been one month.

---

*From the Department of Medicine, University of Minnesota and the Cardiology Section, Minneapolis Veterans Administration Hospital, Minneapolis, Minnesota.

Case 3

This 59-year-old male was admitted to the Veterans Hospital with an eight-year history of angina on exertion and at rest. A past history of three documented myocardial infarctions was obtained.

Examination

B.P. 110/70, cholesterol 393, FBS 97; electrocardiogram showed evidence of old inferior infarction and nonspecific ST-T changes; cardiac cine revealed left coronary artery calcification.

Course

Following propranolol 120 mg/D the patient demonstrated a decrease in nitroglycerin requirement, an increase in exercise tolerance, an improvement in the electrocardiogram, and an increased sense of well being. Duration of follow-up has been three months.

Case 4

This 77-year-old male was admitted to the Veterans Hospital with a three-month history of angina on exertion and at rest not improved by nitroglycerin.

Examination

B.P. 170/70, cholesterol 207, FBS 85; electrocardiogram showed PVC's and nonspecific ST-T changes; cardiac cine revealed left coronary artery calcification.

Course

Following propranolol 80 mg/D the patient demonstrated a decrease in nitroglycerin requirement, an increase in exercise tolerance, an improvement in the electrocardiogram, and an increased sense of well being. Duration of follow-up has been one month.

Case 5

This 59-year-old male was admitted to the Veterans Hospital with a three-month history of angina on exertion and at rest not improved with nitroglycerin.

Examination

B.P. 130/70, cholesterol 276, FBS 141, (abnormal G.T.T.), electrocardiogram showed ST-T changes compatible with subendocardiac ischemia; cardiac cine revealed left coronary artery calcification and left ventricular enlargement.

Course

Following propranolol 120 mg/D the patient demonstrated a decrease in nitroglycerin requirement, an increase in exercise tolerance, an improvement in electrocardiogram, and an increased sense of well being. Duration of follow-up has been three months.

Case 6

This 77-year-old male was admitted to the Veterans Hospital with a three-year history of angina on exertion and at rest not controlled by nitroglycerin or improved by long-acting nitrates.

Examination

B.P. 140/76, cholesterol 330, FBS 165 (diabetic, 1965); electrocardiogram showed nonspecific ST-T changes; cardiac cine revealed left coronary artery calcification.

Course

Following propranolol 120 mg/D there was a decrease in nitroglycerin requirement, an increase in exercise tolerance, and an increased sense of well being. Duration of follow-up has been one month.

Our therapeutic approach to the treatment of intractable angina pectoris with propranolol is to begin with 40 mg/day in four divided doses, increasing every three days by 40 mg until 280 mg/day has been attained. If at this level the patient has not demonstrated improvement he is considered a therapeutic failure and consideration is then given for internal mammary artery implantation for control of angina pectoris.

Discussion

In 1964 propranolol, a beta-adrenergic* agent, was released for clinical investigation.[5,6] A related compound, pronetholol was removed from investigative use after it was shown to produce thymic tumor in mice in 1962.

Physiology

The beta-adrenergic receptors in the myocardium mediate the positive ionotropic effects of the sympathetic nervous system and circulating catecholamines, their main response being to stimulate heart rate and contractility. Besides these actions the sympathetic nervous system has effects on vascular and visceral smooth muscle and on the metabolism of fat and carbohydrate. The two principal mediators of sympathetic nerve stimulation are noradrenaline released from the sympathetic nerve endings and epinephrine released from the adrenal medulla. Beta receptors are inhibitory to bronchial muscle and to vascular tone in skeletal muscle but stimulate the heart, resulting in an increased rate, accelerated A-V conduction, and improved contractility. Beta adrenergic blockade by propranolol causes a reduction in heart rate at rest, after exercise, and following excitement, accompanied by a fall in cardiac output and myocardial oxygen consumption.[7,8] Alpha-adrenergic receptors mediate stimulator response, notably vasoconstriction in skin, kidney and other viscera, and dilatation of the pupil. An alpha-adrenergic blocker (phentolamine) occupies the receptor site and prevents the action of natural or synthetic amines at that site, as in the treatment for pheochromocytoma.

Review of Literature

Wolfson[9] found 30 of 37 patients with angina pectoris improved while on propranolol as judged by an increase in exercise tolerance, at least a 50% decrease in the number of anginal episodes, complete cessation of pain from nocturnal and post-prandial angina and a reduction of at least 50% in the number of nitroglycerin tablets needed to relieve pain. The patients were followed from six to 15 months.

Furberg[10] studied 14 patients for a period of two weeks, nine of whom were considered improved, requiring less nitroglycerin, and showing increased exercise tolerance.

In a double-blind crossover study involving 49 patients, Grant[11] found that propranolol in doses up to 240 mg/day relieved angina pectoris.

Gianelly,[12] also in a double blind study, found that propranolol produced clinical improvement in 15 of 19 patients with angina pectoris, as manifested by a reduction in the number of pain episodes, decreased nitroglycerin consump-

*Fredrickson Type IV

tion, and increased exercise tolerance as measured by a treadmill test. The amount of work necessary to produce ischemic ST depression was not consistently increased. The most striking physiologic effect of propranolol was a decrease in heart rate both at rest and on exercise. Blood pressure on exercise also fell.

Frieden,[13] in a review of 200 cases of angina pectoris treated with propranolol, reported general improvement in over half of the subjects when adequate dosages were used. Less benefit was noted when the dose was less than 120 mg/day.

Hebb[14] conducted a double-blind study of propranolol in the prophylactic treatment of angina pectoris. Patients received either a placebo or propranolol for four weeks. The dose of propranolol was 40 mg/day for the first week, 80 mg/day for the second week, and 160 mg/day for the third and fourth weeks. No significant reduction in the attack rate occurred at the 40-mg/day dose, but with 80 mg/day the reduction was significant ($p < .05$), and at 160 mg/day it was very significant ($p < .001$).

Combination Therapy

The rationale for combining propranolol with the nitrates rests on the belief that nitrates increase oxygen supply to ischemic myocardium, while propranolol, by decreasing heart rate and ventricular systolic force, appears to reduce myocardial oxygen requirements to a level more readily satisfied by restricted coronary flow.

Russek[15] studied 12 patients with exertional angina of at least two years' duration with placebo, isosorbide dinitrate (Isordil®), propranolol and the combination of Isordil and propranolol. In the standard exercise test, Isordil prevented the onset of pain in four of 12 patients and diminished its severity in seven. Propranolol (40 mg) prevented its onset in three and diminished its severity in nine. Combined therapy prevented all 12 patients from experiencing any discomfort as a result of exercise. Prior to exercise the heart rate after propranolol was 20% below that of placebo, but with Isordil 12% faster. The reduction in maximal heart rate with exercise averaged 25 beats per minute with propranolol alone or in combination with Isordil. In all 12 patients the greatest ST-T depression followed administration of placebo. The average increase in exercise tolerance with propranolol or Isordil alone was 24%, whereas with combination therapy it averaged 76%. All patients were followed for two months with striking relief of symptoms. A second paper by Russek[16] added an additional 16 patients who were followed for six months without evidence of tolerance or escape from the medication.

Side effects from propranolol are uncommon. Death was associated with propranolol administration in 26 of 5000 cases.[17] In only three of the 26 deaths was propranolol suspected as a contributing factor. Since the intravenous form of propranolol became available in our hospital we have experienced three deaths after 5 mg was given for arrhythmia. Two of the patients were in chronic heart failure and shortly after the intravenous administration became hypotensive and refractory to the usual vasopressors even in very large doses (metaraminal (Aramine®)) 200 mg in 500 cc D5W and levarterenol bitartrate (Levophed®) 12 mg in 500 cc D5W. This is not surprising since Aramine is a false transmitter, acting to release noradrenalin at the receptor site now blocked by propranolol. The third patient had a significant element of bronchospasm prior to the administration of the drug. Following the intravenous administration he developed acute bronchospasm which did not respond to conventional therapy.

In those patients in whom heroic measures may be justified, we currently recommend intravenous propranolol 1-2 mg given slowly for control of cardiac arrhythmia.

Early reports of BUN and SGOT elevation have not been confirmed and cases of bone marrow depression have been unusual. Hypotension has been uncommon except in those patients with congestive heart failure. Other investigators have reported protracted hypoglycemia in patients receiving a combination of propranolol and sulfonoureas.

Propranolol is contraindicated in heart block, congestive heart failure, asthma, chronic obstructive lung disease and in patients receiving monoamine oxidase inhibitors.

Summary

Six patients have been described who have responded to propranolol for control of angina pectoris and have thus escaped a surgical procedure with significant morbidity and mortality.

Three other patients have been presented who died shortly after the administration of IV propranolol (5 mg) for control of a cardiac arrhythmia. It is suggested that alternate methods should be utilized for control of arrhythmia in patients with congestive heart failure or hypotension.

On Posture

It is well when the patient is found by his physician reclining upon either his right or his left side, having his hands, neck, and legs slightly bent, and the whole body lying in a relaxed state, for thus the most of persons in health recline, and these are the best of postures which most resemble those of healthy persons. But to lie upon one's back, with the hands, neck, and the legs extended, is far less favorable. And if the patient incline forward, and sink down to the foot of the bed, it is a still more dangerous symptom; but if he be found with his feet naked and not sufficiently warm, and the hands, neck, and legs tossed about in a disorderly manner and naked, it is bad, for it indicates aberration of intellect. It is a deadly symptom, also, when the patient sleeps constantly with his mouth open, having his legs strongly bent and plaited together, while he lies upon his back; and to lie upon one's belly, when not habitual to the patient to sleep thus while in good health, indicates delirium, or pain in the abdominal regions.

And for the patient to wish to sit erect at the acme of a disease is a bad symptom in all acute diseases, but particularly so in pneumonia. To grind the teeth in fevers, when such has not been the custom of the patient from childhood, indicates madness and death, both which dangers are to be announced beforehand as likely to happen; and if a person in delirium do this it is a very deadly symptom.*

Julius Wagner-Jauregg

For his discovery of the therapeutic value of
malaria inoculation in the treatment of dementia paralytica

"Progressive paralysis has always been considered an incurable disease, leading in the course of a few years to dementia and death.

"Nevertheless there was on record a series of cases of progressive paralysis which had been cured; cases in which all the symptoms had disappeared so completely as to permit those affected to be independently active for years, in life and employment.

"The observation was now forthcoming that in the rare cases of healing and in the frequent remissions of progressive paralysis, a febrile infectious malady or a protracted suppuration often preceded the improvement in the state of the disease.

"Therein lay a hint. These cures following febrile infectious diseases, of which I myself had witnessed striking cases, induced me as early as the year 1887 to propose that this natural experiment be imitated by deliberately producing infectious diseases, and at that time I named malaria and erysipelas as suitable diseases. As a particular advantage of malaria, I stressed the fact that it is possible to interrupt the disease at will with quinine, and did not yet suspect at that time to what extent the expectation would be fulfilled through inoculation with malaria.

"Instead, starting in 1890, I attempted to imitate the action of a febrile infectious disease by the use of tuberculin, just introduced by Koch, at first not only in progressive paralysis but also in other mental derangements, and as a matter of fact with favorable results in not a few cases.

"After it had been established that the paralytics treated with tuberculin showed more, and more lasting, remissions than an equal number of untreated paralytics, this treatment was carried out systematically . . . and at the same time an energetic iodine-mercury cure, later combined with injections of salvarsan, was instituted.

"The remissions which were obtained by the mercury-tuberculin treatment did not differ qualitatively from those to be obtained by inoculation with malaria. . . . But the number of relapses was large; the lasting remissions were in the minority.

"Consequently, in 1917, I set about the execution of the proposal I had made in the year 1887, and inoculated nine cases of progressive paralysis with tertian malaria.

"The result was gratifying beyond expectation: six of these nine cases obtained extensive remissions, and in three of these cases the remission proved lasting, so that this year (1927) I was able to present these cases as having carried on their occupations without interruption for ten years."*

Wagner-Jauregg appears to have contemplated the use of malaria in treating paretic dementia for many years, and when, in 1917, a patient with tertian malaria appeared in one of his wards he considered this as a sign of fate and proceeded to carry out his plan.†

Vaginal Hormonal Cytology

OSCAR LITWAK, M.D.*
ELIZABETH MUSSEY, M.D.†
Rochester, Minnesota

THE VAGINAL EPITHELIUM is characterized by great sensitivity to the constant interplay of the hormones produced in health or disease. An analysis of the cellular patterns of exfoliated vaginal cells offers the clinician an opportunity for greater understanding of a woman's endocrine status.

Historical

Pouchet, as early as 1847 in his book *Ovulation and Other Related Phenomena,* gave one of the first descriptions of vaginal smears. Although he had no staining technique to aid him, he was able to recognize a rhythmic change in the vaginal smears.[1] By 1917, Stockard and Papanicolaou[2] described the periodic changes of the constituents of the vaginal smear in the guinea pig, stimulating an interest in study of these changes in the lower animals.

Dierks,[3] studying specimens of vaginal epithelium taken for biopsy, offered the first definite proof of the susceptibility of the epithelium to ovarian secretions. He demonstrated the proliferation of vaginal epithelium in oophorectomized women after the injection of "follicular hormone."

In 1933 Papanicolaou[1] described the staining technique which now bears his name. He presented an analysis of 1,022 vaginal smears obtained from 12 normal menstruating females and 16 patients who had been operated upon for different reasons. In his analysis, a correlation was noted between cytology changes and time of cycle or ovarian status at the time of operation.[1]

Collection of the Smear

A well-prepared smear should be spread neither too thick nor too thin, fixed rapidly and stained correctly,[4] since the diagnostic possibilities depend on the quality of the smear.

Several sites in the vagina have been proposed as ideal for obtaining smears for hormonal evaluation.[5,6] Even study of the urine sediment has been suggested as a method for evaluation of the hormonal status of the patient.

---

*Mayo Graduate School of Medicine (University of Minnesota), Rochester: Resident in Obstetrics and Gynecology.

†Mayo Clinic and Mayo Foundation: Section of Obstetrics and Gynecology.

The upper third part of the lateral vaginal wall provides the freshest and most satisfactory material for the procedure.[5-8] The sample should be obtained with the help of a dry speculum to avoid contamination of the specimen by vulvar and cervical secretions.[9] A cervical smear for detection of malignant cells may be taken at the same time, when indicated. The cervical smear should be taken after the vaginal sample has been obtained, so as not to contaminate the hormonal smear with cervical elements. A wooden spatula is used to scrape the vagina lightly; the material thus obtained is spread on a glass slide which is deposited in a fixative solution containing equal parts of alcohol and ether, or 95% alcohol.[10]

Staining of the Smear

Since Papanicolaou's classical description of his staining technique, several others have been developed,[11,12] most of them with the objective of improving the rapidity of the technique and the color reactions which serve to distinguish the basophilic and eosinophilic cells.

A supravital* technique has been recommended by Rakoff[11] as a rapid stain for office use:

a. Obtain a sample from the vaginal wall with a cotton-tip applicator, preferably dipped previously in a container of 2 cc of isotonic solution of sodium chloride.

b. Drop the applicator into a container of sodium chloride.

c. Add 3 drops of a staining fluid composed of 83 cc of light green 5% aqueous solution and 17 cc of eosin (1% aqueous solution).

d. Agitate the cotton swab in the solution, transfer a drop of the solution to a glass slide and examine under the microscope.

Disadvantages of this supravital technique are the instability of the solution, requiring frequent reconstitution, and the impossibility of keeping the slides for permanent record.

Elements Found in a Normal Smear

Under physiologic conditions smears may contain three different types of cells which correspond to cells in the three layers of the vaginal mucosa.

Parabasal Cells

These are the least mature cells found in a smear. They are small, round and basophilic, with a vesicular nucleus which occupies more than a third of the diameter of a cell. They resemble cervical cells, from which they must be distinguished. Parabasal cells are found in association with absence of estrogens, postmenopausal states, hypopituitarism, postpartum states, and in severe vaginal infection or trauma.

Intermediate Cells

These cells originate from the intermediate layer of the vaginal epithelium and are larger than parabasal cells. They are basophilic polygonal cells, with a thin, vacuolized cytoplasm and a vesicular nucleus. The presence of intermediate cells in the smear is determined by the presence of progesterone. Thus they are characteristic of the luteal phase of the cycle and of the smear obtained during pregnancy. They can be found under the influence of androgenic hormones.

Superficial Cells

These are the largest and most mature cells seen in a vaginal smear. They are polyhedral and flat, with a pyknotic nucleus, and stain red with a polychromatic stain. The appearance of superficial cells is titrated by the unopposed action of estrogens.

Other elements which can be found in vaginal smears include cervical and endometrial cells, *Candida albicans and Trichomonas vaginalis.*

Interpretation of Cytologic Results

Several indices based on this procedure may be of assistance in the determination of the hormonal status. Of these, three will be described.

Karyopyknotic Index

The karyopyknotic index refers to determination of the percentage of cells which have a pyknotic nucleus: that is, a nucleus which measures less than 6 micra, without an identifiable chromatin pattern. This is a reliable index because nonhormonal factors have little effect upon it.

---

*See Test Your Word Score Page 759.

Eosinophilic Index

The eosinophilic index is the percentage of eosinophilic cells counted from a least 200 superficial cells. Since pseudoeosinophilia may be produced by vaginal infections, drying of the slide, or prolapse of the vagina, this index is useful only when it parallels the karyopyknotic index.

Maturation Index

This index involves the estimation of the percentage of each of the three types of exfoliated cells found. It is reported by three numbers which correspond from left to right to the parabasal, intermediate and superficial cells.

Normal Menstrual Cycle

The presence of erythrocytes, leukocytes, intermediate and superficial cells exemplify the menstrual phase of a normal menstrual cycle. The normal karyopyknotic index is then between 20 and 50%, the eosinophilic index 5 to 20%, and the maturation index 0/70/30.

Preovulatory Phase

Isolated superficial cells with a clean background free of Döderlein bacilli are typical of a high estrogenic effect. It comes about gradually, the intermediate cells being replaced by superficial ones having a higher number of pyknotic nuclei. The indices representative of this preovulatory phase are: eosinophilic index 70%, karyopyknotic index 70 to 85%, maturation index 0/20/80.

Detection of Ovulation

Ovulation may be detected as early as six hours after it has occurred by noting the decrease of the eosinophilic index and the karyopyknotic index. This means obtaining two or three smears daily from the patient, especially in the preovulatory interval.

Progesterone Effect

The changes caused by progesterone, representing the secretory phase of the cycle, become definite 48 hours after ovulation. The typical smear obtained at that time exhibits a predominance of intermediate cells which tend to group themselves in clusters. There is a reappearance of leukocytes and Döderlein bacilli as well as large amounts of cellular detritus which give to the slide a "dirty background." Eosinophilic cells with pyknotic nuclei become scarce and isolated. The indices are eosinophilic index 15%, karyopyknotic index 30% and maturation index 0/70/30.

It is of practical interest to report the findings of the Gillespies'[13] study of 300 vaginal smears. A correlation was established between the maturation index estimated by a cytotechnician and that estimated by the attending obstetrician after a superficial scanning of the smear. The difference between the two estimates was in the range of 10%.

Clinical Syndromes

Climacteric

The term "climacteric" corresponds to the transition period of ovarian decline during which the menstrual periods cease and the characteristic vasomotor changes, nervousness and so on, appear.[14]

De Neef[4] described three types of smears that can be obtained in women near the menopause. Others[15,16] have written that there is no smear pathognomonic of this state. Smears range from those disclosing advanced atrophy, in which only parabasal cells are found (maturation index 80/20/0), to those exhibiting hyperestrogenic changes (maturation index 0/20/80). Peters[17] obtained smears reflecting estrogenic changes from 53% of women younger than 55 years, and similar smears from 37% of patients older than 55 years. However, the possible presence of an estrogen-producing ovarian tumor, such as the granulosa-cell tumor, should always be kept in mind when a smear suggestive of estrogenic effect is seen. The ingestion of digitalis preparations is another mechanism by which a smear connoting estrogen production may be obtained in the postmenopausal woman.

Estrogen Therapy

Much has been written in the lay press about the use of hormonal colpocytology* to regulate the administration of exogenous estrogens. A decision to use sedation as the basic treatment of a patient complaining of hot flashes may follow the finding of estrogenic effects in her smear. On the other hand, the association of climacteric complaints and a smear which reflects vaginal atrophy is of value to the clinician as an indication for therapy with estrogen. Gaudefroy,[16] studying the effects of varying doses of different estrogens, concluded that therapeutic doses produce proliferation with karyopyknosis of the superficial cells. This raises the karyopyknotic index to 90% as early as 48 hours after the first dose. A karyopyknotic index higher than 70% should not be sought, because vaginal bleeding frequently occurs when the index exceeds that figure.[4]

---

*See Test Your Word Score Page 759.

Menstrual Disorders

Smears typical of atrophy in patients who have primary amenorrhea point to a pituitary lesion, Turner's syndrome or other causes of which the lack of estrogen production is a major sign. Detection of a cyclical estrogen-progesterone effect in the smears from these patients indicates the integrity of the pituitary-ovarian axis. Such a finding would mean that the diagnosis of unresponsiveness of the endometrium or congenital absence of the uterus might be entertained.

Pregnancy

Although advocates of hormonal colpocytology say that the procedure permits the diagnosis of pregnancy shortly after conception has occurred, most authors agree that a typical pregnancy smear cannot be obtained until after the first trimester of gestation.[18,19] To quote Von Haam's[9] opinion of the procedure thus employed: "The diagnosis of pregnancy by the vaginal smear method is feasible but impractical since quicker and more reliable methods are available."

Threatened Abortion

During pregnancy the smears will reveal the increase of progesterone by showing increasing numbers of glycogen-rich intermediate cells which have a characteristic navicular form, clear cytoplasm, heavy outline and a round, vesicular nucleus. The number of these cells increases greatly after the fourth month of pregnancy, while the number of superficial cells decreases substantially. The representative indices are not higher than 15% (eosinophilic index) or 20% (karyopyknotic index). The maturation index is 0/80/20. A change from a normal pregnancy smear to a smear suggestive of estrogenic influence has been considered a prelude of abortion.[20]

Pundel,[21] studying 3,800 pregnant women, found 407 from whom vaginal smears reflecting abnormalities were obtained; 117 of these women had no clinical evidence of threatened abortion. All 117 patients were offered hormonal therapy on the basis of studies of the smears alone; 28 refused it. The outcome of the pregnancies was revealing: of the 28 untreated patients 14 aborted (50%); of the 89 treated patients only 21 aborted (22%). On the other hand, Pundel reported that normal term pregnancies ensued for 99.41% of 3,393 pregnant women in whom cytologic studies yielded normal results.

Placental Nonfunction

Knowledge that estrogens administered during a pregnancy in which the fetus is viable do not produce maturation of the vaginal mucosa, thereby failing to increase the eosinophilic index and karyopyknotic index, has led to the development of a sensitive test for determination of the death in utero of a fetus. An increase in the eosinophilic and karyopyknotic indices is a sign of placental nonfunction. This same principle can be employed in the differential diagnosis between imminent menopause and pregnancy in a patient with amenorrhea.

Ruptured Membrane

The finding of anucleated squamous cells in a smear from a pregnant patient in whom uterine prolapse or leukoplakia of the cervix has been ruled out is positive evidence of rupture of the membranes. Use of the hormonal colpocytologic procedure to determine term pregnancies,[22] to predict labor[23] and to predict the sex of the infant is of equivocal value and is simply mentioned here.

Hormonal Cytologic Studies in Children

Under the influence of the maternal hormones, the vaginal epithelium of the newborn has a thick and well-developed intermediate layer which is lost a few days after birth. It remains as a thin layer of basal cells until shortly before the onset of puberty.

The local or systemic administration of estrogens, frequently employed in the treatment of vaginitis in children, is often the reason for vaginal smears in the prepuberal female to show features reflecting stimulation by estrogen. Other causes for this activity reflected in smears include sexual precocity, feminizing tumors of the ovary and conditions of stress.

Summary

The known sensitivity of the vaginal epithelium to the effects of hormonal activity in the presence of both health and disease constitutes a source of some diagnostic value to the clinician when it is studied and appraised by means of analysis of the cellular patterns of exfoliated vaginal cells. The procedure is uncomplicated, inexpensive and reliable. Those conditions in which the procedure will give significant results, as well as those in which it is of only theoretical or doubtful value, have been reviewed briefly here.

On Sleep

With regard to sleep—as is usual with us in health, the patient should wake during the day and sleep during the night. If this rule be anywise altered it is so far worse: but there will be little harm provided he sleep in the morning for the third part of the day; such sleep as takes place after this time is more unfavourable: but the worst of all is to get no sleep either night or day; for it follows from this symptom that the insomnolency is connected with sorrow and pains, or that he is about to become delirious.*

Don't relive bad moments or review them for others.—Marianne Moore

A Patriarch's Ordeal

Poor Job! None the less to be commiserated with whether his afflictions were malevolent visitations or psychosomatic manifestations of utter despair!

A catalogue of his woes is horrendous—not so much in severity as in obduracy. The milieu for his trial was set by two personal calamities: first, his oxen, asses and camels were caused to be stolen (the word "caused" is here used advisedly); and second, his servants and sons were killed off. At this nadir of destitution and bereavement Job's harrowing physical and psychical ordeal began.

First came boils! One boil would be bad enough, but Job was literally covered "from the sole of his foot unto his crown." With no doctor at hand, he dealt with the boils himself by scraping them with a potsherd (a shard of broken pot)—a procedure that hardly sounds therapeutic and must have aggravated rather than alleviated the acute discomfort.

Following the boils came hallucinations: "Then a spirit passed before my face; the hair of my flesh stood up: It stood still, but I could not discern the form thereof: an image was before mine eyes."

Then insomnia and nightmares ensued: "I am full of tossings to and fro unto the dawning of the day. Then thou scarest me with dreams."

These were succeeded by more skin disorders: "My flesh is clothed with worms; my skin is broken and become loathsome."

Then, as if he had not undergone sufficient suffering and humiliation, his wounds were exacerbated and he had trouble breathing: "For he breaketh me with a tempest, and multiplieth my wounds without cause. He will not suffer me to take my breath."

Next, to add insult to injury, he developed wrinkles: "And thou hast filled me with wrinkles, which is a witness against me: and my leanness rising up in me beareth witness to my face."

A sequence of shocking assaults next descended upon him: "He hath broken me asunder: he hath also taken me by the neck, and shaken me to pieces, and set me up for his mark. He cleaveth my reins asunder, and doth not spare; he poureth out my gall upon the ground. He breaketh me with breach upon breach, he runneth upon me like a giant."

The sense of frustration, alienation and repudiation that resulted from his relentless persecution was abysmal! "But now they that are younger than I have me in derision. They abhor me, they flee far from me, and spare not to spit in my face."

But what appeared to be the proverbial "last straw" still did not end Job's appalling endurance test. He had yet to undergo one final shattering assault: "My bones are pierced in me in the night season: and my sinews take no rest. By the great force of my disease is my garment changed: it bindeth me about as the collar of my coat. He hath cast me into the mire, and I am become like dust and ashes. My bowels boiled and rested not. My skin is black upon me, and my bones are burned with heat."

We wholly conquer only what we assimilate.—Gide

Toxoplasmosis and Pneumocystis Carinii Pneumonitis

in a Patient with Chronic Lymphatic Leukemia

A. THEOLOGIDES, M.D., Ph.D.*
O. H. PFLUEGER, Jr., M.D.*
B. J. KENNEDY, M.D.*
Minneapolis, Minnesota

Opportunistic protozoal and fungal infections occur in patients with lymphoreticular or hematopoietic malignancies treated with corticosteroids, radiation, alkylating agents, and antimetabolites. The prolongation of life provided by these therapies has been shadowed by uncommon complications associated with changes in the immune mechanism. New clinical entities have evolved under these circumstances. This is demonstrated by a patient with chronic lymphatic leukemia of nine years duration who died because of two unusual infections: toxoplasmosis and pneumocystis carinii pneumonitis. Early recognition of such infections is of utmost clinical importance, because they may be potentially curable.

Case Report

A 50-year-old man had a seminoma of the left testis removed in 1954, followed by radiation therapy to the pelvis and abdomen. In 1959 the diagnosis of chronic lymphatic leukemia was established by peripheral blood examination and biopsy of a cervical node. Radiation therapy was given to the cervical, axillary, and inguinal nodes.

He was well until January 1962, when anemia developed. Blood transfusions were administered, and in March 1962, an enlarged spleen was treated with radiation therapy. Oral iron and corticosteroids were given.

When first seen at the University of Minnesota Hospitals in April 1962, there was generalized lymphadenopathy and hepatosplenomegaly. The hemoglobin was 6.4 g/100 ml, leucocytes 10,950 per mm^3 with 71 percent mature lymphocytes, and the platelets were 62,000 per mm^3. Mild hemolysis was noted. A bone marrow biopsy revealed erythroid hypoplasia, a decreased number of granulocytes and megakaryocytes, and lymphocytosis.

Treatment

Therapy with 40 mg of prednisone was begun and in May 1962, testosterone enanthate, 600 mg twice a week intramuscularly, was added. The hemoglobin increased over the next five months to 18 g/100 ml. Erythrocytosis as a response to androgen therapy was previously reported.[1]

The disease remained controlled with prednisone and

This research was supported by grants No. CA-05158, CA-05862, CA-08101 and CA-08832 from the National Cancer Institute, United States Public Health Service.

testosterone enanthate until April 1967, when generalized lymph node enlargement and hepatosplenomegaly recurred. The hemoglobin was 14.3 g/100 ml, leukocytes 56,300 per mm^3 with 96 percent lymphocytes, and platelets 196,000 per mm^3. Serum electrophoresis showed 0.2 g percent of gamma globulin. Treatment included prednisone and uracil mustard; later cyclophosphamide was added. In September 1967 progression of the disease was partially controlled with radiation therapy to the mediastinal lymph nodes and subsequently vinblastine sulfate.

Progress

On December 5, 1967, he was admitted because of progressive weakness and fever. There were multiple superficial ulcerations of the oral mucosa and lips and necrotic ulcerated areas of the skin with petechiae and ecchymoses on the extremities. Multiple soft, nontender 0.5 to 1-cm cutaneous nodules were present throughout the body. There was generalized lymphadenopathy, right pleural effusion, hepatosplenomegaly, and 4 + pitting edema in the lower extremities.

The hemoglobin was 9.0 g/100 ml, leukocytes 5,650 per mm^3 with 50 percent lymphocytes, reticulocytes 3.5 percent, and platelets 49,000 per mm^3. Urinalysis showed granular and hyaline casts. The BUN was 41 mg/100 ml, creatinine 1.7 mg/100 ml, total bilirubin 0.8 mg/ml, serum alkaline phosphatase 10 KAU/100 ml, and serum lactic dehydrogenase 544 IU/liter (126 IU/liter heat stable). The prothrombin time was 13.7 seconds, the serum fibrinogen was 0.2 gm percent. Roentgenograms of the chest demonstrated anterior mediastinal masses and right pleural effusion obscuring the pulmonary parenchyma. In the left lung there was a perihilar infiltrate suggestive of pulmonary edema or pneumonitis. This infiltrate showed significant resolution four days later.

Skin tests for tuberculosis, histoplasmosis, blastomycosis, and coccidiomycosis were negative. A culture of the sputum showed growth of many coagulase-positive staphylococci, many Leisseriae species, many alpha streptococci and a few gamma streptococci. Sputum cultures for fungi grew Candida albicans. There was no growth on the blood, urine, and pleural fluid cultures. The pleural fluid was hemorrhagic. Culture of a skin ulcer grew many coagulase-positive staphylococci.

On the third hospital day anterior chest pain occurred; subsequently electrocardiographic and enzyme changes were consistent with the diagnosis of a recent small anterior myocardial infarction.

The hospital course was characterized by fever, cough, respiratory distress, increasing weakness and confusion. Antibiotics, corticosteroids, diuretics, and blood transfusions were administered. The patient expired 18 days after admission.

Pathologic Findings

Gross

At autopsy there were subcutaneous nodules, lymphadenopathy, hepatosplenomegaly, and bilateral hemorrhagic pleural effusion. The heart weighed 310 gm and the myocardium showed a slightly mottled yellowish discoloration in the left ventricle; the coronary arteries had marked arteriosclerotic narrowing; the left circumflex artery was narrowed almost to occlusion just beyond its origin. The appearance of the lungs was suggestive of pulmonary edema with foci of pneumonitis. The brain disclosed prominent blood vessels, particularly in the white matter of the cerebral hemispheres, consistent with congestion. In the white matter of the temporal and occipital lobes there were faintly grey, punctate areas.

Microscopic

On microscopic examination the lymph nodes, liver, spleen, and bone marrow were involved by a lymphomatous process. The lungs showed increased numbers of macrophages within the alveoli in the absence of polymorphonuclear leukocytes, lymphocytes or plasma cells. Some alveoli contained, in addition, a fibrillar, eosinophilic material. Small clusters of eosinophilic, slightly grayish bodies, each about six microns in size, were found, sometimes in association with this material, but more often lying along alveolar walls. A Grocott-Gomori's methenamine silver nitrate stain confirmed that these bodies were Pneumocystis carinii organisms (Figure 1). The alveolar septa were variably widened due to congestion or edema, but they did not contain an inflammatory cell infiltrate.

In the myocardium there were foci of chronic inflammatory cells between muscle fibers consistent with a mild myocarditis. Occasional widened myocardial fibers contained clusters of small organisms, each less than two microns in size. These "psuedocysts" contained a hundred or more microorganisms, and their appearance was that of myocardial toxoplasmosis (Figure 2). No free organisms could be found.

The brain revealed widespread reactive microglial* foci in all parts, often surrounding blood vessels and occasionally associated with central areas of necrosis. Pseudocysts of Toxoplasma gondii were found in the absence of any reaction in all sections of brain studied (Figure 3) and occasionally with the microglial foci. Free toxoplasma organisms were found in one small area. The areas of necrosis and microglial reaction were considered unrelated to the presence of toxoplasma organisms. The neuropathological diagnosis was meningoencephalitis probably of viral etiology, and toxoplasma organisms in the brain.

Discussion

A patient with chronic lymphatic leukemia during the nine-year duration of the illness received radiation therapy, corticosteroids, alkylating agents, and vinca alkaloids. During one phase of the disease, erythroid hypoplasia improved dramatically with massive doses of an androgen. While the disease was in exacerbation, he developed fever, progressive confusion, cough, respiratory distress, and then died. At post-mortem examination Toxoplasma gondii was discovered in the brain and myocardium, and Pneumocystis carinii was found in the lungs.

Patients with lymphoma, Hodgkin's disease, or leukemia treated with corticosteroids, chemotherapeutic agents, and radiation develop in the course of their disease new symptoms and signs from the brain, lungs, myocardium, liver, kidneys, and bladder. Three diagnostic possibilities are usually considered: progression of the disease, drug toxicity, and superimposed infection.

Infections

Opportunistic infections with bacteria, viruses, fungi, and protozoa of limited pathogenicity for healthy individuals are frequently the cause of death in these debilitated patients. Some of these infections are treatable and potentially curable.

Infection in the adult with the protozoan, Toxoplasma gondii, can involve several organs and give a great variety of clinical manifestations. This infection can be glandular, involving only the lymph nodes, miliary with widespread dissemination, or localized, affecting one or two organs.[2] There have been an increasing number of reports of toxoplasmosis complicating malignancies especially of the lymphoreticular and hematopoietic tissues.[3-5]

Malignancy

Toxoplasmosis associated with malignancy and involving the brain and myocardium has been observed.[5] The involvement of the brain

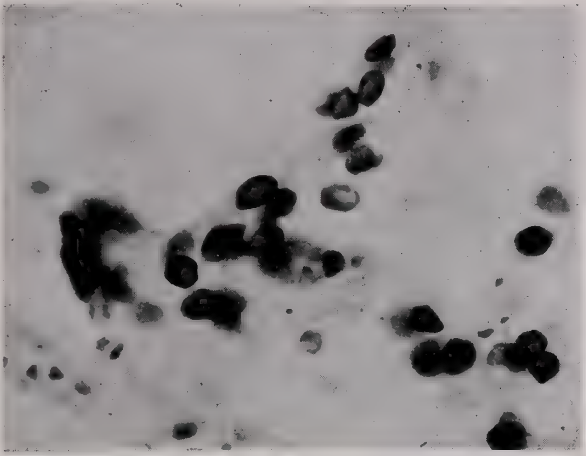

Fig. 1—A cluster of pneumocystis organisms within an alveolus. The dark-staining saccular cystic forms contain a pair of "parentheses-like" bodies. Connections at the ends of the structures form "rings." Crocott-Gomori methenamine silver nitrate stain, magnification 800 x.

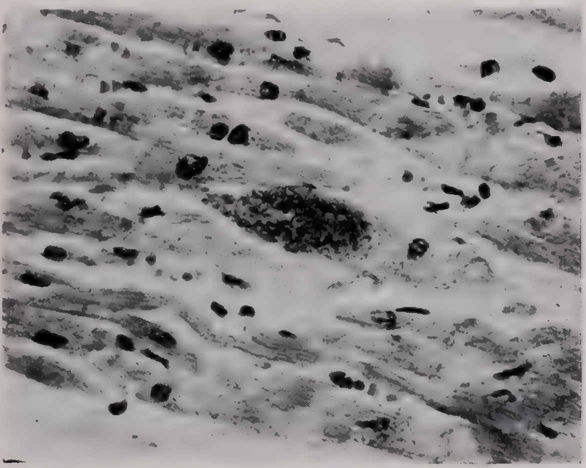

Fig. 2—A pseudocyst of toxoplasma organisms within a myocardial fiber. H and E stain, 400 x magnification.

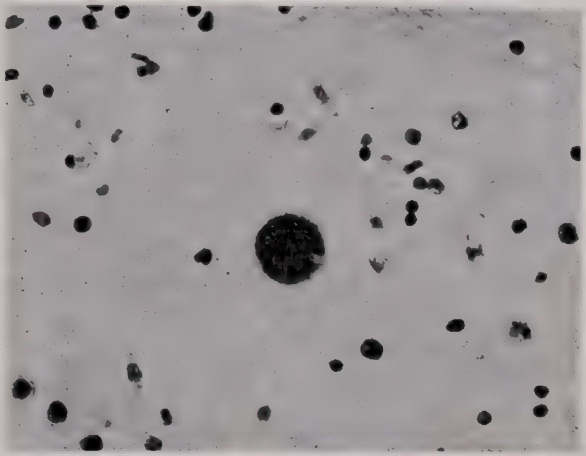

Fig. 3—A pseudocyst of toxoplasma organisms in brain tissue. Inflammatory and glial reaction is absent. H and E stain, 320 x magnification.

may manifest itself either as a diffuse or focal encephalitis or as a space-occupying lesion.[3] The electroencephalogram may show diffuse or focal abnormalities, and the cerebrospinal fluid frequently shows elevated pressure and protein values, and pleocytosis. The myocardial involvement may remain subclinical or manifest itself as myocarditis with cardiac enlargement, tachycardia, arrhythmias, gallop rhythm, heart failure, and electrocardiographic changes.

Our patient had progressive mental confusion but no focal neurologic manifestations. He had mild congestive heart failure, and on the fourth hospital day electrocardiographic changes were consistent with a myocardial infarction. Although the myocardial toxoplasmosis may have contributed to the initial congestive heart failure, the old occlusion of the circumflex coronary artery and the anemia may also have been contributory factors.

Mixed infection with Toxoplasma gondii and cytomegalovirus have been observed with unexpected frequency in patients with advanced malignant disease.[5] This mixed infection with a protozoan and a deoxyribonucleic acid virus has been studied recently in vitro in human fibroblasts.[6] An unusual patient with toxoplasmosis of the lung and stomach, herpetic esophagitis, cytomegalic inclusion disease of the lung, and sarcocystis infection of the heart has been reported.[7]

When toxoplasmosis is suspected, the diagnosis can be made by a rising titer of anti-toxoplasma antibodies detected with the Sabin-Feldman dye test, a hemagglutination and a complement fixation test, and more recently as 19S and 7S anti-toxoplasma antibodies with the 19S demonstrable in the acute phase sera.[8] Occasionally free and encysted organisms can be seen in biopsy sections, and they might be isolated following inoculation of infected tissue or body fluids into the peritoneal cavities or the brain of mice.

*Taxonomy**

There is no general agreement for the taxonomic classification of Pneumocystis carinii.[9] The morphology of this organism and the susceptibility to pentamidine therapy have been the main factors in accepting this parasite as a protozoan. However, strong evidence has been advanced for a fungal nature.[10]

Pneumocystis carinii infection in humans demonstrates a limited range of tissue specificity involving almost exclusively the lungs. It manifests itself clinically and pathologically as an interstitial pneumonitis. The disease is common in debilitated premature infants, but it has been considered a rare nosologic entity in adults.[11,12]

Most of the reported cases in adults have been observed in patients with lymphoreticular and hematopoietic malignancies after prolonged administration of antibiotics, corticosteroids, cytotoxic chemotherapy, or radiation therapy.[12,13] Certain cases have been associated with secondary immunological deficiency states resulting from immunosuppressive therapy following kidney transplantation.[14] Our patient had a low serum gamma globulin level.

Subclinical

The Pneumocystis carinii pneumonitis in the adult may remain subclinical or may have an insidious onset with increasing cough, fever, tachypnea, dyspnea, and cyanosis. The findings on physical examination are limited to the chest, with scattered rales occasionally present. The pathophysiology of the disease is the result of an alveolar capillary block secondary to inflamed and thickened alveolar septa.[9] Pleurisy and pleural effusions have not been reported with this pneumonia in adults. In our patient the pleural effusion was associated with the malignant process.

Most of the reported cases of pneumocystis pneumonitis in adults were diagnosed incidentally at autopsy. Recently, with an increasing awareness of this clinical entity, the disease is suspected antemortem. X-ray findings of diffuse bilateral interstitial pneumonitis and the pulmonary function findings of alveolar capillary block are suggestive of the process. The diagnosis can be established only by the identification of the pneumocystis cysts in the sputum, in hypopharyngeal aspirates, in percutaneous lung aspiration biopsy or in open-chest lung biopsy. Laboratory tests have been of no value, and an introduced complement fixation test needs additional evaluation. Since this infection appears potentially curable, early recognition is important.

---

*See Test Your Word Score Page 759.

Concomitant infections with Pneumocystis carinii and cytomegalovirus have been reported with surprising incidence.[13,14] Mixed infections with Aspergillus, Nocardia, Candida albicans, and Histoplasma capsulatum have been observed.[13,14] Combined toxoplasmosis and Pneumocystis carinii pneumonitis in the same patient has not been reported.

Summary

Chronic lymphatic leukemia in an adult male was controlled for nine years by treatment with radiation, corticosteroids, alkylating agents, vinca alkaloids, and androgens. During a period of exacerbation of the disease the patient died following an acute illness with fever, cough, dyspnea, progressive weakness, and confusion. Post-mortem examination demonstrated toxoplasmosis of the brain and myocardium and pneumocystis carinii pneumonitis.

Advice from a Medieval Physician

And of those things which are incumbent on the student of this Art (Medicine) are that he should constantly attend the hospitals and sick-houses; pay unremitting attention to the conditions and circumstances of their inmates, in company with the most acute professors of Medicine; and enquire frequently as to the state of the patients and the symptoms apparent in them, bearing in mind what he has read about these variations, and what they indicate of good or evil. If he does this, he will reach a high degree in this Art. Therefore it behooves him who desires to be an accomplished physician to follow closely these injunctions, to form his character in accordance with what we have mentioned therein, and not to neglect them. If he does this, his treatment of the sick will be successful; people will have confidence in him and be favourably disposed towards him, and he will win their affection and respect and a good reputation; nor withal will he lack profit and advantage from them. And God Most High knoweth best.*

Illusions

Don't part with your illusions. When they are gone you may still exist, but you have ceased to live.—Mark Twain

Famous Men and Their Bad Health

Thomas de Quincey

De Profundis

"Ecce, this child has been in hell!" So spoke Coleridge of his friend Thomas De Quincey, the English opium addict. No other seven words could have said more!

For thirty years, beginning as a student, Thomas De Quincey (1785-1859) took opium for respite from the throes of excruciating facial neuralgia accompanied by agonizing toothache. Out of his long ordeal of addiction came his Confessions, written to show the medical value of opium as a pain reliever and to reveal its mastery over the mind dream-wise. During the depths of his thralldom his biographer, Horace Eaton, says that De Quincey kept a decanter of laudanum constantly at his elbow, his daily dosage at one time ultimating to 8,000 drops, the equivalent of 300 grains of opium.

The Confessions of an English Opium Eater is an open sesame to that fantastic other-dimensional dream world whose door only a powerful drug can open—and also close after admittance. So cogent is De Quincey's literary magic that when we read the Confessions we lose our personal identity and merge with the author in his compulsive descent to Avernus. Not all the dreams are hideous phantasmagorias; some are glorious extravaganzas; yet all alike are permeated with a sense of Final-Judgment doom.

"I seemed every night to descend, not metaphorically, but literally to descend into chasms and sunless abysses, from which it seemed hopeless that I should ever reascend. Not did I, even by waking, feel that I had reascended."

After thirty years of seduction by and dependence on opium De Quincey finally conquered the habit. Of the interval between bondage and freedom he said:

"During the whole period of diminishing the opium I had the torments of a man passing out of one mode of existence into another. The issue was not death, but a sort of physical regeneration."

Revelations are rare! For the unique one presented in the Confessions we are forever indebted to Thomas De Quincey.

Levity in Medical Writing

I would never suggest that the physician writer not take his medicine seriously. I do hope, however, he will occasionally laugh at himself, amuse his readers when it helps to get and to hold their attention, warm up his facts before he serves them, and use humor whenever it adds a touch of humanity.

—Richard L. Reece, M.D.

It is Difficult

As Sam said, "You can't no more explain what you don't know, than you can come back from where you ain't been."

Cheese

The main difference between Swiss cheese and Camembert is that the ventilation is a little better.—Anon.

I'll say this for adversity: people seem to be able to stand it, and that's more than I can say for prosperity.—Frank McKinney Hubbard

Treatment of Myocardial Infarction

in a Coronary Care Unit

LORENZO F. TRAJANO, M.D.*
DAVID A. BERMAN, M.D.*
BENJIE GOLDFARB, M.D.*
MARY B. STARK, B.S., R.N.*
REUBEN BERMAN, M.D.*
Minneapolis, Minnesota

STIMULATED BY REPORTS of reduction in mortality from acute myocardial infarction in patients treated in a coronary care unit we established such a unit at Mt. Sinai Hospital in September, 1966.

The unit proved valuable in treatment of patients with acute myocardial infarction and other problems, such as cardiac arrhythmias, postoperative heart surgery, and artificial pacemakers. Of 280 patients treated during the first year, 146 were suspected to have myocardial infarctions and, of these, 100 had proven myocardial infarctions with electrocardiographic and enzyme abnormalities.

In the 100 patients with acute myocardial infarction treated in the coronary care unit the hospital mortality was 21 per cent. During the same period among 39 patients with acute myocardial infarction not treated in the unit the mortality was 32 percent. During the year prior to the establishment of the unit the mortality of 161 patients with acute myocardial infarction was 34 percent. Most of the improvement in mortality was due to more effective treatment of arrhythmias. Seven of eleven patients who developed ventricular fibrillation were successfully resuscitated; they all recovered without signs of brain damage and were subsequently discharged from the hospital. These results compare favorably with those reported by others as shown in Table 1. The incidence of arrhythmias and other complications is shown in Table 2, with corresponding postmortem findings.

Comment

In hospitals with established coronary care units the mortality of acute myocardial infarction varies but is markedly reduced compared to the pre-coronary care unit era. The successful operation of a coronary care unit depends to a large degree on the nurses. In emergency situations they must be prepared to apply external cardiac massage, mouth-to-mouth respiration, and external counter-shock defibrillation. We have been fortunate in having a devoted and enthusiastic group of nurses who have accepted this responsibility, even though it goes beyond the boundaries of traditional nursing care.[8]

---

*From the Department of Medicine, Mount Sinai Hospital, Minneapolis, Minnesota. Presented at the Minnesota Society of Internal Medicine, Duluth, Minnesota, May, 1968.

Lown and his colleagues have shown that ventricular fibrillation (as a primary event) can be almost eliminated by treatment of rhythm disturbances, particularly multiple premature ventricular contraction (especially "R on T" variety), second or third degree heart block, and marked sinus bradycardia.[9] The present treatment of these complications includes intravenous lidocaine, intravenous catheter pacemaker, and atropine or isoproterenol.

The coronary care unit has so far not reduced the dismally high mortality resulting from cardiogenic shock.

Summary

The mortality of acute myocardial infarction at Mount Sinai Hospital in Minneapolis has been reduced by the coronary care unit. Most of the improvement in mortality has been due to more effective treatment of arrhythmias.

Silence is the unbearable repartee.—Chesterton

From Mister to Doctor

Of all the branches of medicine with which the medical student is confronted, none is more exciting, none more nerve-racking, sweat-producing, and awe-inspiring than is surgery. Surely, every student looks forward with fear and trepidation to the time when, as a senior, he must scrub, don his mask, cap, gown and gloves and stand with the surgical chief at the operating table. . . You perspire, the nose itches, one arm falls asleep, don't dare move now! A Bleeder! A hemostat to the chief! "No not the scissors!" You are in the way—he cracks your fingers—but he dares, for he is the chief. He asks what is this and you sweat, and what is that and you stutter and stammer, can't tell bone from muscle! It's really a nightmare and goes something like this:

10:00 A.M.—Called for first time to assist the chief in surgery.

10:45—Chief entered operating room with a scowl and began to scrub. Pulse jumped to 120.

11:15—Operation began. Assigned a position behind and to the right of the chief. That "knock, knock" noise is from the knees.

11:25—Left leg asleep. Attempted to shift left foot to get relief, thereby kicking the chief in the back of the leg. Received explosive warning for clumsiness. Everyone glared.

11:28—Nose itched. Almost scratched it with sterile glove. Stopped just in time by scowl from friend (?) nurse.

11:30—Couldn't tell chief the name of the nerve that he had picked up. Acidly advised to return to freshman year and study anatomy.

11:33—A bead of perspiration fell from forehead onto sterile drape. Hastily covered by sterile towel by nurse. Bless her! Chief pretended not to see.

11:38—Left leg dead from toes to hip.

11:40—Leaned over to see a structure pointed out by the chief. Anesthetic left leg buckled. Collapsed on chief's right shoulder, causing him to apply his jelly belly to the operative field. Muffled curse came from beneath his mask.

11:40.10—Tried to straighten up but fell off chief's shoulder to the floor, knocking over instrument tray and spot light and sprawled at full length on back, among the buckets and sponges on the floor! Chief straightened up, turned toward me and with a hideous growl grabbed me about the throat, choking me and banging my head against the floor.

11:40.20—"Hey DOC, DOC! Wake up, wake up! You're next to get your diploma." — — THANK GOD!!*

Honesty

The teacher asked Johnny if the world was round. He answered, "No."
"Is it flat?"
"No."
"If it isn't round and it isn't flat, what is it?"
"Daddy says it's crooked."

Jacob Braude: Speaker's Encyclopedia

Let's be specific about Campbell's Soups... and *reducing diets*

There are more than 30 million people in America who are overweight. During the next year, you probably will see more than 1,000 of them in your own practice.

One good way to help these patients is to give them a reducing diet based on ordinary eating patterns.

Campbell has prepared a sensible plan for weight control based on ordinary eating patterns. The plan consists of a patient instruction booklet and a set of menus which provide approximately 1,400 calories daily. The menus are balanced to provide the minimum daily requirements of nutrients.

To obtain a supply for your office write to:
Campbell Soup Company, Box 265, Camden, N. J. 08101

Campbell's
SOUP

No two women are quite alike...

Ovulen-21 Com
Directions

and no other oral contraceptive is quite like Ovulen-21®

Each tablet contains ethynodiol diacetate 1 mg., mestranol 0.1 mg.

The progestin is distinctive, and for some women this may mean a different clinical response. The Compack® tablet dispenser is distinctive; its functional simplicity makes it virtually patient-proof. The acceptance of Ovulen-21 is distinctive... together with Ovulen®, it is more often prescribed than any other individual contraceptive product currently available.

Indication—Oral contraception.

Contraindications—Thrombophlebitis, thromboembolic disorders, cerebral apoplexy or a past history of these conditions, markedly impaired liver function, known or suspected carcinoma of the breast, known or suspected estrogen-dependent neoplasia, undiagnosed abnormal genital bleeding.

Warnings—Watch for the earliest manifestations of thrombotic disorders (thrombophlebitis, cerebrovascular disorders, pulmonary embolism, retinal thrombosis); if present or suspected discontinue the drug immediately.

British studies reported in April 1968[1,2] estimate there is a seven- to tenfold increase in mortality and morbidity due to thromboembolic diseases in women taking oral contraceptives. In these controlled retrospective studies, involving 36 reported deaths and 58 hospitalizations due to "idiopathic" thromboembolism, statistical evaluation indicated that the differences observed between users and non-users were highly significant. The conclusions reached in the studies are summarized in the table below:

Comparison of Mortality and Hospitalization Rates Due to Thromboembolic Disease in Users and Non-Users of Oral Contraceptives in Britain.

Category	Mortality Rates		Hospitalization Rates (Morbidity)
	Age 20-34	Age 35-44	Age 20-44
Users of Oral Contraceptives	1.5/100,000	3.9/100,000	47/100,000
Non-Users	0.2/100,000	0.5/100,000	5/100,000

No comparable studies are yet available in the United States. The British data, especially as they indicate the magnitude of the increased risk to the individual patient, cannot be applied directly to women in other countries in which the incidences of spontaneously occurring thromboembolic disease may differ.

Discontinue medication pending examination if there is sudden partial or complete loss of vision, or sudden onset of proptosis, diplopia or migraine. Withdraw medication if papilledema or retinal vascular lesions are found.

Since the safety of Ovulen in pregnancy has not been demonstrated, it is recommended that pregnancy be ruled out for any patient who has missed two consecutive periods before continuing the contraceptive regimen. If the patient has not adhered to the prescribed schedule the possibility of pregnancy should be considered at the first missed period.

A small fraction of the hormone agents in oral contraceptives has been identified in the milk of mothers receiving these drugs. The long-range effect to the nursing infant cannot be determined at this time.

Precautions—Pretreatment physical examination should include special reference to the breasts and pelvic organs, and a Papanicolaou smear.

Endocrine and possibly liver function tests may be affected by Ovulen. Therefore, it is recommended that such tests if abnormal be repeated after the drug has been withdrawn for two months.

Pre-existing uterine fibromyomas may increase in size under the influence of progestogen-estrogen preparations.

Because these agents may cause some degree of fluid retention, conditions which might be influenced by this factor, such as epilepsy, migraine, asthma, cardiac or renal dysfunction, require careful observation.

In breakthrough bleeding, and all irregular vaginal bleeding, consider nonfunctional causes. Adequate diagnostic measures are indicated in undiagnosed vaginal bleeding.

Carefully observe patients with a history of psychic depression and discontinue the drug if severe depression recurs.

Any possible influence of prolonged Ovulen therapy on pituitary, ovarian, adrenal, hepatic or uterine function awaits further study.

A decrease in glucose tolerance has occurred in a significant percentage of patients on oral contraceptives. The mechanism of this decrease is obscure. For this reason, diabetic patients should be observed carefully while receiving Ovulen.

Because of the effects of estrogens on epiphyseal closure Ovulen should be used judiciously in young patients in whom bone growth is not complete.

The age of the patient constitutes no absolute limiting factor, although Ovulen therapy may mask the onset of the climacteric.

The pathologist should be informed of Ovulen therapy when relevant specimens are submitted.

Adverse Reactions—A statistically significant association has been shown between use of oral contraceptives and the following serious adverse reactions: thrombophlebitis, pulmonary embolism.

Although available evidence is suggestive of an association, such a relationship has been neither confirmed nor refuted for the following serious adverse reactions: cerebrovascular accidents, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.

The following adverse reactions are known to occur in patients receiving oral contraceptives: nausea, vomiting, gastrointestinal symptoms (such as abdominal cramps and bloating), breakthrough bleeding, spotting, change in menstrual flow, amenorrhea during and after treatment, edema, chloasma or melasma, breast changes (tenderness, enlargement, secretion), change in weight, changes in cervical erosion and cervical secretions, suppression of lactation when given immediately post partum, cholestatic jaundice, migraine, allergic rash, rise in blood pressure in susceptible individuals, mental depression.

Although the following adverse reactions have been reported in users of oral contraceptives, an association has been neither confirmed nor refuted: anovulation post treatment, premenstrual-like syndrome, changes in libido, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, fatigue, backache, hirsutism, loss of scalp hair, erythema multiforme and nodosum, hemorrhagic eruption, itching.

The following laboratory results may be altered by oral contraceptives: hepatic function: increased sulfobromophthalein and other tests; coagulation tests: increase in prothrombin, Factors VII, VIII, IX and X; thyroid function: increase in PBI and butanol extractable protein bound iodine, and decrease in T^3 uptake values; metyrapone test; pregnanediol determination.

Before prescribing see Detailed Product Information.

SEARLE Where "The Pill" Began
G. D. SEARLE & CO., P. O. Box 5110, Chicago, Illinois 60680

In the complex picture of moderate to severe anxiety...

there is a new reason for prescribing Mellaril (Thioridazine HCl)

effectiveness in mixed anxiety-depression

Long recognized for its usefulness in the treatment of moderate to severe anxiety, Mellaril is now also known to be effective against mixed anxiety-depression.

Often the symptoms of anxiety states are difficult to sort out—even with the most careful probing. The patient may manifest symptoms of agitation, restlessness, insomnia, somatic complaints. But what of the depression that may be mixed in the total picture? It is reassuring to know that Mellaril may be prescribed—with strong possibilities of success—when there is anxiety alone or a mixture of anxiety and depression.

Before prescribing or administering, see Sandoz literature for full product information, including adverse reactions reported with phenothiazines. The following is a brief precautionary statement.

Contraindications: Severe central nervous system depression, comatose states from any cause, hypertensive or hypotensive heart disease of extreme degree.

Warnings: Administer cautiously to patients who have previously exhibited a hypersensitivity reaction (e.g., blood dyscrasias, jaundice) to phenothiazines. Phenothiazines are capable of potentiating central nervous system depressants (e.g., anesthetics, opiates, alcohol, etc.) as well as atropine and phosphorus insecticides. During pregnancy, administer only when necessary.

Precautions: There have been infrequent reports of leukopenia and/or agranulocytosis and convulsive seizures. In epileptic patients, anticonvulsant medication should also be maintained. Pigmentary retinopathy may be avoided by remaining within the recommended limits of dosage. Administer cautiously to patients participating in activities requiring complete mental alertness (e.g., driving). Orthostatic hypotension is more common in females than in males. Do not use epinephrine in treating drug-induced hypotension. Daily doses in excess of 300 mg. should be used only in severe neuropsychiatric conditions.

Adverse Reactions: *Central Nervous System*—Drowsiness, especially with large doses, early in treatment; infrequently, pseudoparkinsonism and other extrapyramidal symptoms; nocturnal confusion, hyperactivity, lethargy, psychotic reactions, restlessness, and headache. *Autonomic Nervous System*—Dryness of mouth, blurred vision, constipation, nausea, vomiting, diarrhea, nasal stuffiness, and pallor. *Endocrine System*—Galactorrhea, breast engorgement, amenorrhea, inhibition of ejaculation, and peripheral edema. *Skin*—Dermatitis and skin eruptions of the urticarial type, photosensitivity. *Cardiovascular System*—Changes in the terminal portion of the electrocardiogram have been observed in some patients receiving the phenothiazine tranquilizers, including Mellaril (thioridazine hydrochloride). While there is no evidence at present that these changes are in any way precursors of any significant disturbance of cardiac rhythm, several sudden and unexpected deaths apparently due to cardiac arrest have occurred in patients previously showing electrocardiographic changes. The use of periodic electrocardiograms has been proposed but would appear to be of questionable value as a predictive device. *Other*—A single case described as parotid swelling.

Mellaril®
(Thioridazine HCl)
25 mg. t.i.d.

The Computers Are Coming, O-ho, O-ho*

MAKE NO MISTAKE about it, the computers are coming. At this moment they are crunching through hospital walls into business offices, laboratories, and right up to the bedside. Fed the correct diet of numbers, these electronic marvels can keep track of the patients' and hospitals' money; digest, store, retrieve, and type out laboratory test results;[1,2] and even take a history,[3] auscultate a heart,[4] and help with physicals.[5]

This march of machines is a welcome one, at least in the laboratory. Properly instructed, computers can make up blood drawing lists for technologists, indicate the amount of blood to draw and the type of tubes and anticoagulants to use; reduce clerical work and minimize recording errors, cull out those tests that have gone awry because of errors or artifacts; flag abnormal results for pathologists and clinicians, calculate normal ranges, spot errors due to faulty methods or instruments, and do it all with blazing speed.

Just how these transistorized subhumans go about their tasks is detailed in part in this issue of MINNESOTA MEDICINE, pages 847 and 853.

From these articles I learned that in nanoseconds† a computer can ingest test results, swallow the information, remember, calculate, store, and then regurgitate the printed results; and I learned that computers fundamentally carry out three jobs: "business data processing, general scientific computing, and real-time, on-line control."

Furthermore, I learned that computers, like people, differ: there are small ones, large ones, cheap ones, expensive ones, slow ones, fast ones, generalized ones, and specialized ones. But unlike people, computers are passive and inflexible. Humans have to spoon-feed them with programmed pabulum: a combination of letters, numbers, punctuation marks, and mathematical symbols.

The problem of conversing with a computer seems to lie in the human mind. Not only do programmers have to nurse computers, but to understand and communicate with them they have to use them in about 2000 special languages; among them, COBOL (Common Business Oriented Language), FORTRAN (Formula Translation), MAD (Michigan Algorithmic Decoder), and JOVIAL (Jule's Own Version of the International Algebraic Language).

Computers process information in nondigital form, but their masters do not follow rigid rules when they think, read, or write. Physicians instinctively sense what is important, what to concentrate on, and what to ignore; we grimace, gesticulate, smile, or modulate our voices to drive a point home. The computer can

Smiles speak louder than words

for the good taste of Soyalac

Milk-free, hypo-allergenic Soyalac has a pleasing taste that is eagerly accepted by most infants. It's similar to mother's milk in composition and assimilation, much like cow's milk in consistency and completely free of fibre. Extensive clinical data support Soyalac's value in promoting growth and development. Soyalac is also excellent for growing children and adults.

only flash its lights.

Yet, in the world of numbers, the computers reign supreme, and clinical laboratories, you no doubt have noticed, produce myriads of numbers. By processing these numbers and relieving technologists and pathologists of statistical and repetitive drudgery, computers ought to liberate mind power for more creative and thoughtful things—such as interpreting what the numbers mean.

"Worms"

THIS CASE REPORT by Drs. Carlson and Zinneman is excellent not only because of their skill in presentation and documentation but also for the educational service it renders in alerting the medical practitioner to the problems of those returning from military service or from other foreign travel.

There is a need for recognition of the parasitic diseases associated with worms and for enlightenment on the problem of "worms," so aptly described by the late Professor Asa C. Chandler when he wrote: "The name 'worm' is an indefinite though suggestive term popularly applied to any elongated creeping thing that is not obviously something else."

In this age of rapid transit via jet aircraft, one can become infected with a number of parasitic diseases but not present symptoms until some time after one returns to his home locale and his local physician. Outstanding among these parasitic diseases are malaria and the additional examples provided by Drs. Carlson and Zinneman.

Constant awareness of the possibilities for infection by various parasitic forms is increasingly required of the medical practitioner, and this case report is a worthy contribution toward that awareness. Awareness of the possibilities, however, is not sufficient. The practitioner must have some background knowledge of the life cycles of these parasitic organisms and the various approaches to diagnosis, treatment, and eradication from the host.

The real problem is one of education and of sufficient emphasis on parasitic diseases. The subject of parasitism is generally relegated to showing a few typical slides and the sincere hope that the student will eventually look through a textbook. The concept of parasitism can and should be taught in the very beginning of a youngster's contact with the subject of animal and plant biology. From this point on, the emphasis needs to be on enlargement of the concept, and this should progress with as much firsthand experience as possible until, when in medical school, the student is ready and able to correlate organisms with disease processes and their diagnosis and treatment.

There are a number of approaches to supplying the firsthand experience mentioned above. One is to utilize, as demonstration material, specimens taken from animals housed in the medical school's animal colony or to maintain (as teaching material) animals which harbor such blood forms as malaria, the various filarial worms, and trypanosomes. The life cycles of typical protozoan forms can be readily demonstrated in fecal samples from mice, rats, guinea pigs, and other laboratory animals; and many typical helminths can be found in common laboratory animals.

There is nothing quite so dead, or deadly, from an educational standpoint, as a slide of a fixed and stained organism—especially when this organism or a comparable animal form could be shown alive and moving about in a microscopic field! The experience of seeing and discussing the live organism enhances the whole educational process and cannot be overemphasized. Obviously, care must be exercised if any of these organisms are potential human pathogens. In fact, the whole subject of zoonotic infections—those suffered primarily by animals other than man but secondarily transmissible to man—is poorly treated. Our knowledge of host specificity and ranges is broadening within the field of animal parasitology, but this knowledge needs to reach further into the realms of medical and veterinary education.

It is realized that those of us in specialty areas such as medical parasitology have a ten-

Ambar No 2 Extentabs
Rx
THE Cost of AMBAR EXTENTABS IS APPROXIMATELY ONE-HALF THAT OF OTHER LEADING APPETITE SUPPRESSANTS.
AN IMPORTANT FACTOR IN LONG-TERM THERAPY!

CONTROL FOOD AND MOOD ALL DAY LONG WITH A SINGLE MORNING DOSE

AMBAR #2 EXTENTABS®

methamphetamine HCl 15 mg.,
phenobarbital 64.8 mg. (1 gr.)
(Warning: may be habit forming).

One Ambar Extentab before breakfast can help control most patients' appetite for up to 12 hours. Methamphetamine, the appetite suppressant, gently elevates mood and helps overcome dieting frustrations. Phenobarbital, the sedative in Ambar, controls irritability and anxiety...helps maintain a state of mental calm and equanimity. Both work together to ease the tensions that erode the willpower during periods of dieting.

Also available: Ambar #1 Extentabs®—methamphetamine hydrochloride 10 mg., phenobarbital 64.8 mg. (1 gr.) (Warning: may be habit forming).

BRIEF SUMMARY/**Indications:** Ambar suppresses appetite and helps offset emotional reactions to dieting. **Contraindications:** Hypersensitivity to barbiturates or sympathomimetics; patients with advanced renal or hepatic disease. **Precautions:** Administer with caution in the presence of cardiovascular disease or hypertension. **Side Effects:** Nervousness or excitement occasionally noted, but usually infrequent at recommended dosages. Slight drowsiness has been reported rarely. See package insert for further details.

dency to demand emphasis on our particular field in the educational program. However, it must be realized also that the demands made on the general practitioner are increasingly those of these very areas of specialization. It is to be hoped that, with the creation of Health Science Centers and Community Health Programs, this needed broadening of the educational base may be attained and constantly maintained—even between wars. In the meantime, the appearance of articles such as this one by Drs. Carlson and Zinneman is of genuine educational benefit to all.

Vascular Fistulas of the Dura*

WITH A VASCULAR FISTULA of the dura, the most common presenting symptom is a bruit which the patient complains of and which frequently can be heard with a stethoscope. Because the fistula is most commonly between the middle meningeal artery and a nearby dural sinus, the bruit is heard best over the ear and side of the head rather than over the eye and orbit, as it is with a carotid cavernous fistula. Another common presenting complaint is focal headache, usually localized over the area of the fistula. With a fistula which occurs spontaneously, the headache is frequently of sudden onset and, after it appears, persists.

If the fistula is located along the base of the skull, the predominant drainage is into the petrosal or cavernous sinus. A fistula from the meningeal branches of the external carotid artery to the cavernous sinus causes proptosis,† conjunctival injection, blurring of vision, and extraocular nerve palsies as seen with a carotid cavernous fistula. If the fistula is located more distally in the course of the middle meningeal artery, it may drain into the superior sagittal sinus. Direct transmission of the arterial pressure to the venous sinuses may increase the intracranial pressure and give rise to the type of picture described in Huber and Joos's first case.

I have recently seen one patient in whom a fistula developed between the meningeal branch of the anterior ethmoidal artery and the dural sinuses over the anterior portion of the cranial fossa. This patient experienced sudden onset of pain above the left eye, which mimicked trigeminal neuralgia. Fistulas of this type may also give rise to focal cortical disturbances such as seizures. The mechanism for this is transmission of the arterial pressure into the venous sinuses and then retrogradely into the adjacent cortical veins where it causes a focal cortical disturbance. These patients not uncommonly have learned that pressure over the carotid artery will relieve their bruit and headache.

Rupture of this type of fistula may give rise to spontaneously occurring subdural and epidural hematomas. Although these fistulas, especially those of traumatic origin, may thrombose spontaneously, more frequently they require surgical therapy. Ligation of the external carotid artery is a frequently used method of treatment. When this method has failed or does not seem reasonable, the fistula is approached directly by craniotomy with excision of the dura containing the fistula or direct ligation of the middle meningeal artery.

Dog-Bite Wounds Should be Considered Tetanus Prone*

IN THE MARCH ISSUE of MINNESOTA MEDICINE,* Col. George H. Chambers and Major John F. Payne report their unique and interesting experience in the treatment of patients with dog-bite wounds. They conclude that such wounds, when significant, must be viewed as "infected crush wounds" rather than mere puncture wounds and are best managed by thorough cleansing, splinting, bulk dressings, elevation, and the use of soaks. Secondary closure and split-thickness skin grafting can be performed later if the wound does not close satisfactorily by secondary intention.
